THE EFFECTS OF SQUATTING FOOTWEAR ON THREE-DIMENSIONAL LOWER LIMB AND SPINE KINETICS.

Shane Petersen [1,*] Daniel Southwell [1] Tyson Beach [2] Ryan Graham [1]

[1]School of Physical and Health Education, Nipissing University, North Bay, [2]Faculty of Kinesiology and Physical Education, University of Toronto, Toronto, Canada

Introduction and Objectives: The barbell back squat is widely accepted and prescribed as an effective exercise for increasing muscular strength in the lower extremities. There has been some debate as to the best footwear for squatting. Benefits of weightlifting shoes may include providing a firmer base and the maintenance of a more upright posture to reduce external shear forces on the spine [1]. Conversely, benefits of squatting barefoot may include improved proprioception, balance, and training of the intrinsic musculature of the foot and ankle [2]. While various studies have attempted to assess the overall effectiveness and safety of the various shoe types (i.e. barefoot, shod, weightlifting shoe) during the back squat [e.g. 1-2], they have been limited to 2-D analyses. To address this, a recent paper assessed the influence of the three footwear types on 3-D kinematics and muscle activation during a 70% 1-RM back squat in males [3]. The authors found that compared to barefoot the running shoe was associated with increased squat depth, knee flexion, and rectus femoris activation [3]. However, to better understand the effects of these shoe types on the human body, kinetic analyses of joint loading are also required. Thus, the purpose of this study was to examine 3-D lower limb and spine kinetics to comprehensively evaluate the benefits and limitations of each type of squatting footwear.

Methods: 24 experienced weightlifters (12M, 12F) performed one trial per footwear condition (barefoot, shod, weightlifting) in a randomized order. Each trial required participants to perform three repetitions of 80% 1RM barbell back squats at a self-selected speed, depth, and body positioning (average mass lifted = 97±38.3kg). During all trials, 3-D kinematic data were collected from body segments at 200 Hz (Oqus 400+, Qualisys, Sweden). Participants placed one foot on each of two force plates (FP6090, Bertec, USA), which recorded the 3-D ground reaction forces and moments at 2000Hz. Using Visual-3D (C-Motion Inc., USA) an inverse dynamical linked-segment model was developed to calculate lower extremity and lumbar spine moments. Furthermore, lumbosacral joint compression and shear forces were calculated in Visual-3D by combining the estimated force from a single-muscle equivalent with the reaction forces resulting from the inverse dynamics analyses [4]. Ensemble averages across the repetitions were taken, and minimum and maximum values were extracted for each shoe condition and compared using repeated-measures ANOVAs with post-hoc tests in SPSS 22 (IBM Corporation, USA). The critical p-value was adjusted to 0.01 using the false discovery rate technique.

Results: There was no effect of footwear on ankle moments in any body-fixed movement plane. For the knee there was a significant main effect of shoe type on the knee extension moment ($p = 0.001$), where post-hoc testing revealed that the running and weightlifting shoes produced significantly larger moments than the barefoot condition. There was also a main effect of shoe type on internal knee rotation moments ($p = 0.002$), where the weightlifting shoe produced significantly larger moments than both other conditions. Conversely, for the hip there was also a main effect of shoe type on the extension moment ($p = 0.004$), where the barefoot condition produced significantly larger moments than either the shod or weightlifting shoe condition. Lastly, there was also a significant main effect of shoe type on both internal ($p=0.005$) and

external (p=0.003) hip rotation moments, where the barefoot condition produced greater external rotation and less internal rotation than either shoe type condition. There were no differences in lumbar spine moments (p>0.01) or lumbosacral compression (p= 0.18) or shear (p= 0.954) forces between conditions.

Conclusion: The results from this novel 3-D kinetic analysis indicate that altering footwear conditions appears to redistribute the internal biomechanical loading amongst the lower extremity joints during the back squat exercise and would perhaps alter the musculoskeletal adaptations elicited. Thus, trainers and coaches may be able to modify both squat difficulty (i.e. joint targeting) as well as musculoskeletal injury risk (i.e. joint unloading) via footwear modifications. However, between-condition differences in joint kinetics were relatively small in magnitude (~3-20 Nm) and therefore future research should incorporate more sophisticated modelling approaches to discern the practical significance of these findings, and how they may fluctuate across individuals (i.e. experience) and squat variations (i.e, frequency, intensity, time, and type).

AS-0002

THE EFFECT OF AUGMENTED FEEDBACK ON IMPULSE GENERATION DURING A QUICK FIRST STEP

Christopher D. Ramos [1,*] Ben Sidaway [2] Jill McNitt-Gray [3]

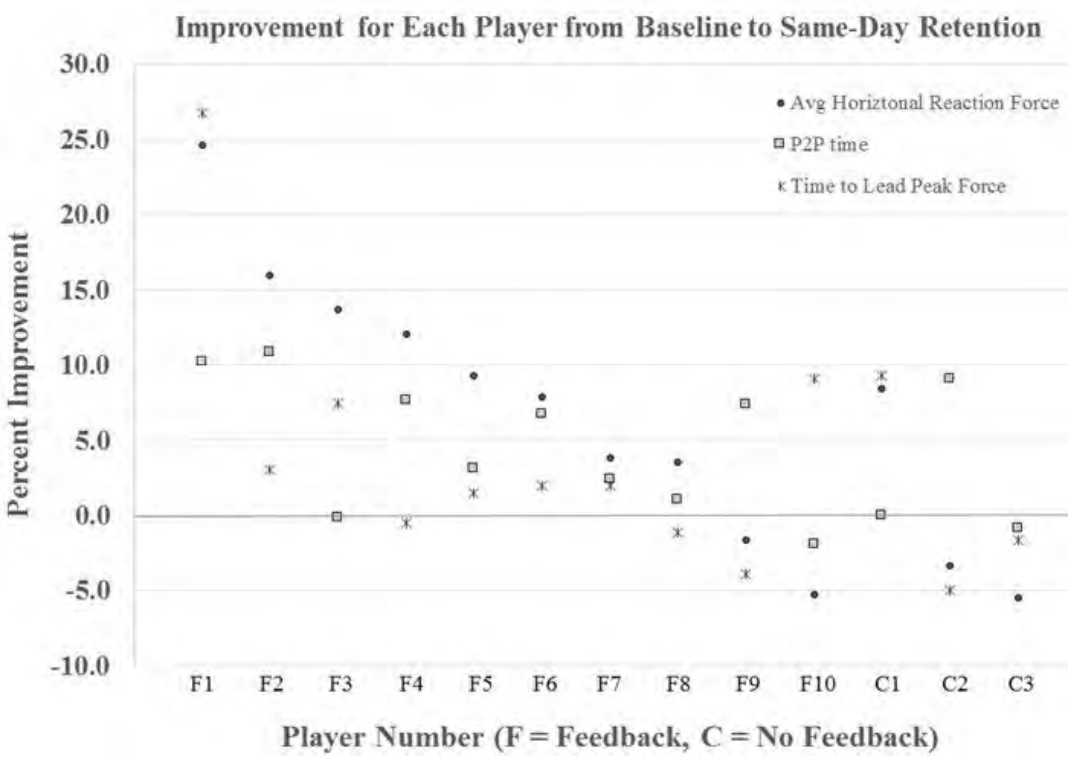
[1]Biomedical Engineering, University of Southern California, Los Angeles, [2]Physical Therapy, Husson University, Bangor, [3]Biological Sciences, University of Southern California, Los Angeles, United States

Introduction and Objectives: A quick first step is advantageous when navigating through challenging environments. Individuals often need to read and react to an unexpected event and then quickly configure their body so that they can quickly redirect the center of mass (CM) trajectory by generating impulse in a desired direction. Initiating a quick first step out of a relatively stationary position involves adopting postures in which the lead leg center of pressure is behind the CM prior to initiation of rapid joint extension [1,2]. Central to development of a quick first step, we hypothesized that performance could be enhanced by providing individuals with augmented feedback regarding horizontal-reaction forces generated during foot contact [3]. To facilitate skill acquisition and visualize the reaction forces causing the observed movement, augmented feedback was generated in the form of video replay of the individuals movements with the lead and lag leg reaction force-time curves overlaid onto the video. To determine the influence of this augmented feedback on performance, differences in horizontal reaction force-time characteristics during quick first steps performed before, after, and two days following practice with augmented feedback were compared. Comparisons were also made to players who practiced quick first steps without access to this feedback. Improvements in horizontal impulse generation were expected to involve greater lead leg average force during impulse generation, quicker time to peak force associated with rapid joint extension, and shorter times between peak forces generated by the lag and lead legs (P2P)[4].

Methods: Female volleyball players (n=13, 10 with feedback, 3 no feedback) competing on top-10 collegiate varsity teams volunteered to participate in accordance with the institutional review board. Players faced a ball-launching machine in their self-selected ‘ready position’ and were instructed to move as quickly as possible toward a ball launched in an unexpected direction, either to their left (4 times) or in front (2 times). Force plates (Kistler, 1200 Hz) recorded ground reaction forces for each foot while frontal plane kinematics were recorded using high-speed video (Casio, 300 Hz). RF-time curves for both lead and lag legs were overlaid onto frontal plane video (Panasonic, 30 Hz) and later shown to the players as augmented feedback between performance rounds (6 trials each). Baseline performance was determined by having players complete 2 blocks of 6 performance trials without any feedback. Ten players then practiced 3 blocks of 6 trials with augmented feedback provided after each block of 6 trials. Three players practiced in a similar manner but without feedback. Ten minutes after practice was completed, all players performed a retention test consisting of 2 blocks of trials without feedback to determine if any benefit derived from the feedback was maintained. A similar retention test was completed 2 days after the practice session to assess whether there were any long-term benefits of practicing with the feedback. Feedback was directed primarily toward quick horizontal impulse generation (area under the curve) by increasing the force magnitude (vertical axis) over time (horizontal axis). Lead leg average force during horizontal impulse generation (normalized by body mass), time to lead leg peak force, and P2P time were then computed and compared within-player between sessions using medians.

Results: Ten minutes following completion of practice, eight of the ten players receiving feedback showed improvement in parameters associated with quick horizontal impulse generation in a quick first step. In contrast, only one player in the no-feedback control group improved. Improvement in horizontal impulse generation was manifested by an increase in normalized average force (associated with greater horizontal force generation during foot contact), reduction in P2P time (associated with an initial placement of the lead leg foot more posterior to the CM), and a reduction in time to lead-leg peak force (associated with a greater rate of lead leg joint extension). These movement initiation related parameters showed a significant decline from the 10-minute to the 2-day retention test but were nevertheless still improved over baseline measures.

Figure:



Conclusion: The findings from this initial study are promising given that augmented feedback, in the form of video replay of the individuals movements with the lead and lag leg reaction force-time curves overlaid onto the video improved a number of movement initiation related parameters after only 18 performance trials. It remains to be seen if more practice trials with this feedback is able to establish lasting improvements in the performance of a quick first step.

AN INTEGRATED MULTISCALE ANALYSIS OF INJURY MECHANISMS IN SPORT IMPACTS: AN APPLICATION TO CERVICAL SPINE BIOMECHANICS IN RUGBY UNION SCRUMMAGING

Ezio Preatoni [1,*] Dario Cazzola [1] Tim P Holsgrove [2] Sabina Gheduzzi [2] Anthony W Miles [2] Keith Stokes [1] Richie HS Gill [2] Grant Trewartha [1]

[1]Department for Health, [2]Department of Mechanical Engineering, University of Bath, Bath, United Kingdom

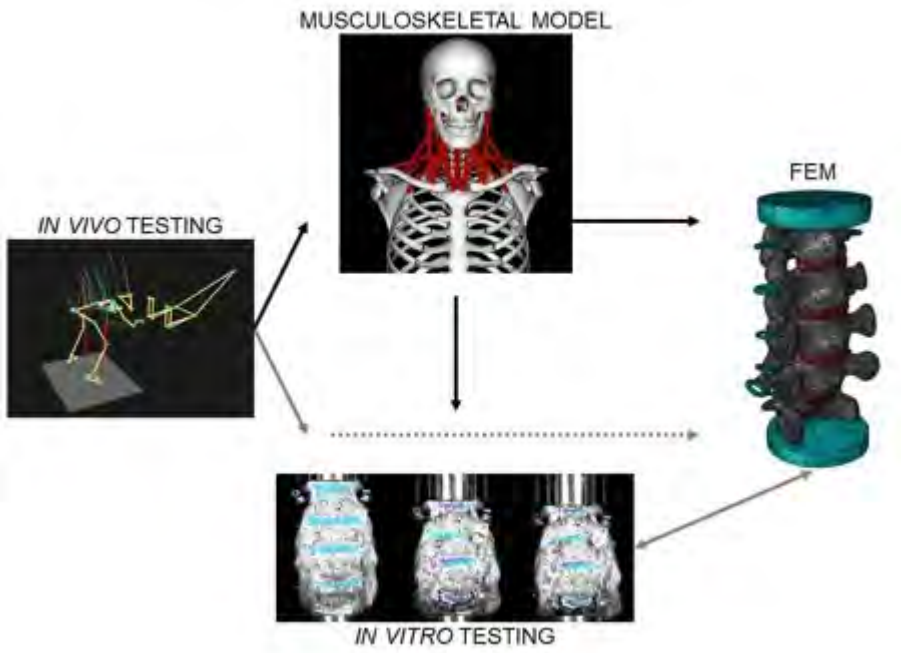
Introduction and Objectives: By generating repetitive high-energy impacts (during the engagement phase) and intense sustained loads (during the sustained push phase) under unstable conditions [1], the Rugby Union scrum has been indicated as a possible risk factor for degenerative spinal injuries for forward players, and has been associated with ~40% of all catastrophic injuries in rugby [2]. However, little is known about how these external loading conditions translate into internal stresses on the spinal structures. The aim of this study was to investigate the biomechanics of cervical spine injury during rugby activities using an integrative approach: in-vivo and in-vitro experiments combined with musculoskeletal modelling.

Methods: Three levels of analysis (Levels 1-3) were integrated. Level 1 was a biomechanical study of scrummaging (N=9 experienced rugby forwards) including motion capture (Oqus, Qualisys, Sweden), force measurement (force plates: Kistler 92876BA, Switzerland; and instrumented scrum machine, [1]), and EMG of neck and trunk muscles (Delsys Trigno, Delsys Inc, USA), carried out to assess the external kinematic and kinetic conditions acting on front row players. The subsequent phases of scrummaging, initial engagament (impact and shock absorption) and sustained push, were observed. Level 2 developed a bespoke musculoskeletal model (Rugby Model, [3]), consisting of 27 anatomical segments, 26 joints, 78 cervical muscles, and 11 torque actuators, in OpenSim (OpenSim 3.2, SimTK, USA). The Rugby Model was driven by the experimental data from Level 1 and was used to estimate joint dynamics, with a specific interest in cervical joint motions and moments. Level 3 performed an in-vitro laboratory experiment to study the injury mechanisms of porcine cervical spines subjected to impact loading conditions similar to those during scrummaging. Load (2 load cells: SLC41/005000, RDP Electronics Ltd, UK) and deformations caused by impacts (mass of 12.86 kg dropped from a height of 250 mm to give an impact velocity of ~2.2 m/s) were measured in a custom made impact rig, and high-speed videos (2 Fastcam SA3, Photron Europe Ltd, UK) were used to investigate the mechanisms of injury through digital image correlation (Vic-3D 2009.1.0, Correlated Solutions Inc, USA).

Results: Results from the biomechanical analysis confirmed that the load acting on the players, especially during the initial engagement, was of a considerable magnitude (~2.8 kN compression force in single-player machine scrummaging). Muscle activation patterns were affected by scrummaging conditions (e.g. machine vs. contested scrummaging; 'Crouch-touch-set' vs. 'Crouch-bind-set' sequence) and phases of the scrum (e.g. pre-engagement vs. engagement vs. sustaned push). For example, the activity of the *erector spinae* was significantly lower (in excess of 65%) in machine scrummaging than in contested scrummaging, and the activation of *sternocleidomastoid* and *upper trapezius* through pre-engagement and engagement were higher in the current 'Crouch-bind-set' technique than in the past 'Crouch-touch-set' one. The computational musculoskeletal model highlighted an antiphase change in movement and loading patterns between the

upper and lower cervical levels (i.e. flexion load on the lower vertebrae and extension on the upper vertebrae), and resulted in a “flattening” of the lordotic cervical curve during the impact phase. The present findings do not provide direct evidence for injury mechanisms but seem in line with the patterns of injury that previous authors have described in relation with scrum-related neck traumas [2]. The patterns of strain, load and resulting damages on the cervical structures of the impacted porcine specimens were also similar to those clinically observed in injured players, with the caudal vertebrae (C4-C6) more prone to damages (6 out of 8 specimens) as a consequence of the impact. Fractures resulted from tension in the vertebral bodies due to first order buckling of the cervical spine in extension. The mean maximum load in the cranial and caudal load cells was 5.8±2.0 kN and 6.0±2.1 kN and was reached at a time of 5.1±1.0 ms and 5.6±1.1 ms after impact, respectively.

Figure:



Conclusion: The proposed integrative approch provided novel and more thorough insight into how external loading conditions, muscular activity and body posture affect the internal stresses acting on the cervical spine structures. This understanding will help in elucidating injury factors related to scrummaging and represents a promising framework for future research in the area of impact-related injuries in sports. It will be further developed by including forward dynamics simulations and finite element analysis.

EFFECTS OF PEDALLING CADENCE ON VASTUS LATERALIS FASCICLES BEHAVIOUR

Julio Cézar Lima Da Silva [1,*] Rodrigo Rico Bini [2] Fábio Juner Lanferdini [3] Tiago Canal Jacques [3] Anton Arndt [1] Marco Aurélio Vaz [3]

[1]The Swedish School of Sport and Health Sciences, Stockholm, Sweden, [2]School of Physical Education of the Army, Rio de Janeiro, [3]Federal University of Rio Grande do Sul, Porto Alegre, Brazil

Introduction and Objectives: Pedalling cadence is important in cycling power production because of its influence on muscle fibers shortening velocities and cycling performance [1]. Previous studies evaluated muscle architecture parameters during cycling to assess the behaviour of active muscle components. One study reported that changes in pedalling cadence (50 vs. 80 rpm) did not affect vastus lateralis (VL) fascicle length [2]. However, this study was limited to non-cyclists, which may not reflect training adaptations. Therefore, the purpose of this study was to compare the effects of two pedalling cadences (70 and 90 rpm) on VL muscle architecture of cyclists.

Methods: Nineteen competitive cyclists performed an incremental cycling test to exhaustion to determine their maximal power output, oxygen uptake and the workload of their second ventilatory threshold. They warmed up at 150 W for 10-min using their own bicycles on a stationary cycling trainer (Computrainer, Racermate, USA). The test started at 100 W with increments of 25 W/min until exhaustion while cadence was controlled at 90±2 rpm. After 48 hours they cycled for 1-min at their maximal workload measured during the first session at 90 rpm. After 1-min of rest, cyclists cycled for 2-min at the workload of their second ventilatory threshold at 90 and 70 rpm, in random order, separated by 1-min of rest. The cycling trainer was configured at constant workload mode. Muscle architecture parameters for their right VL were acquired using a linear probe (60 mm, 7.5 MHz) connected to an ultrasound system (ALOKA, SSD 4000, Tokyo, Japan). Video files with ultrasound images were stored at 30 Hz. Frames were digitized by two technicians using a motion analysis software (Skill Spector, Video4Coach, Denmark). Fascicle length, muscle thickness and pennation angle were defined as shown in Figure 1. Variables were averaged for the propulsion phase (45° to 135°) of the crank cycle for each cyclist [3]. Student's t-tests were employed for statistical comparison between the 70 and 90 rpm trials and significant differences were assumed when $p<0.05$.

Results: The VL fascicle length increased by 12% at the higher cadence ($p=0.01$). A decrease of 19% in pennation angle ($p<0.01$) without changes in muscle thickness were observed ($p=0.14$) (Table 1).

In this study, longer fascicle lengths and smaller pennation angles for VL were seen at 90 rpm. Austin et al.[2] assessed non-cyclists pedalling at workloads of ~250 W, which differed from the present study (324±37 W). Differences to Austin's study may be due to greater fascicle strain and due to the larger contribution from muscle passive elements in our study. Therefore, further research is warranted to assess if cyclists and non-athletes would differ in terms of VL muscle architecture behaviour during pedalling. Less skilled subjects may have greater co-contraction [4], which could affect VL muscle force and change muscle architecture for cycling at similar workloads.

Figure:

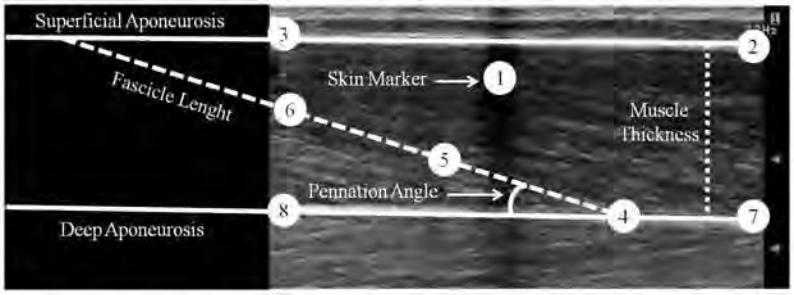

Figure 1. Illustration of vastus lateralis architecture. Markers (numbers) digitized for each video frame taken from ultrasound: (1) skin marker; (2-3) superficial aponeurosis; (4) fascicle insertion at the deep aponeurosis; (5-6) fascicle; and (7-8) deep aponeurosis. Fascicle length defined as the distance between fascicle insertion at the deep and at the superficial aponeuroses. Pennation angle defined as the angle between the deep aponeurosis and the fascicle. Muscle thickness defined as the perpendicular distance between superficial and the deep aponeurosis.

Conclusion: In conclusion, changing pedalling cadence from 70 to 90 rpm at constant workload increases VL fascicle length and decreases pennation angle.

Table: Table 1. Vastus lateralis fascicle length, pennation angle and muscle thickness at 70 and 90 rpm.

(%POmax trial)	70 rpm	90 rpm
Fascicle length	#74±33 %	#86±35 %
Pennation angle	#115±45 %	#96±34 %
Muscle thickness	101±5%	99±6%

# indicates significant difference between pedalling cadences ($p \leq 0.05$).

FORCE PRODUCTION AND WEIGHT SHIFTING DURING OLYMPIC LIFTS UNDER DIFFERENT ATTENTIONAL FOCUS CONDITIONS

James Becker [1] Natalie Maltz [1,*] Anthony Vidal [1] Will Wu [1]

[1] Kinesiology, California State University, Long Beach, Long Beach, United States

Introduction and Objectives: When providing coaching cues for snatch lift (SL), coaches may manipulate verbal instructions to elicit different attentional focus (AF) strategies from the athlete. Altering the AF directly affects the performance outcome[1], with instructions which direct the AF of the performer externally yielding greater improvements in performance than instructions which direct the participant's AF internally [1-4]. While some mechanisms behind these effects have been examined, how AF affects the forces generated by a lifter during a SL has not been examined. Therefore, the purpose of this study was to examine the force production and weight shift during first pull (1P), transition (T), and second pull(2P) of the SL and whether different AFs change the pattern of weight shift and ground reaction forces. It was hypothesized that the lifters would produce greater impulses with instructions which focused their attention externally compared instructions which focused their attention internally.

Methods: Nine experienced lifters (age: 24.5±3.02 years, experience lifting: 3.1±1.90 years). Participants performed snatch lifts at 80% of their 1-repetition maximum under three different attentional focus conditions: baseline (B), internal focus of attention (IF), and external focus of attention (EF). For the IF condition participants were instructed to "raise their elbow up rapidly" while in the EF condition they were instructed to "lift the bar up as fast as possible." The F-Scan (Tekscan Inc., Boston MA) in shoe plantar pressure system was used to measure normal forces under the foot, sampling at 500 Hz. A custom LabView (National Instruments, Austin TX) program was used to trim each lift from immediately before the lift began to just before the feet contacted the ground at the end of the second pull. Vertical impulse and peak vertical force were then extracted for analysis. Additionally, the forces under the whole foot, heel region, and metatarsal region were evaluated at the local peak force maximum during the 1P, T, and 2P phases of the lift. Differences in peak force and vertical impulse between conditions were evaluated using a one-way repeated measure ANOVA. Differences in forces under each region and between the three attentional focus conditions were evaluated using a 2-way repeated measure ANOVA.

Results: Peak force through the entire lift was not different between conditions (B: 2241.8 N ±559.8; IF: 2316.8±491.0 N; EF: 2345.7±475.8 N; $p = 0.575$). Propulsive impulse throughout the entire lift was lower in the EF condition than in the B condition (EF: 611.2±66.7 N*s; B: 667.1±67.2 N*s; $p = 009$), but there were no differences in propulsive impulse between EF and IF condition (IF: 624.9±71.9 N*s; $p = .395$).

There was no focus by phase interaction effect for force under the heel ($F_{1,1} = 4.8$, $p = 0.2$) or force under the metatarsals ($F_{1,1} = 1.2$, $p = 0.06$). Similarly, there was no main effect of attentional focus for force under the heel ($F_{1,17} = 1.7$, $p = 0.2$) or force under the metatarsals ($F_{1,17} = 1.5$, $p = 0.2$). There was no main effect for force under the heel at any phase of the lift ($F_{2,17} = 1.9$, $p = 0.2$). There was a significant difference between the forces under the metatarsals for the three phases, with force under the metatarsals being significantly higher in the 1P and 2P phases than during the T phase (T:

168.6±20.8 N, p=0.0). Finally, forces under the metatarsals were higher in the 2P than then 1P (1P: 373.2 ± 32.2 N, 2P: 513.3± 39.2 N, p=0.002).

Conclusion: The results of this study suggest focus of attention cues affect the impulses but not peak forces generated during the SL. The hypothesis was not supported by the results in that the external focus cue would be associated with a larger propulsive impulse. This seemingly contradictory finding may be partially explained by the constrained action hypothesis which suggests an external focus of attention results in a more efficient neuromuscular system. That peak vertical force was not affected by the application of different attentional focus cues agrees with previous results[1]. However, despite a difference in force production, improved performance outcomes were observed. Previous research on performance of the SL has suggested the rearward shifting of weight during the transition phase was a key element for a successful lift. While the results of this study do not fully support this hypothesis, there was a significant decrease in force under the metatarsals during the transition phase. Future research is required to examine if the magnitude of this weight shift is related to successful completion of the lift.

3D MOTION ANALYSIS OF WRIST ENGAGEMENT AND MALLET TRAJECTORY IN CROQUET

Jenny C. Clarke [1,*] Gavin Blackwell [1]

[1]School of Sport and Physical Education, University of Canterbury, Christchurch, New Zealand

Introduction and Objectives: A croquet swing is generated by holding the mallet with one hand gripping the mallet shaft above the other, and swinging so that the head of the mallet moves between the ankles backwards then forwards to strike a croquet ball. The swing is generated primarily from movement at the shoulders, though some body movement and flexion of the elbows and wrists can be involved.

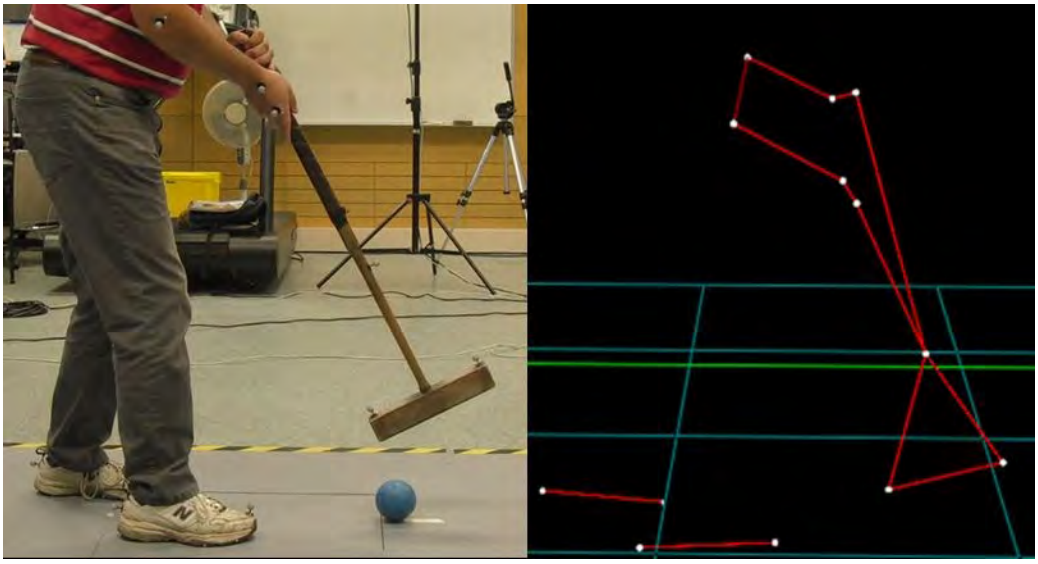
The aim of this study was to investigate the dynamics of the swing of a croquet mallet with specific attention to the wrist flexion of the lower hand and lateral deviation of the mallet head during the swing. Excessive wrist flexion has been associated with discomfort, particularly among older croquet players who dominate the sport's demographic. Lateral deviation of the mallet, a twisting of the mallet about its shaft, leads to a swing in which the mallet head does not follow a desirable straight trajectory, requiring the player to accurately correct the trajectory of the mallet at the moment of impact for a straight hit. This research sought to determine if there was a correlation between excessive wrist flexion and lateral rotation of the mallet head.

Methods: Twenty-six association croquet players (17 male, 9 female) with ages ranging from 21 to 85 yeas old participated in the croquet swing study. All respondents use the 'standard' croquet grip with the knuckles of the top hand facing forward, the palm of the lower hand facing forward, and both hands either very close together or slightly overlapping. A BTS 3D imaging system was used which utilizes 4 infra-red cameras to track reflective markers placed on the arms, hands, feet of the participants. Additional tracked markers were placed at the front and back of the head of the mallet and at the top of the shaft of the mallet. Dynamic position information was recorded with an accuracy of 0.5mm. In addition, high definition and high-speed (300 frames per second) cameras were used to capture visual footage of the strokes.

Each participant had 2-3 practise strokes in the lab before taking 10 shots hitting a croquet ball with their own mallet in their usual stance and style at a stationary croquet ball which was 4.5m from the striker’s ball. The flexion of the wrist from the starting point of the swing to the peak of the backswing was measured for each stroke, as well as the angle of lateral rotation of the mallet at the peak of the backswing compared to the neutral position at the starting position of the swing. A Pearson correlation was used to test if there was a relationship between wrist flexion and rotation of the mallet about the shaft (lateral deviation) at the peak of the backswing. The peak of the backswing is the point at which the swing is most crooked.

Results: A significant correlation was found between the flexion of the wrist on the lower hand gripping the mallet and the rotation of the mallet head about the shaft of the mallet. This provides evidence that an undesirable twisting motion in the croquet swing is caused, at least in part, by excessive engagement of the wrist.

Figure:



Caption: Placement of markers for 3D motion capture analysis of croquet swing and marker tracking using BTS Smart Tracker. The lower hand markers clearly indicate the wrist angle of interest.

Conclusion: The study sought to determine if there is a relationship between flexion of the lower wrist of a standard grip croquet player between the start of the backswing and at the peak of the backswing.

A straight backward and forward swing produces a longer period of path of the swing during which contact between the mallet and ball will result in a straight and accurate shot. While a crooked swing can still be straight at the time of impact, numerous anecdotal evidence suggests that extended periods of inaccurate shooting can affect players with crooked swings, and that these “bad spells” can be harder to correct or recover from. Additionally,

A significant relationship was found between the lateral deviation at peak backswing and flexion of the lower wrist from the start of the swing to the peak of the backswing. This provides strong evidence that a significant mechanism generating the crooked backswing is lower wrist flexion.

This study has found both an anatomical mechanism for an undesirable swing characteristic in the mallet sport of croquet, and suggests an 8-week intervention using psychological and physical training in the form of visualisation and non-striking swinging practice to reduce this characteristic and affect an improvement in shooting performance of croquet players.

Future work involves testing the intervention in-season on a group of croquet players, while monitoring swing accuracy and physical comfort. The next stage involves developing and implementing a more detailed/methodological intervention for croquet coaches to disseminate to club and higher level players. Finally, this analysis can be immediately applied to putting in golf.

MODELLING AND SIMULATION OF OSTEOCHONDRAL AUTOGRAFT TRANSFER: QUANTIFYING THE EFFECTS OF CARTILAGE THICKNESS MISMATCH BY FINITE ELEMENT ANALYSIS

Yuxing Wang [1,*] Richard A. Black [2] Yubo Fan [1]

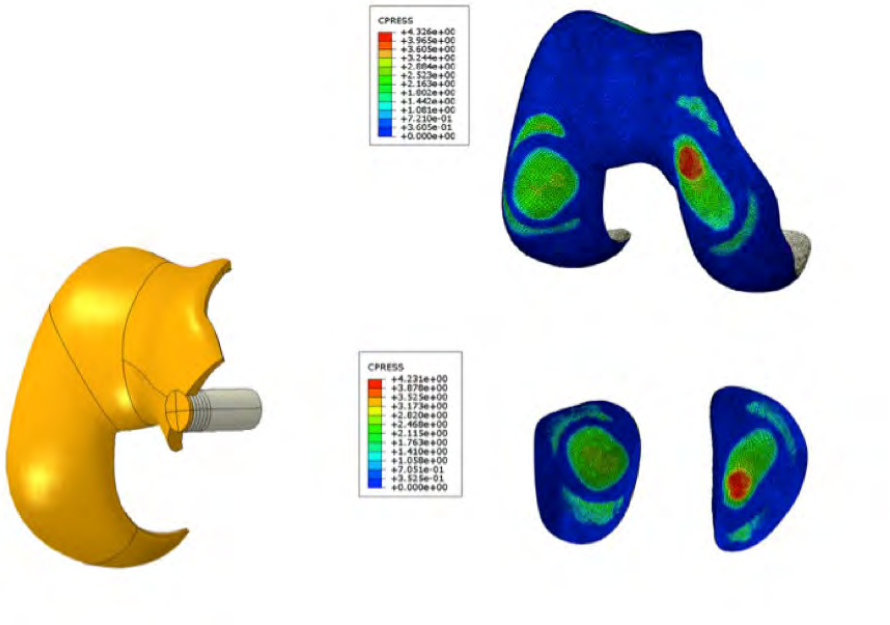
[1]School of Biological Science and Medical Engineering, Beihang University, Beijing, China, [2]Department of Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Injuries sustained by articular cartilage are relatively common and lesions persist as cartilage is avascular and has a relatively poor capacity for healing. Acute injuries and degeneration of the joints affect not only the elderly but younger, physically active people also. Without treatment, these lesions can easily aggregate and progress to osteoarthritis so it is important that patients are treated at an early stage. Surgical approaches such as Osteochondral Autograft Transfer (OATS), autologous chondrocyte transplantation or articular resurfacing may be considered in such cases. OATS involves harvesting 'plugs' of cartilage and underlying bone from healthy regions to restore damaged areas, but the biomechanical basis for this procedure is unclear. While the size, mechanical properties, and shape of such grafts have been the subject of previous studies, little attention has been paid to the differential properties of the tissues involved: grafts are harvested from non-load bearing sites on the periphery and transplanted to the damaged area, which is usually located more centrally (see Figure). Consequently, there is likely to be a mismatch of cartilage thickness between the implant and surrounding tissue. The aim of this study, therefore, was to quantify the impact of this mismatch on the stress distribution and contact pressures generated within the cartilage of the apposing surfaces, and within the graft itself, under loading conditions representative of the human knee joint.

Methods: A parametric analysis was carried out to investigate the influence of cartilage thickness mismatch using a finite element model of the human knee joint [1]. The 3D model was developed in MIMICS, and was based on magnetic resonance images of a healthy knee, including bony parts, cartilages, menisci and major ligaments. The individual components were meshed with hexahedral elements within Abaqus, and assigned mechanical properties determined from the literature. A cylindrical defect was created at the medial condyle of the femur; likewise, a cylindrical osteochondral ‘graft’ was added to simulate the transplantation. The cartilage thickness of the graft was varied from one third up to twice the original thickness to simulate the thickness mismatch, as shown in the Figure. A static compressive load of 1000N was applied during each simulation. Forces originating from the surrounding musculature were also represented, and assigned values reported in the literature – quadriceps (215N), biceps femoris (31N), and semimembranosus muscles (54N).

Results: The results of the simulations are tabulated in terms of Von Mises stresses and contact pressures that develop within the cartilage compartments in each case. Here, the mismatch in cartilage thickness is expressed as a ratio of autograft to intact thickness. The results indicate that a mismatch in cartilage thickness where the cartilage of the autograft is thinner than the surrounding cartilage gives rise to greater contact pressures and stresses, and that these stresses return to the levels seen in the intact tissue as the thickness of the cartilage increases. It follows that a graft having a greater cartilage thickness is to be preferred in cases where a perfect match is difficult to achieve.

Figure:



Caption: Contact pressures (MPa) following osteochondral autograft transfer (OATs) procedure. The knee model is based on that developed by Wang et al., 2014 [1].

Conclusion: The finite element model of the intact knee was originally developed to determine the stresses developed in knee cartilage during kneeling and standing [1]. Here, the model has been modified to determine the contact pressures and stress distribution in human knee cartilage following osteochondral autograft transfer. The results of the present study suggest that better matching of graft dimensions may improve the quality of engraftment, but it remains to be shown whether improvements in fixation will lead to better outcomes in the longer term. With further refinement, however, we believe that modelling approaches of this kind will improve our understanding of the role of tissue properties and biomechanical factors in the fixation of osteochondral grafts during surgery, and their subsequent remodelling post operatively.

Table:

	Femoral Surface		**Tibial Surface**	
Autograft/Intact Cartilage Ratios	Peak von-Mises Stress (MPa)	Peak Contact Pressure (MPa)	Peak von-Mises Stress (MPa)	Peak Contact Pressure (MPa)
Intact Cartilage	1.62	3.27	1.49	3.27
Void (autograft absent)	3.15	3.95	1.72	3.89
1/3	1.71	3.70	2.14	4.23
2/3	1.62	3.21	1.76	3.67
Full thickness autograft	1.72	3.06	1.50	3.27
4/3	1.91	3.03	1.48	3.05
5/3	1.95	3.02	1.46	3.00
6/3	1.97	3.00	1.45	2.99

BOTTOM-UP MECHANO-STRUCTURAL MODELING OF THE CARTILAGE MATRIX

Ying-Chun Chen [1,*] Minsi Chen [2] Andrew Price [1] Cameron Brown [1]

[1]Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, University of Oxford, Oxford,

[2]Department of Computing and Mathematics, University of Derby, Derby, United Kingdom

Introduction and Objectives: To understand early interventions for diseases such as osteoarthritis, we need to understand what constitutes functionally viable tissue, and the 'tipping point' at which damage becomes irreversible. As one of the major structural components and determinants of function in the cartilage matrix, collagen plays a central role in the disease process.[1] Collagen meshwork disruption is rarely repaired,[2] and reconfiguration in early stages of disease has been observed before histological changes become apparent.[3]

Modeling can be used to explore mechano-structural changes in both disease and repair. Cartilage modeling has been extensively pursued using continuum approaches, with a number of recent approaches considering collagen organisation.[e.g. 4] Simulating local restructuring or damage progression on a relevant scale for early disease is challenging. The aim of this study is to develop a structure-based computational model to explore ultrastructural responses to the load with time accumulation and local damage feedbacks. We take a 'bottom-up' approach to set the arrangement, orientation and properties of each constituent part at the nano- to micro-scale, and assemble them into a tissue structure. Here, we report our development of a collagen-fluid interaction model.

Methods: Our current model comprises of the interstitial fluids (e.g. collagen, proteoglycan) and the extracelluar collagen matrix. The incompressible interstitial fluids are modeled using the Navier-Stokes equation over a regular Eulerian grid. We use an FFT based solver for the incompressible fluids. The collagen matrix consists of a collection of masses interconnected by non-linear springs. The configuration of the matrix including the mass connectivity is taken directly from previous experiments.[3] With this approach, the mechanical properties of the collagen fibril [5] are embedded in the non-linear spring force connecting the masses. Our current implementation is written in C++ which utilises the GPU for fluids related computation and the host CPU for simulating the collagen structure.

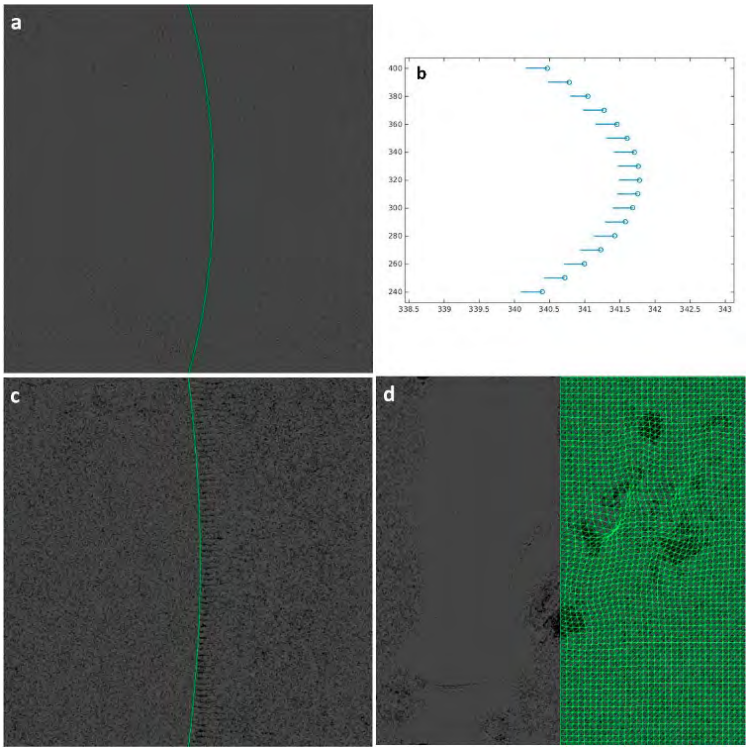
The resolution of matrix-fluid interaction is divided into two phases similar to the immersed boundary methods. Firstly, masses on the collagen matrix are advected over the fluid grid. Following the advection, each matrix mass exerts a force to the fluid based on the strain in connecting springs. We tested different levels of abstraction/simplification on a single-fibril system under a far-field constant fluid velocity. The interaction was calculated and applied at the nearest fluid-grid node to the mass-spring node, at ±3 and ±5 fluid-grid nodes, and at the fluid-grid nodes along the fiber. Impulse-based collision calculations were also tested. Once interactions were established in the single fibril configuration, they were applied to a regular grid.

Results: Under a constant far-field fluid velocity applied perpendicular to the single fibre, the fibril deformed and settled in the configuration shown in Figure 1a. Solid node reactions of the single fibril, accelerating against the direction of fluid flow, are given in Figure 1b. Upon resetting the fluid velocity field to zero, the spring returns to its original position over a period of 3.5 minutes. Altering the interaction implementation had little effect on the global response of the fluid and solid,

however the local fluid field was adversely affected for the single fluid-grid node and ±3 node setups (Figure 1c). This effect was limited at low fluid velocities.

Using a regular grid configuration and locally applied fluid velocity fields or collagen meshwork deformations (Figure 1d), the constraints added by adjacent solid nodes further limited the adverse effects of simplified interactions. Again, the system deformed under the applied load and returned to its original configuration when the fluid velocity field was reset. Enabling damage feedbacks in the solid caused irrecoverable deformation.

Figure:



Caption: Collagen-fluid interaction results: (a) Typical single fibril deformation under fluid flow; (b) reaction of solid nodes opposing fluid flow; (c) nearest-neighbour interaction showing local fluid field inhomogeneity to right of fibril; (d) deformation and fluid field patterns in regular grid configuration.

Conclusion: The current implementation of the 'bottom-up' spring-mass-fluid model can simulate the interaction between fluid and the collagen meshwork on a scale relevant for early damage. Using this structure-centred approach, physical and biological feedbacks can be used to simulate degradation and repair processes. Further work will be required to include aggrecan behaviour and interactions, and to link structural damage with diagnostic parameters.

COMPARISON BETWEEN ELASTIC AND POROELASTIC MODEL TO SIMULATE CARTILAGE-MENISCUS-CARTILAGE INTERACTIONS

Bernardo Innocenti [1,*] Cristiano Vitanza [2] Leonardo Ruggiero [3] Alberto Audenino [2] Thierry Massart [4] Walter Pascale [5] Silvia Pianigiani [5]

[1]BEAMS Department, Université Libre de Bruxelles, Bruxelles, Belgium, [2]Politecnico di Torino, Torino, Italy, [3]Department of Mechanics of Materials and Constructions, Vrije Universiteit Brussel, [4]Building, Architecture & Town Planning, Université Libre de Bruxelles, Bruxelles, Belgium, [5]IRCCS, Istituto Ortopedico Galeazzi, Milano, Italy

Introduction and Objectives: Articular cartilage and menisci are two soft tissues playing an important role in the knee joint biomechanics. In fact, they act as load bearing structures and shock absorbers. However, in the literature, there is not agreement in describing these two soft tissues mechanical behaviour. Usually, they are mainly modeled with elestic or poroelestic in order to develop close-to-real native knee finite element models, but discordant approaches can be found. For these reasons, the aim of this work is to develop and compare different models to simulate the femoral cartilage-meniscus-tibial cartilage (CMC) interaction by means of finite element analysis (FEA).

Methods: Both cartilages and meniscus were modelled as simplified geometries. Similar rectangles in a frictionless contact where considered for 2D-axisymmetric simulations in which both the cartilage and the meniscus material were modelled as poroelastic or elastic only. The values to characterize the properties for the two selected models were based on literature studies.

The same mesh element was chosen for both material models. The addiction of the bilinear pore pressure characteristic was considered for the poroelastic model.

Developing a model with poroelastic properties, boundary conditions (BCs) must differentiate in mechanical and fluid BCs. Particularly, in a poroelastic numerical model, the contact between two or more structures has a fundamental role. A literature study analysed the contact with sealed and contact dependent surfaces, and they obtained that surfaces have the same behaviour for the first two seconds of a simulation. According with these results, the cartilage surfaces contacting were assumed sealed and the interaction between the two structures frictionless. Based on these findings, the CMC model was set to simulate a soil analysis and Nlgeom, parameter to consider finite deformation. As presented in experimental studies, a homogeneous pressure of 12 kPa was axially applied on the top of the rectangular representing the femur cartilage.

Contact pressures, stresses and displacements are analysed under these conditions.

Results: A significant difference, particularly in terms of contact pressure and displacements, is shown by the obtained outputs comparing the poroelastic and elastic model. The contact pressure (Figure 1a) of the elastic model decreases up to 38% for the poroelastic configuration with respect the elastic one. Analysing the displacements, in both the radial (Figure 1b) and in the axial direction (Figure 1c), the poroelastic model presents higher values than the elastic (up to 2-3%). The mechanical response in term of Von Mises stresses (Figure 1d) shows no differences between the two modelling approaches and also a similar qualitative distribution can be observed.

Figure:

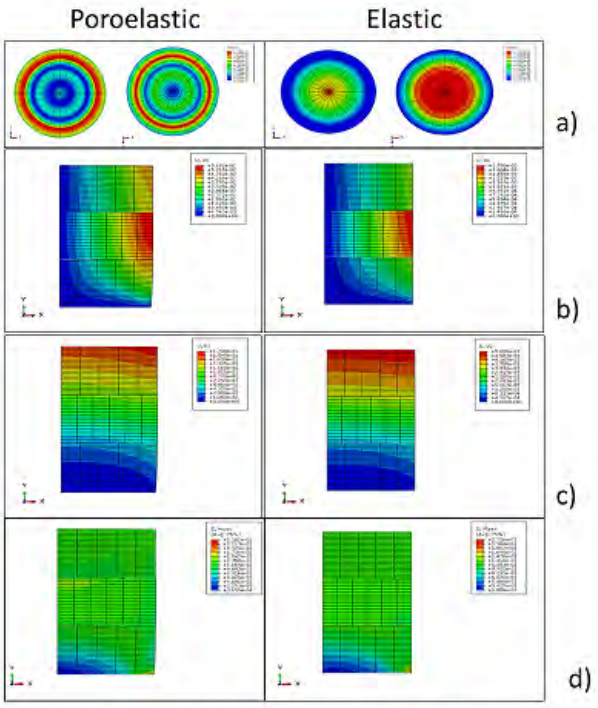

Figure 1: a) contact pressure; b) radial displacement; c) axial displacement; d) qualitative stress distribution

Conclusion: The aim of this study was to develop a methodology to compare different models to simulate the CMC interactions by means of FEA. For this reasons, the CMC interaction has been modeled using elastic and poroelastic material characteristics under boundary conditions replicating experimental tests.

The results show that the elastic model is more rigid than the poroelastic one, above all comparing the contact pressure and displacements, nevertheless the same mechanical response in terms of stress was obtained. One limitation of this study is the use of 2D-axisymmetric model with simplified geometries to simulate real CMC in a knee joint. Moreover, permeability depends on the deformation state of the soft tissue, but in the present study was assumed to be constant. However, this assumption does not reply in the analysis of other outputs, as contact pressure and displacements, which requires the development of a poroelastic model. In addition, these simplifications allow reducing the computational time for the solutions of both models, in particular of the poroelestic one.

For these reasons, we can conclude that our findings are important in order to simulate close-to-real native knee FEA models and different approaches in material definition can be followed dependently on the investigation type. Our model can be improved considering real geometries of the analysed soft-tissue structures, but it can deliver a first important advice for the modelling and the understanding of these structures behaviour under different loading conditions. The use of the outcomes of this work are useful in providing replies for question related to cartilage and meniscus behaviour derived from clinical practice and to provide useful information for the development of new material replicating these structures.

POROELASTIC FINITE ELEMENT MODEL OF OSTEOGENESIS WITHIN A TITANIUM SCAFFOLD COUPLING BIOLOGY AND MECHANICS

Mary Schmitt [1,*] Rachele Allena [1] philippe Rouch [1]

[1] LBM / Institut de Biomécanique Humaine Georges Charpak, Arts et MétiersParisTech, Paris, France

Introduction and Objectives: Bone is a living tissue able to restore itself when it is injured. However, when a defect exceeds a critical size a structural support such as a scaffold is required in order to enhance osteogenesis. Recently, several experimental [1] and numerical works [2,3] have been developed to better understand the complex process of osteogenesis within scaffolds.

Following a preliminary study [4], we propose here a more exhaustive three-dimensional poroelastic finite element model, which couples mechanics and biology and simulates bone ingrowth within a titanium scaffold implanted into ewes' mandibles during twelve weeks. The main goal of the present work is to evaluate the effects of the mechanics on the cellular activity (*i.e.* the mechano-transduction phenomenon).

Methods: Our model is based on an experimental study, which aims to evaluate the osteogenesis within a titanium scaffold implanted on the non-toothed part of ewes' mandible during 12 weeks. We use a simplified 3D beam to represent the titanium scaffold (18mm long and 12mm width, Figure 1a). The left boundary of the scaffold is clamped, while the right boundary is submitted to a cyclic load describing the ewe's mastication with a period of 1s.

For the sake of computation time, an algorithm has been developed.

First, since the interstitial fluid may have a real impact on cells activity [5], the scaffold is considered as a poro-elastic material and the poroelasticity equations are solved during one mastication cycle. More specifically, the total stress is related to the effective stress in the solid phase and to the interstitial pressure in the fluid phase. Furthermore, the variation of the pressure satisfies a partial differential equation depending on the porosity, on the permeability of the scaffold, on the compressibility and the viscosity of the interstitial fluid as well as on the global displacement of the structure. We assume that the external boundaries of the system are free draining.

At the end of the mastication cycle, the average fluid velocity, which will be involved in the differentiation pathway of the mesenchymal stem cells (MSCs), is stored.

Second, the reaction-diffusion equations which describe the complex cellular activity within the scaffold are solved for 1 week. This complex cellular activity occurs in 4 successive steps and involves different type of cells: i) the migration and the proliferation of the MSCs ii) the differentiation of the MSCs into either osteoblasts, chondrocytes or fibroblasts iii) the proliferations of the osteoblasts, chondrocytes and the fibroblasts and iv) the formation of the extracellular matrix (bone, cartilage and fibrous tissues respectively). Thus, the evolution of the different cells concentrations in the scaffold are regulated by three processes: migration, proliferation and differentiation. The migration term allows coupling the cells concentrations with the principal stress and directions of the structure. The proliferation term allows simulating the cell division (mitosis) until the maximum total cells concentration is not reached. Finally, the differentiation term allows the MSCs differentiation into either osteoblasts, chondrocytes or fibroblasts and starts after a maturation time of 14 days.

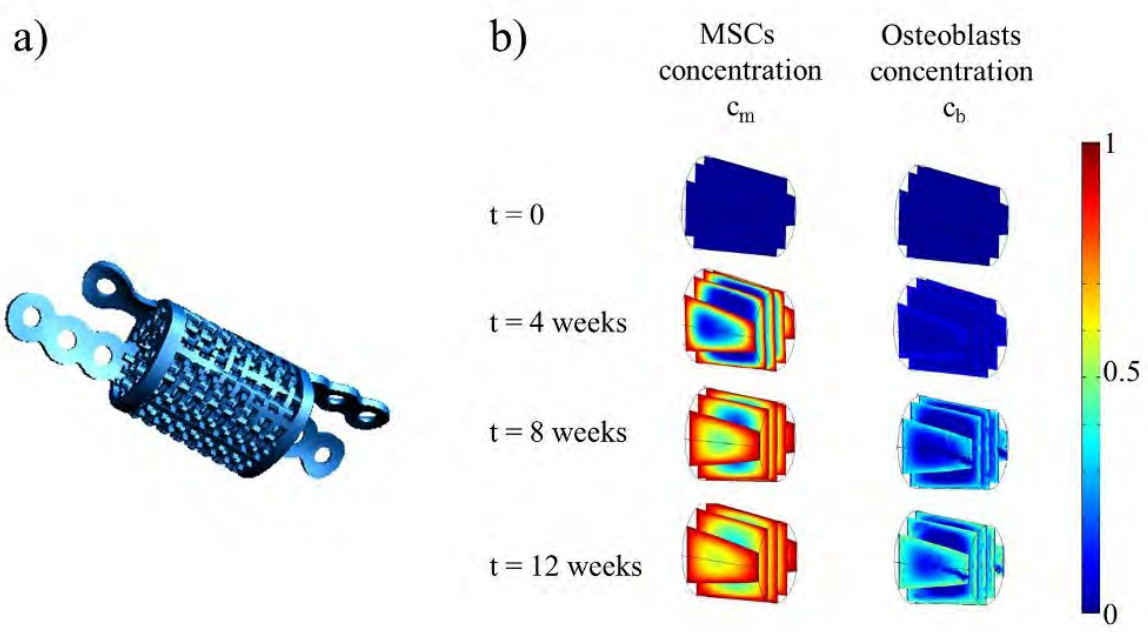
Moreover, since cells differentiation may be affected by the mechanical environment, the differentiation pathway is regulated by two biophysical stimuli: the shear strain and the interstitial fluid velocity [2].

After 1 week, the cells distribution and the mechanical properties of the scaffold are updated and stored. Then, steps one and two are recomputed to cover a time interval of 12 weeks.

Results: In Figure 1b, the evolution with respect to time of MSCs and osteoblasts concentrations is represented. We can observe that the cellular colonization of the MSCs takes place from the exterior towards the interior of the scaffold as it has been experimentally observed. Moreover, since the differentiation process starts after 14 days of maturation, we observe that after 4 weeks, there are few osteoblasts.

Currently, micro-computed tomography scanners of the 12 weeks explanted hemi-mandibles are being performed in order to validate our mechano-biological approach.

Figure:



Caption: (a) Titanium scaffold (b) MSCs and osteoblasts concentration cm and cob respectively at 0, 4, 8 and 12 weeks.

Conclusion: In conclusion, we propose a 3D poroelastic finite element model of osteogenesis able to predict bone ingrowth during 12 weeks within a titanium scaffold submitted to a cyclic load while keeping a reasonable computation time.

A NEW STRAIN ENERGY FUNCTION FOR THE HYPERELASTIC MODELLING OF LIGAMENTS AND TENDONS BASED ON FASCICLE MICROSTRUCTURE

Tom Shearer [1,*]

[1]School of Mathematics, University of Manchester, Manchester, United Kingdom

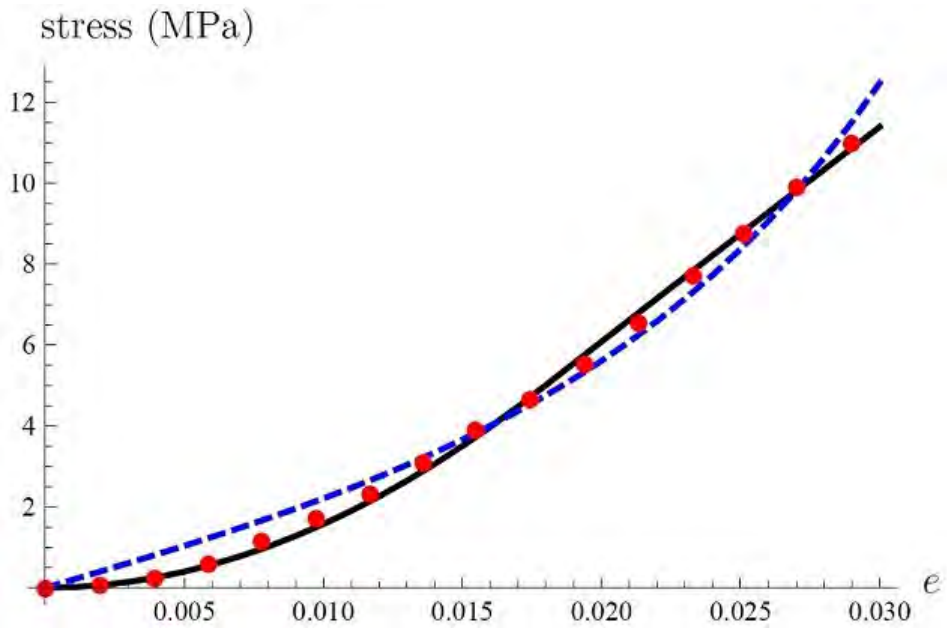
Introduction and Objectives: Ligaments and tendons are fundamental structures in the musculoskeletal systems of vertebrates. Ligaments connect bone to bone to provide stability and allow joints to function correctly, whereas tendons connect bone to muscle to allow the transfer of forces generated by muscles to the skeleton. The wide variety of roles played by different ligaments and tendons requires them to have considerably different mechanical responses to applied forces, and their differing stress-strain behaviours have been well documented.

Ligaments and tendons consist of collagenous fibres organised in a hierarchical structure. Their main subunit is the fascicle which consists of fibrils arranged in a crimped pattern. In this talk I will derive a new strain energy function for the hyperelastic modelling of ligaments and tendons based on the geometrical arrangement of their fibrils, and will compare the ability of the new model to match experimental data with that of the commonly-used Holzapfel-Gasser-Ogden (HGO) model [1]. There have been many attempts to mathematically model the behaviour of ligaments and tendons within a non-linear elastic framework; however, the vast majority of these (including the HGO model) are phenomenological. A micro-structurally based model will allow us to understand *how* the mechanical reponse of ligaments and tendons results from the arrangement of their constituent subunits.

Methods: Kastelic et al. [2] derived the stress-strain response of a fascicle under uniaxial tension as a function of the microstructural arrangement of its fibrils. Unfortunately, however, an error in the implementation of Hooke's law in that paper led to the derived stress-strain relationship being incorrect. In this talk, I correct the mistake in [2] and use a new functional form for the radial crimp angle distribution in order to derive an analytical expression for the stress-strain response of a single fascicle and use this expression to derive the new strain energy function.

Results: The new model is compared with the HGO model and it is shown that the new model gives a better match to exisiting stress-strain data for human patellar tendon [3] than the HGO model, with the average relative error when using the new model being 0.053 (compared with 0.57 when using the HGO model), and the average absolute error when using the new model being 0.12MPa (compared with 0.31MPa when using the HGO model). In the figure, the experimental and theoretical stresses are plotted as a function of the longitudinal strain; the red dots are the experimental data taken from [3], the solid black line is the new model, and the dashed blue line is the HGO model.

Figure:



Conclusion: The new model shows excellent agreement with experimental data and also has the advantage of only containing parameters that can be *directly measured via experiments*. Since the model is expressed in terms of a strain energy function, it can easily be implemented into finite element software in order to decribe complex mechanical deformations. In the future, it will hopefully be possible to extend this model to incorporate viscoelasticity in order to understand phenomena such as hysteresis and stress-relaxtion, which have been observed experimentally in ligaments and tendons.

KINETIC COMPARISON OF WALKING ON AN INSTRUMENTED TREADMILL VERSUS OVER GROUND IN CHILDREN WITH AND WITHOUT CEREBRAL PALSY

Marjolein M. Van Der Krogt [1,*] Lizeth Sloot [1] Jaap Harlaar [1]

[1] Rehabilitation Medicine, VU University Medical Center, Amsterdam, Netherlands

Introduction and Objectives: Instrumented treadmills are increasingly used in clinical gait analysis and gait (re)training, since they allow for measurement of many consecutive steps and facilitate use of feedback and perturbations. Previous studies found consistent but small differences between overground (OG) and treadmill (TM) walking for healthy adults [1,2]. These include slower walking speed, shorter and wider steps, and small differences in kinematics, kinetics and EMG.

Recently it has been shown that kinematics are generally similar between OG and TM for typically developing children and children with cerebral palsy (CP) [3]. However, kinetics have not yet been compared for children nor for individuals with CP.

The aim of this study was to compare kinetic outcomes (ground reaction forces (GRF), center of pressure (CoP), joint moments and joint powers) between OG and TM walking in a virtual environment, for typically developing (TD) children and children with spastic CP.

Methods: 20 children were included: 9 children with spastic CP (4 male, 5 female; age 11.6±2.1 years, range 8-14; height 1.49±0.13 m; weight 40.9±10.3 kg) and 11 TD children (7 male, 4 female; age 10.6±2.2 years, range 8-15; height 1.52±0.15 m; weight 38.2±10.5 kg).

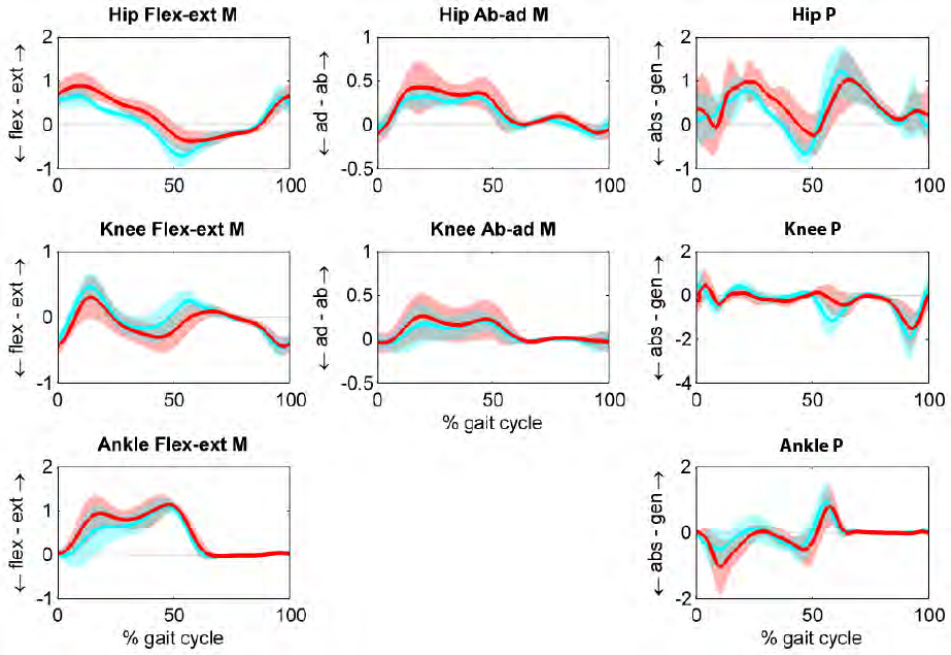
In one session, subjects walked in random order 1) OG in a conventional gait lab with two embedded force plates (AMTI); and 2) on a dual-belt instrumented TM (R-Mill, Forcelink), placed in a speed-matched virtual environment (GRAIL system, Motek Medical BV). The speed of the belt was real-time adjusted to match the subject's time-varying walking speed, by means of a self-paced speed algorithm [4]. 3D motion capture data were collected using identical systems in both labs (Optotrak, Northern Digital Inc.).

Joint moments and powers were calculated using ISB definitions [5]. As outcome measures, key peak values were calculated for GRF, CoP (relative to heel marker), hip, knee, and ankle moments and powers, as well as the total amount of positive and negative work done by hip, knee and ankle. Walking speed was analyzed as a potential confounding factor. All data was averaged over five strides per subject for each lab. Condition (OG/TM), group (TD/CP) and interaction effects were determined using an ANOVA for repeated measurements.

Results: Peaks of vertical and anterior-posterior GRF were identical between OG and TM, but mediolateral GRF was on average 96% larger in TM ($p<0.001$). CoP was 10% of foot length more posterior in TD and 13% more anterior in CP (interaction $p<0.001$). Furthermore, CoP was more medial in TD (20% of foot width, $p=0.004$), but similar in CP children. Peak hip extension moment and hip and knee abduction moments were increased in TM by 35% and 36% respectively ($p<0.01$; Fig. 1). Peak ankle extension moments were decreased by 7% in TD but increased by 9% in CP (interaction

p=0.039). Total positive hip work increased by 15% in TM (p=0.014), while total positive ankle work decreased by 25% (p=0.002). Peak ankle power tended to be lower (p=0.09). Walking speed did not differ significantly.

Figure:



Caption: Figure 1. Hip, knee, and ankle moments (M) and powers (P) averaged over all children with CP for OG (cyan) and TM (red).

Conclusion: Kinetics differed considerably between TM and OG walking. Mediolateral GRF and joint moments were larger in TM than OG, which could be explained by a 3-4 cm larger stride width in TM for these subjects [3]. A shift was observed from ankle to hip work, indicating that subjects relied more heavily on a hip strategy in TM. Despite similar vertical and anterior-posterior GRF, no consistent shift in CoP, and very similar kinematics [3], hip extension moments were considerably larger in TM. This could be explained by 4° more forward lean of the trunk on the TM, possibly due to looking more downward. This resulted in a more backward positioning of the hip relative to the CoP (too subtle to be visible in individual joint angles) and hence a larger hip moment. The increased ankle moment (Fig.1) and anterior shift of the CoP in early stance in CP are consistent with increased ankle dorsiflexion angle found for these subjects in this same phase [3]. Differences were larger than previously found for healthy adults [1,2].

This study indicates that CP and TD children show differences in joint moments and powers on a TM, and hence kinetic data collected on a TM cannot be readily compared with OG data. For clinical applications, it must be considered that both OG and TM conditions constitute highly controlled experimental settings. Therefore the key clinical question - which controlled situation is most relevant for clinical treatment decision and evaluation to improve walking performance - remains open.

IMPROVED CALIBRATION OF INSTRUMENTED TREADMILLS USING AN INSTRUMENTED STICK

Lizeth Sloot [1,*] Han Houdijk [2] Marjolein van der Krogt [1] Jaap Harlaar [1]

[1]Rehabilitation Medicine, VU University Medical Center, [2]Faculty of Movement Sciences, VU University, Amsterdam, Netherlands

Introduction and Objectives: Accurate measurement of ground reaction forces and centre of pressure (COP) is essential for calculation of joint moments in gait analysis. Since instrumented treadmills are more prone to measurement error compared to traditional force plates, because of their large and compliant structure, it is important to improve their accuracy by means of precise calibration.

Until now, only one protocol has been published to calibrate treadmill-embedded force plates over all axes [1], by manually exerting a range of known forces at different spots on the belt. While this method increased the COP accuracy considerably [1], the optimal number of spots or duration of trials is not known, possible non-homogeneity in COP error across the belt surface is not corrected for, and the calibration is not performed under experimental conditions. This study examined if the calibration could be improved by 1) variation of the measurement time per spot and the number of spots; 2) correction of non-homogeneous distribution of COP error; and 3) by performing the calibration on an operative belt, i.e. dynamic calibration.

Methods: An instrumented stick, equipped with 3 optical markers for motion tracking and a 1DOF axial load cell, was used to manually apply a range of forces over all axes, starting by maximal vertical force application followed by a circular movement, on a dual-belt instrumented treadmill (R-Mill, ForceLink). To construct different calibration matrices, 85 calibration trials of 5s each were performed at different spots equally spread over the area of each belt. A validation dataset consisting of 11 trials per belt was captured to determine the mean accuracy of the different calibration matrices. For dynamic calibration, 12 calibration and 3 validation trials were measured per belt at 1 km/h, exerting force with the stick while walking aside the treadmill.

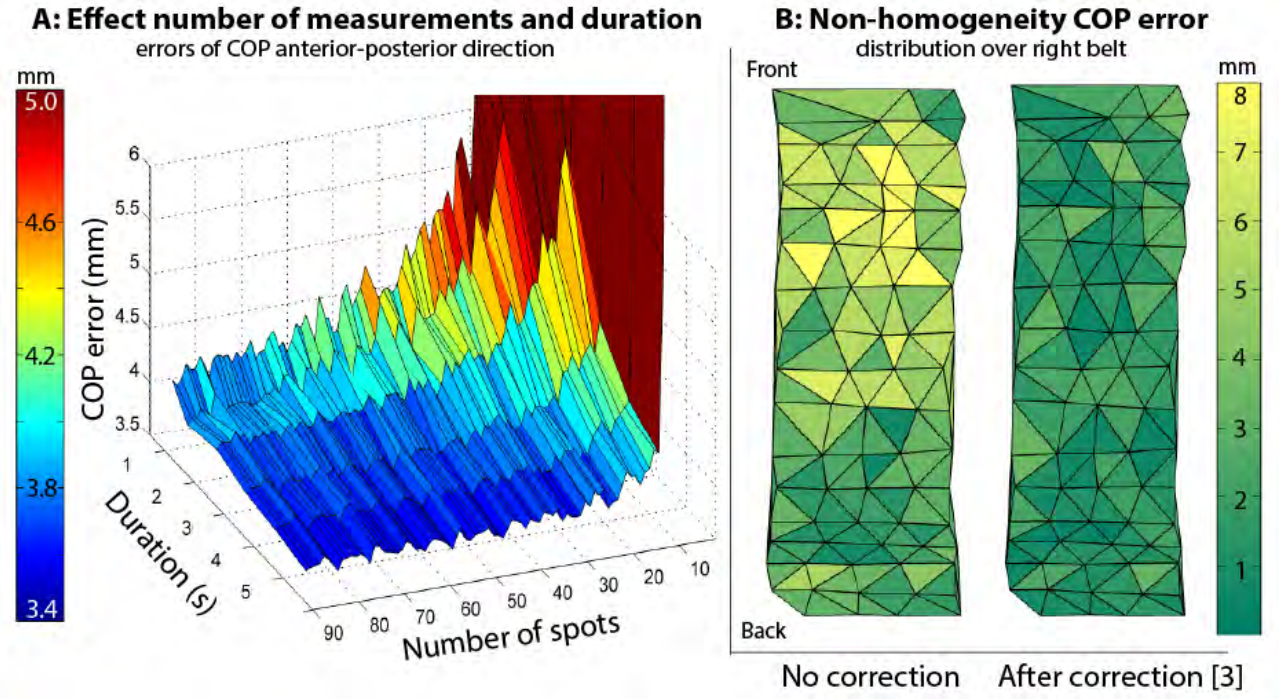
First, a reference calibration matrix was constructed using 20 datasets of 5s, similar to Collins [1,]by minimizing the mean-square error between reference (stick) and offset-corrected treadmill outputs. To examine the effect of measurement time and number of spots, new calibration matrices were constructed using from 0.5 to 5 seconds of the included trials and from 4 up to 85 spots using a selective bootstrapping procedure of 50 repetitions. The ‘optimal’ duration and number of spots was defined as less reduction in error than 0.1%. For correction of non-homogeneity in COP error, 2 correction algorithms were fitted to the COP errors calculated from the 85 trials per belt [2,3] and applied to the validation data. To evaluate the effect of dynamic calibration, both the reference static matrix and a constructed dynamic calibration (using the dynamic calibration data) matrix were evaluated with the dynamic validation trials.

Results: The reference calibration resulted in mean COP error of 6.5 mm. The accuracy of COP increased with increasing measurement time (up to 5 seconds) and number of spots (up to 31), reducing the error to 5.4 mm (figure 1A). Vertical force accuracy was most optimal when using only the first 2 seconds of each trial, during which the highest vertical forces were applied.

One correction algorithm [3] resulted in reduced non-homogeneity in the COP error compared to the reference calibration (figure 1B), with an average error of 6.1 mm, in contrast to the 6.5 mm of the other [2].

Under dynamic conditions, the COP error of the static calibration increased up to 4 times. The dynamic calibration resulted in 24% lower COP errors than the static calibration under these conditions.

Figure:



Caption: Figure 1 A) Effect of the number of spots and duration on the COP error of the left belt; B) distribution of the average COP error over the right belt, before and after correction

Conclusion: We found that the result of calibration of instrumented treadmills depends on the measurement duration and number of spots, with capturing 31 points for 5 seconds proving best results. However, the relation between accuracy and exerted force during the stick movement found for the vertical force, suggests that the movement could be further optimized.

Correction of the presented non-homogeneity also reduced the COP error. Such a correction is specifically important for measurements where subjects use the entire belt, eg. during self-paced walking, and might be further optimized by creating a correction algorithm for the treadmills' specific distortions.

Most calibrations are performed under static conditions, however, the accuracy considerably decreases when examined under experimental conditions, even at the slow speed we measured. This, together with the finding that dynamic calibration provided better accuracy, underlines the need for further development of dynamic calibration methods.

FUNCTIONAL ESTIMATION OF THE METACARPOPHALANGEAL JOINT AXES OF ROTATION

Pierre Devos [1,*] Clint Hansen [1] Khalil Ben Mansour [1] Frédéric Marin [1]

[1] Laboratoire de biomécanique et bioingénierie - CNRS UMR 7338, Université de Technologie de Compiègne, Compiègne, France

Introduction and Objectives: In order to prevent injuries of the hand and to improve therapies, it is essential to understand the hand kinematics (Vignais et al, 2013). Kinematic description of the hand requires the estimation of the joint axes of rotation (AoR). The aim of this paper is to compare two functional methods to estimate the metacarpophalangeal (MCP) joint AoR of fingers.

Methods: Ten healthy volunteers aged from 19 to 54 years participated in the experiment. Subjects were asked to do three repetitions in flexion-extension (F-E) and abduction-adduction (Abd-Add) of the MCP joints from the index finger to the little finger.

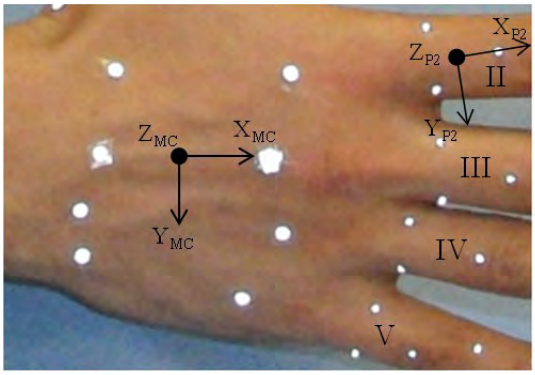
Three 1.5 mm diameter markers were fixed on each proximal phalanx, and six 6 mm diameter markers were fixed on metacarpals (figure). Data were collected using a motion capture system (17 cameras T160, Vicon, Oxford Metrics Ltd, Oxford, UK). The data analyses were performed using MATLAB 7.6 (Mathworks, Inc.; Natick, MA).

Two functional methods were used to estimate the joint AoR. In the Plane-Fitting (PF) method, movements of the distal segment are assumed to be planar and circular. Least squares planes and least squares circles are calculated from the markers trajectories. The orientation and the location of the joint AoR are obtained from the normal vector of the least squares plane and the center of the least squares circle, respectively. In the Sphere-Fitting (SP) method, marker trajectories of the distal segment are assumed to belong to a sphere. Least squares spheres are calculated from these trajectories. The AoR is estimated by computing the square line from the centers of the spheres.

RMS of the least squares planes and circles in the PF method were compared to the RMS of the least squares spheres in order to find the most appropriate method of estimation of the MCP joint AoR in F-E and in Abd-Add.

Results: In Abd-Add and F-E, the RMS computed from the least squares planes are much smaller than the ones computed from the least squares circles and spheres (table). Moreover, the RMS computed from the least squares circles are substantially greater than the least squares spheres in Abd-Add. Thus, the results show that the SF method is more appropriate for the AoR estimation of MCP joints in Abd-Add. However, the difference between the RMS computed from the circles least squares and the spheres least squares in F-E are not as large as the one in Abd-Add. Thus, it is difficult to find which between the PF method and the SF method is more appropriated in F-E.

Figure:



Caption: Location of skin-fixed markers on the proximal phalanxes and the dorsal face of the hand.

Conclusion: RMS results from Plane-Fitting and Sphere-Fitting methods were presented in order to find the most appropriate method for the AoR estimation of the MCP joints in abduction-adduction. No results were presented for the MCP3 joints because no movement was observed during the natural motion of fingers in Abd-Add.

RMS tend to increase from the index finger to the little finger. This tendency may be due to the skin movement artefacts, which add errors in the measurement data (Chèze et al, 1995). Markers were carefully fixed distant from the joints in order to minimize errors due to skin movement. However, the length of proximal phalanges decreases from the index finger to the little finger; thus, the impact of skin movements on marker trajectories is more important. (Devos et al 2014).

Results of the RMS show that movement in F-E of the MCP joints is planar. However, the assumption about the circular movement was not proved. One possible explanation may be that the MCP joints should not be considered as a spherical joint but rather as an ellipsoidal joint based on the geometry of this joint (Kapandji et al., 2002). Computations of a least-square ellipsoid should be considered rather than a circle in order to improve the fit of marker trajectories and have a better estimation of the MCP joints AoR.

In conclusion, the aim of this study was to present two functional methods for the estimation of the AoR of the MCP joints and find the most appropriate one in F-E and Abd-Add. SF is the most appropriate method in Abd-Add but ellipsoidal joint assumption should be considered.

JOINT KINEMATIC CALCULATIONS BASED ON STANDARD CLINICAL DIRECT KINEMATIC VERSUS CONTEMPORARY INVERSE KINEMATIC APPROACHES: HOW LARGE IS THE DIFFERENCE?

Hans Kainz [1 2,*] Luca Modenese [1] Lee Barber [3] John Walsh [2] Roslyn N Boyd [3] David G Lloyd [1] Christopher P Carty [1 2]

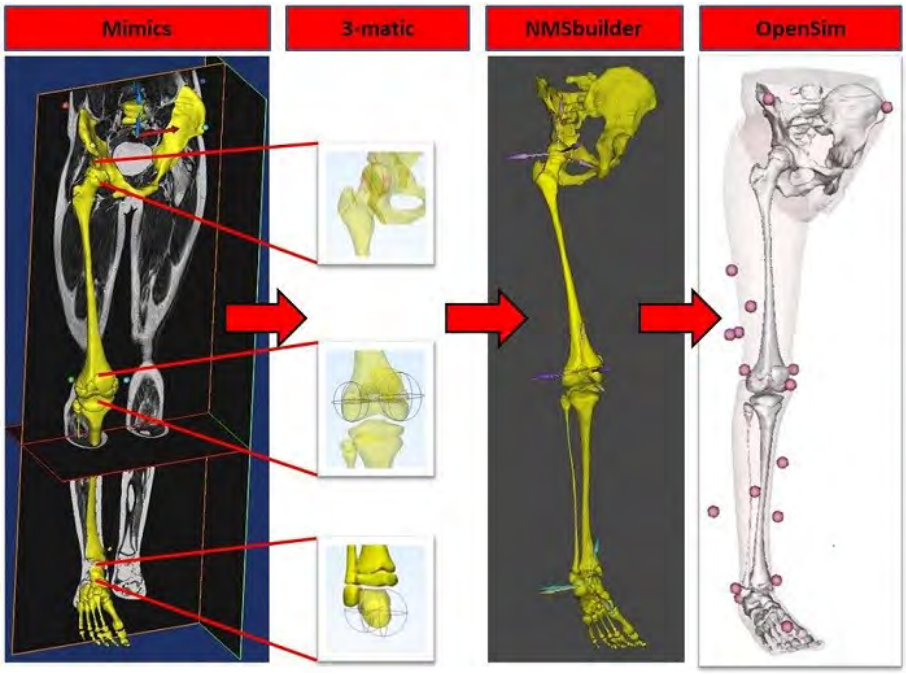
[1]Centre for Musculoskeletal Research, Griffith University, Gold Coast, [2]Queensland Children's Gait Laboratory, Children's Health Queensland, [3]Queensland Cerebral Palsy and Rehabilitation Research Centre, Brisbane, Australia

Introduction and Objectives: Clinical gait analyses typically use Direct Kinematics (DK) to estimate segment and joint kinematics directly from markers that are attached to the skin by assuming rigid connection between bone and markers. In contrast, Inverse Kinematics (IK), now preferably used for research, estimates joint kinematics by moving a musculoskeletal model to best match the motion of skin based markers without violating predefined anatomical constraints, and additionally enables musculoskeletal analyses (e.g. muscle tendon length analysis). Direct comparison between DK and IK is difficult due in part to different definitions of joint coordinate frames and errors due to scaling and marker placement. The aim of the current study was to create subject-specific kinematic models from magnetic resonance imaging (MRI) to directly evaluate the difference in joint kinematic estimates between DK and IK.

Methods: MRI and 3D motion capture data were collected from four children with cerebral palsy with a mean (SD) age of 11.3 (3.2)years, height 1.46 (0.18)m, weight 37.6 (13.5)kg, and BMI 17.2 (3.1). The conventional Vicon Plug-in-Gait DK (PiG-DK) [1] model and the standard 2392 OpenSim IK (OS-IK) model [2] were used to obtain standard DK and IK lower limb joint kinematics. For the MRI based models the pelvis and bones of the lower limbs were manually segmented using Mimics (Materialise, Belgium) and used to derive subject-specific joint centres and coordinate frames using pre-defined anatomical landmarks (Figure 1). NMSbuilder (NMSPhysiome) was used to create a DK and IK based subject-specific OpenSim model for each participant (similar to [3]). Joint kinematic waveforms derived from standard DK (PiG-DK) and IK models (OS-IK), as well as between both MRI based models (MRI-DK and MRI-IK) were compared using a modified coefficient of multiple correlation (CMC) [4]. Since CMC is a dimensionless measure, the following nine clinically relevant kinematic variables derived from each model were also compared: average hip rotation in stance, knee flexion at initial contact, range of pelvis tilt, average pelvis rotation, range of pelvis rotation, peak knee flexion during swing, peak dorsiflexion during swing, peak dorsiflexion in stance and minimum hip flexion.

Results: Joint kinematics from PiG-DK and OS-IK models had a mean (SD) CMC of 0.79 (0.18), whereas the MRI based DK and IK models showed better agreements with a CMC of 0.94 (0.06). The mean (SD) difference in discrete variable between the PiG-DK and OS-IK models was 5.6 (4.9)degrees, whereas difference of the MRI models was 1.0 (0.7)degrees (Table 1).

Figure:



Caption: Workflow for creating patient-specific kinematic models: (1) Mimics was used for segmenting lower limb bones and the external skin shell. (2) Joint centres and axes were defined by fitting geometrical shapes to the bone structures using 3-matic. (3) NMSbuilder was used to create patient-specific DK and IK OpenSim models. (4) Joint kinematics were calculated in OpenSim.

Conclusion: We found moderate-to-good CMC values, with discrete variables differences of up to 16.4 degrees, between the standard clinical PiG-DK and OS-IK models. In comparison the medical imaging DK and IK models produce very similar joint kinematic outputs, with excellent CMC values with discrete variables differences below 3.2 degrees). However, the MRI-DK model did permit unacceptable non-physiological joint displacements (e.g. hip joint displacements up to 24mm). Therefore, we recommend using IK to calculate joint kinematics in clinical gait analyses if a reliable anatomical model is available as this ensures anatomically viable joint movement. IK also enables additional musculoskeletal analysis that may improve clinical decision-making. Future research should evaluate the sensitivity of joint angles to potential errors introduced with the anatomical model, establish more reliable and accurate methods to scale generic models, and estimate joint centers and axes as these factors have substantial impacts on joint kinematics.

Table:

Variables Analyzed	**PiG-DK and OS-IK** model differences	**MRI-DK and MRI-IK** model differences
Average Hip Rotation Stance	6.5 (5.3)	1.6 (0.5)
Knee Flexion Initial Contact	3.4 (2.6)	0.8 (0.6)
Average Pelvis Tilt	15.6 (0.8)	0.7 (0.5)

Average Pelvis Rotation	1.2 (0.8)	0.3 (0.1)
Range of Pelvis Rotation	2.1 (2.2)	0.7 (0.4)
Peak Knee Flexion Swing	5.0 (2.1)	0.8 (0.4)
Peak DorsiFlexion Swing	3.3 (1.6)	2.5 (1.2)
Peak DorsiFlexion Stance	5.3 (1.8)	0.4 (0.3)
Minimum Hip Flexion	13.0 (2.9)	1.5 (1.2)

GAIT INITIATION IN PATTELAR CHONDROMALACIA SUBJECTS

Georgia Cristina Lehnen [1] Matias Noll [1,*] Thales Baliero Takáo [1] Fernanda Nora [1] Marcus Fraga Vieira [1]

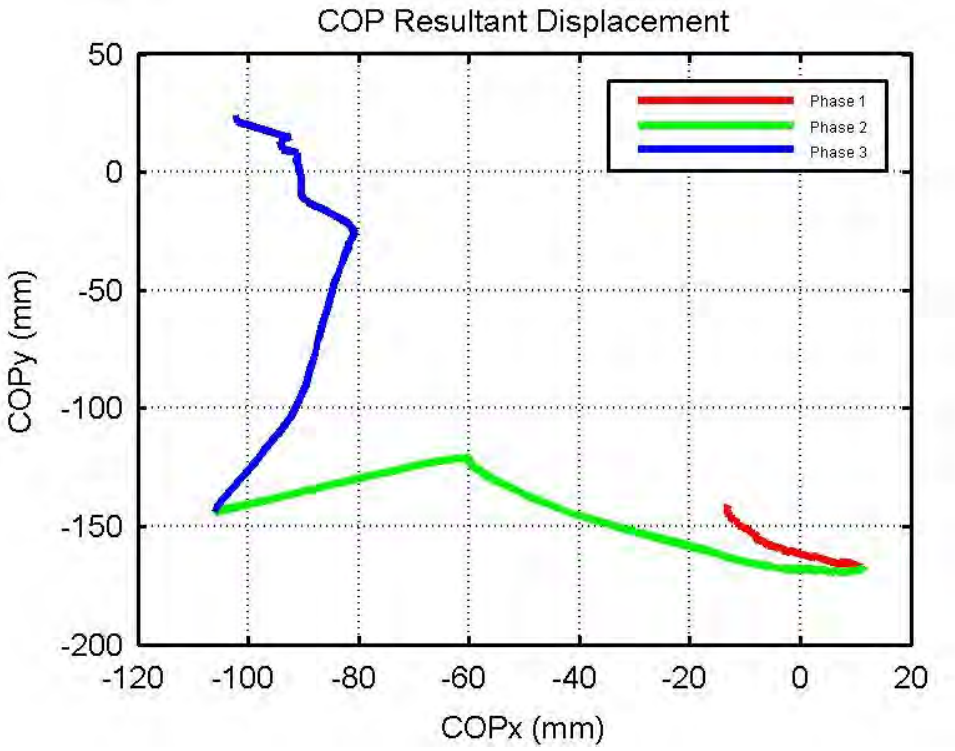
[1] Bioengineering and Biomechanics Laboratory, Universidade Federal de Goiás, Goiânia, Brazil

Introduction and Objectives: Gait initiation is the transition from a standing position to the gait cyclic movement [1]. The transition phase from a static to a dynamic condition involves contradictory postural stabilization functions: to prepare to an action and to recover from the perturbation [2]. Thus, the analysis of gait initiation by means of biomechanical parameters allows a better understanding of the central and peripheral control mechanisms involved in transient tasks [3]. The comparison of these parameters between different groups provides clues as to how certain musculoskeletal restrictions interfere in these control mechanisms. Thus, this study aimed to compare the gait initiation between healthy subjects and subjects with patellar chondromalacia, from kinetic and kinematic parameters, in order to analyze the adjustments due to this pathology to this task.

Methods: Twenty one subjects of both sexes, aged 18-35 years, enrolled in this study. They were divided into healthy group (HG, n = 10) without patellar chondromalacia, and patellar chondromalacia group (CG; n = 11), whose pathological condition was confirmed by magnetic resonance imaging. Data were collected in a laboratory equipped with four AMTI force platforms and ten Bonita Vicon cameras, at a frequency of 100 Hz, using Vicon Nexus 2.0 software with Vicon Plug-in Gait with 35 reflective markers. Kinematic data were processed using the Vicon Polygon software and kinetic data were processed using a custom Matlab code. Both groups performed five trials from a static standing position with one foot on each force platform. Two other force platforms recorded the first and second steps. The participants stood still until a sound command to start the gait with the right limb, walking six meters on a horizontal surface. Data acquisition started two seconds prior the sound command. Kinematic (knee maximum flexion angle) and kinetic parameters (center of pressure - COP) were evaluated. For evaluation of the COP, the gait initiation was divided into three phases [4]: 1) Anticipatory adjustments phase; 2) Swing foot unloading phase and 3) Support foot unloading phase (Figure 1). At each phase, the following COP descriptors were calculated: the anterior-posterior and medial-lateral displacement, calculated as the distance between the maximum and minimum position of the COP in the anterior-posterior and medial-lateral directions, and anterior-posterior and medial-lateral velocity, calculated dividing the COP displacements by the duration of each phase. For statistical analysis, we used the Shapiro-Wilk normality test and the paired T-test for intragroup comparisons and independent T-test for between group comparison ($\alpha = 0.05$).

Results: Only the CG showed significant differences for the maximum knee flexion angle during swing phase of gait, being higher ($p = 0.005$) on the affected knee (51.08 ± 6.11 °) compared to healthy knee (46.38 ± 3.14 °). There was no significant difference for knee angle between the groups. The CG presented significant higher values than the HG for the COP descriptors, particularly in phases 1 and 3 (Table 1).

Figure:



Caption: Figure 1. COP displacement during gait initiation.

Conclusion: In this study, the CG executed the gait initiation faster than HC. Higher values of anterior-posterior COP displacement, especially in the anticipatory phase (phase 1), imply higher steady-state gait velocities [5]. Anticipatory adjustments create the propulsive forces necessary to reach steady-state gait [1]. Besides, higher velocities during gait, within certain limits, are associated with greater stability [6]. Thus, these results suggest that individuals with patellar chondromalacia execute the gait initiation faster in order to ensure greater stability, possibly an adaptation to the studied pathological condition.

COMPARISON OF BIOMECHANICAL PARAMETERS OF HEALTHY ADULT GAIT USING THREE MARKER BASED MODELS

Manunchaya Samala [1,*] Craig Childs [1] Anthony McGarry [1] Philip Rowe [1]

[1]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Biomechanical gait analysis is a systematic measurement, which is becoming an important tool used to assess, plan, and treat individuals with conditions affecting their ability to walk. Gait analysis requires specialized hardware and software for collecting, processing, analyzing biomedical parameters for human locomotion. The common tool, which is one of hardware for tracking and describing the kinematics of the human gait in three dimensions, is marker-based motion capture (Kent & Franklyn-Miller 2011; Pitkin 2006). The most commonly utilized marker model used in clinical environments for gait analysis is Vicon's plug-in gait (PiG; Vicon Motion Systems, Oxford, UK), which is known for its ease of use and fast implementation. However, this conventional marker set provides less repeatable results than cluster based marker set and also takes a lot of preparation time of the subjects. In additional, the thigh and calf markers positions are critical for correct alignment of the knee joint axis in PIG but less so in cluster systems.(Ceseracciu et al. 2014; Duffell et al. 2014; Papi et al. 2014). Different protocols are known to yield different results, specifically for out-of-sagittal plane rotations(Duffell et al. 2014).

The study's aim was to evaluate the inter-protocol variability of kinetics, kinematics and temporal-spatial parameters output of three protocols, using a Strathclyde cluster model(Papi et al. 2014), the Human Body Model(van den Bogert et al. 2013) and Plug-in-Gait model (Vicon).

Methods: Ten healthy adult subjects age between eighteen and fifty year old were analyzed using the a 12 camera Vicon bonita Motion capture system. Each subject wore a single comprehensive set of markers which merged the required markers for the Strathclyde cluster model, the Human Body Model and Plug-in-Gait model to allow a simultaneous data capture for all three models. During the experiment, subjects walked on a treadmill which is part of the CAREN system (Motekforce Link VB, Amsterdam,The Netherland) and include two, 2 metre long force plates one for each leg under two split belts of the treadmill. They walked at up to seven different speeds (very slow 0.3 m/s, slow 0.8 m/s, moderate 1.3 m/s, fast 1.8 m/s, very fast 2.3 m/s, self – paced variable speed and self-selected fixed speed) .

Results: The 3-D marker trajectories and the force data were captured synchronously and joint angles/moments etc were calculated using the three marker models and approriate software. One left and one right gait cycle wiere extracted for each of the three trials.The raw marker trajectory data and ground reaction force data were processed and calculated separately on each data set according to the gait analysis software package for each marker model. All data wee imported to excel and time normalized to the gait cycle. Inter- and intra-model Coefficient of Multiple Correlation (CMC) were calculated for joint kinematics and joint kinetics data and this was achieved by comparing exactly the same gait acquisition from each subject, condition and marker set. Intra-subject variability was also analysed using 3 gait trials for each subject and, inter-subject variability was assessed by comparison of the averages of the 3 walking trials among the 10 participants. The results showed differences between analyses from the 3 models and these will be presented.

Conclusion: The results of study enabled us to select the model which is the easiest, most accurate, and most repeatable to analyses walking performance in below knee amputees. The research will continue by using the selected marker set to analyse the gait of below knee amputees undergoing limb dynamic alignment. In this new procedure the prosthist will remotely control and automatically adjusting lower leg pylon as the subject walks on the treadmill. The selected cluster system will be used to record their gait and visualise it in real time with suitable calculated gait parameters on a screen in real time. The prosthetist will be able to remotely adjust the alignment of the prosthetic leg and hence tune the prosthesis. In this way the system will allow the prosthetist to quickly and effeciently optimise the set up of the below knee prosthetic alignment and maximise patient walking function.

COLLAGEN CROSSLINKING DOES NOT DICTATE STIFFNESS IN A TRANSGENIC MODEL OF SKELETAL MUSCLE FIBROSIS

Mark A. Chapman [1,*] Rajeswari Pichika [2] Richard Lieber [3]

[1]Bioengineering, [2]Orthopaedic Surgery, University of California - San Diego, La Jolla, [3]Rehabilitation Institute of Chicago, Chicago, United States

Introduction and Objectives: Fibrosis results when skeletal muscle is damaged and the regenerative process fails to recapitulate normal development. Skeletal muscle fibrosis is the abnormal accumulation of ECM between myofibers, specifically expressed as increased collagen content [1]. Apart from biochemical changes, biomechanical changes are also observed in skeletal muscle, cardiac and liver fibrosis [2, 3, 1]. While collagen content and tissue stiffness both increase with fibrosis, there is not a strong correlation between these two values [4, 5]. Interestingly, a recent cardiac study showed that collagen crosslinks, not collagen abundance, dictated tissue stiffness [6] which suggests that collagen crosslinks may also explain increased tissue stiffness in muscle fibrosis. Therefore, the goal of this study was to correlate tissue stiffness with lysyl-pyridinoline (LP), hydroxylysyl-pyridinoline (HP), and pentosidine (PE) collagen crosslinks. In this study, we used our recently described nesprin-desmin double knockout mouse (DKO) model of skeletal muscle fibrosis [4].

Methods: Passive mechanical testing of skeletal muscle bundles from wild-type (WT) [n=10], nesprin-1 knockout (nesprin$^{-/-}$) [n=8], desmin knockout (desmin$^{-/-}$) [n=10] and DKO [n=13] mice was conducted as previously described (7). Briefly, muscle bundles were secured to a force transducer one side and a fixed titanium pin connected to a rotational bearing on the other. A stress-relaxation protocol was implemented by increasing sarcomere length by 0.25 μm/stretch and stress-relaxing for 3 minutes. From these data, tangent stiffness was determined by calculating the slope of the stress-sarcomere length plot at a sarcomere length of 3.2 μm.

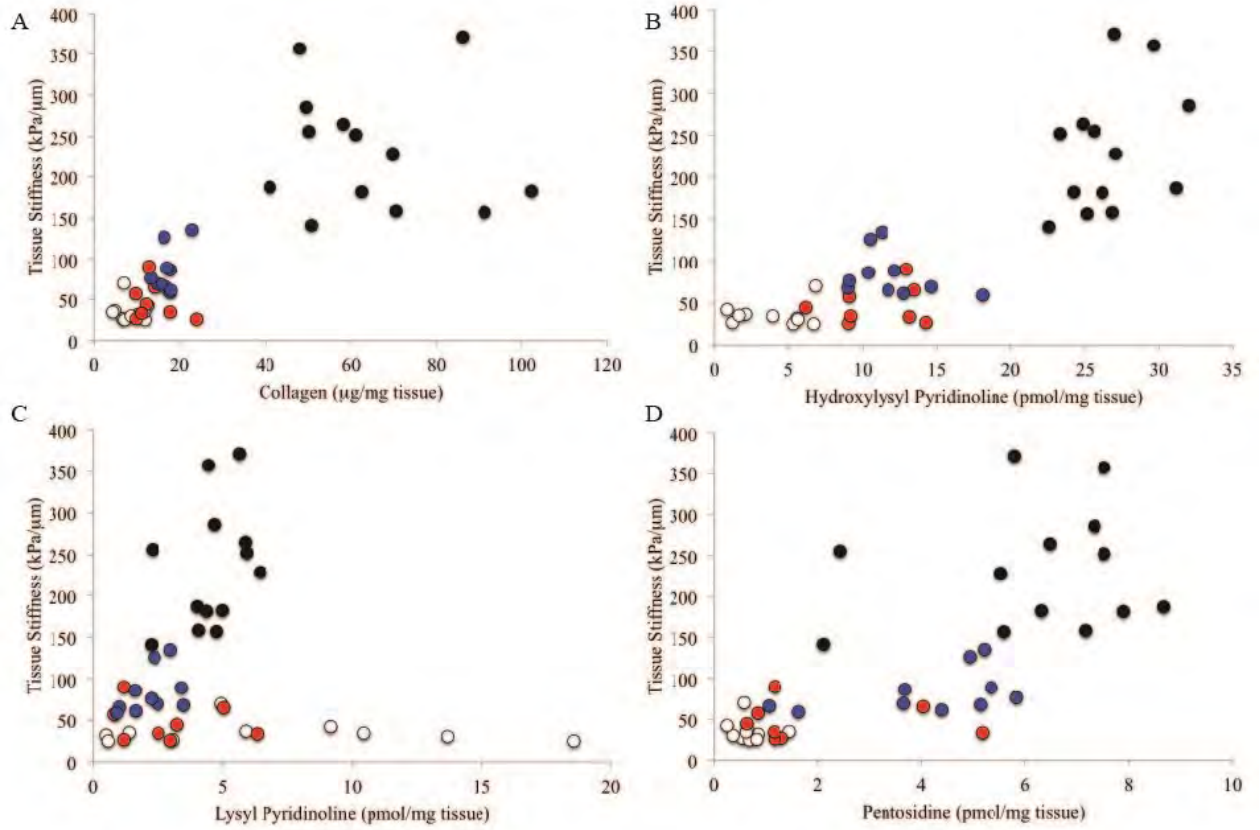
HP, LP and PE concentrations of muscle samples were determined as previously described [8]. These samples were derived from adjacent portions of the same muscle samples used for mechanical testing. Samples were prepared for HPLC and injected into the HPLC column. Elution of crosslinks was achieved at 40°C at a flow rate of 1.0 mL/min in two steps. Hydroxyproline content was determined using an HPLC column.

Stepwise regression analysis was performed using IBM SPSS Statistics (Armonk, NY) to determine which parameters (collagen content, HP, LP, and/or PE if any) could predict muscle tissue stiffness.

Results: When tissue stiffness was plotted against collagen, HP or PE values, there was a significant correlation between stiffness and collagen and crosslink content (collagen:$p<0.05$, $r^2=0.62$; HP:$p<0.05$, $r^2=0.73$; PE:$p<0.05$, $r^2=0.52$; Figs. 1A,B & D). However, when examining each genotype separately, this relationship disappeared. Thus, the correlation was caused by differences between genotypes and created only a pseudocorrelation [9]. LP crosslink content also had no correlation with tissue stiffness (Fig. 1C). These conclusions were further validated using stepwise regression. In the stepwise regression model, the only variable that entered the linear model was HP content ($r^2=0.73$), suggesting a good relationship. However, it should be noted that when data from any single genotype were run through stepwise regression,

no variables were included in the model. Finally, no relationship was found between tissue stiffness and normalized collagen crosslinks.

Figure:



Conclusion: In spite of the current findings, it remains unclear which parameters in skeletal muscle ECM are responsible for dictating tissue stiffness. Although neither collagen content nor collagen crosslinks are highly correlated with tissue stiffness, collagen organization within the ECM remains a potential contributer to tissue stiffness. None of the methods used account in any way for the gross arrangement of collagen bundles which are rich in the perimysial space [10]. Recently, a serial block face scanning electron microscopy method was used to reconstruct skeletal muscle ECM over hundreds of microns [11]. This technology holds great potential for determining collagen/ECM ultrastructure, and could answer questions about whether tissue stiffness is related to ECM organization. Other factors such as proteoglycans may also affect stiffness, as it has been shown that decorin and biglycan are also increased in muscle fibrosis models [12].

LONG-TERM STIMULATION RESULTS IN SARCOMERE LENGTH NON-UNIFORMITY

Maria Engel [1,*] Tim Leonard [1] Walter Herzog [1]

[1] Human Performance Laboratory, University of Calgary, Calgary, Canada

Introduction and Objectives: Muscle spasticity is a condition found in many patients, for example in children with Cerebral Palsy (CP), and it is characterized by muscles that are tight and stiff. Spasticity decreases the range of motion about joints, making every day functions, such as walking or holding a glass of water, very difficult to do. Patients with muscle spasticity have velocity-dependent, hyper-active stretch reflexes, producing increased and undesired muscle activation compared to normal patients without spasticity.

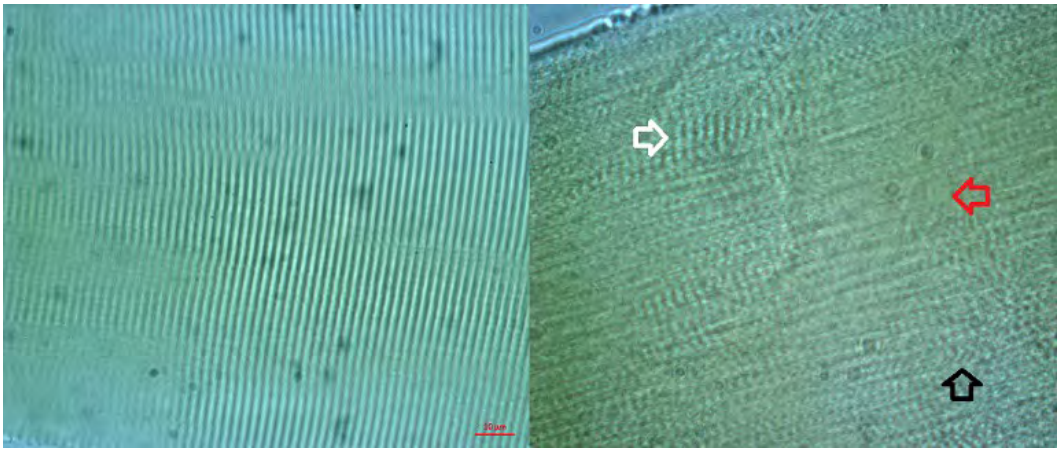
It has been shown that the muscles of CP patients have decreased fascicle lengths and increased sarcomere lengths[1,2]. Intuitively, this implies that spastic muscles have decreased serial sarcomere numbers. Long-term muscle stimulation has been shown to decrease the serial sarcomere number within a muscle in guinea pig and rat models[3,4]. These results been replicated in our laboratory[5] in New Zealand White rabbits and in the medial gastrocnemius (MG), plantaris (PL), and the soleus (SOL) muscles. Ten hours of stimulation of these muscles also resulted in a 25% decrease in serial sarcomere numbers. Within analysis of these experiments, laser diffraction was used to measure the average sarcomere length.

In muscles that have been stimulated for 10 hours, it has been observed that laser diffraction produces a thick band at the first order of diffraction rather than a thin line. This implies that multiple sarcomere lengths are present within the muscle fascicle. Therefore, the purpose of this study was to quantify sarcomere length non-uniformity and qualitatively examine any extent of muscle damage.

Methods: Triceps surae muscles of New Zealand White rabbits (n=3) were stimulated with a nerve cuff at 20 Hz (3x alpha motor neuron threshold) for 10 hours continually. The leg was unrestrained. Muscles examined included the MG, PL, and the SOL. The contralateral limb served as the non-stimulated control. After the stimulation period, muscles were harvested, fixed with 10% formalin, and then digested in 30% nitric acid. Individual fascicles were mounted on slides for analysis. Using a light microscope, images at 64x magnification were taken at 9 sections of the fascicle; 3 at each end, and 3 in the middle. The images were then imported into Matrox Inspector. The average of 4 sarcomere lengths in series was measured. This was repeated in series along the muscle 10 times in each image for a total of 90 data points for each fascicle. To quantify the extent of sarcomere non-uniformity, standard deviations about the mean sarcomere lengths were calculated and reported. The coefficient of variation using means and standard deviations were calculated for the stimulated and non-stimulated muscles. Muscle injury was qualitatively observed by examining the captured images.

Results: The coefficient of variation of sarcomere lengths were consistently larger in the stimulated muscles compared to the non-stimulated contralateral control, implying long-term stimulation results in sarcomere length non-uniformity. For example, in the PL, coefficient of variation in the stimulated muscle was 7.0%, while the non-stimulated muscle resulted in 0.9%. In all three muscles, sarcomere lengths were significantly shorter in stimulated muscles compared to the control ($p<0.05$). Images acquired showed signs of muscle injury including disorganization of A-bands, sarcomere streaming, and areas with completely disorganized protein structure (figure 1).

Figure:



Caption: Figure 1: An example of a non-stimulated contralateral control muscle (left) and a 10 hour stimulated muscle (right). Arrows indicate signs of muscle injury; white indicates A-band disorganization, black indicates streaming of sarcomeres, and red indicates complete disorganization.

Conclusion: Sarcomere length non-uniformity and structural disorganization appears to result from long-term muscle stimulation. Examination of injury sights may give clues as to how sarcomeres are being removed in response to increased stimulation. Due to the force-length relationship of sarcomeres, the muscle may remove sarcomeres to allow remaining sarcomeres to be maintained at their optimal force-producing length[6]. Removal of sarcomeres may occur throughout the muscle fibres, as muscle injury appears along the entire fibre after long-term stimulation.

Patients with muscle spasticity, such as in CP, may be experiencing muscle injury due to chronic increased muscle activity. This could lead to muscle adaptation such as sarcomere loss, resulting in functional mechanical changes to the muscle.

RISK OF FALLS IN WOMEN WITH FIBROMYALGIA

Suelen M. M. Goes [1 2,*] Andre L. F. Rodacki [2] Joice M. F. Stefanello [2] Angelica Lodovico [2] Diogo Homann [2] Neiva Leite [2] Cheryl Hubley-Kozey [1]

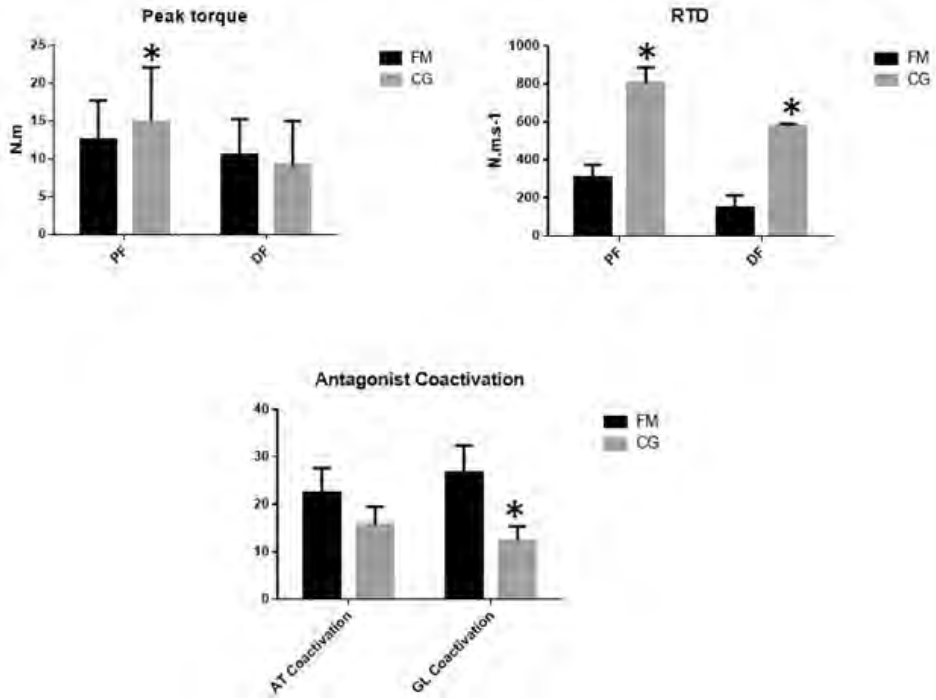
[1]Faculty of Health Professions, Dalhousie University, Halifax, Canada, [2]Physical Education, Federal University of Parana, Curitiba, Brazil

Introduction and Objectives: Fibromyalgia (FM) is a chronic pain condition (Henriksen et al., 2009) associated with reduced muscle strength, which can lead to functional incapacity and higher risk of falls (Goes et al., 2012). The mechanisms for muscle strength reduction may be related to either muscle activation impairment (antagonist co-activation and voluntary activation failure) (Valkeinen et al., 2008; Graven-Nielsen et al., 2002) or metabolic changes (insulin resistance and high glucose levels) (Loevinger et al., 2007) due to FM symptoms. However, how these factors interact is not clear. The purpose of this study was to compare torque production, antagonist co-activation, voluntary activation failure, metabolic changes (glucose levels and insulin resistance), and falls risk between women with and without FM. Additionally, the relationship between FM symptoms, metabolic factors, torque production and falls in women with FM were determined.

Methods: Fifty-nine middle-aged women (29 with FM and 30 as control group) were recruited. Pain intensity and threshold, anthropometric measurements, and fall history (last six months) were assessed. In addition, plasma glucose, glycosylated hemoglobin (HbA1c), and insulin resistance (IR) were determined at the same time. Participants were encourage to perform ankle dorsiflexion and plantar flexion maximum isometric voluntary contractions (MIVC), from which peak torque and rate of torque development (RTD) were calculated, as well as, anterior tibialis and gastrocnemius lateral head (GL) electromyography (EMG), and central activation ratio (CAR) in the anterior tibialis muscle were evaluated. In order to calculate the GL co-activation during dorsiflexion, the integrated EMG (iEMG) was used. The full voluntary muscle activation was evaluated by burst superimposition with supramaximal electrical train stimuli during dorsiflexion MIVC. The CAR was calculated as the maximum voluntary torque produced prior to delivery of the train divided by the maximum torque produced during the superimposition of the train.

Results: Women with FM had lower pain threshold, higher pain intensity, and reported greater number of falls compared to control group (CG) ($p<0.05$). In addition, participants with FM exhibited higher IR (FM: 2.0±1.1; CG: 1.8±0.9; $p<0.05$), although there were no differences in glucose and HbA1c levels between groups. The FM group showed reduced plantar flexors RTD and dorsiflexors RTD compared to CG ($p<0.05$). Additionally, subjects with FM showed lower plantar flexors peak torque, had more antagonist co-activation during dorsiflexion (Figure 1), and decreased CAR (FM: 89.5±12.4%; CG: 97.8±4.3%; $p<0.05$) than the CG. The lower CAR was explained by HbA1c level ($R^2adj=0.21$; $p<0.05$). Reduced plantar flexors and dorsiflexors peak torque explained, together, 80% of falls variance; also, high antagonist co-activation (OR=1.6; $p<0.05$) and high IR (OR=1.8; $p<0.05$) increased the chance of falls in the FM group (Table 1).

Figure:



Caption: Figure 1 – Torque production in the ankle in both groups. Note: FM: Fibromyalgia group; CG: Control group; PF: Plantar flexors; DF: Dorsiflexors; RTD: Rate of Torque Development; AT: Anterior Tibialis; GL: Gastrocnemius lateral head.

Conclusion: Women with FM showed reduced plantar flexors and dorsiflexors torque production, high IR and high number of falls. A combination of factors in FM, such as IR and torque production impairment in the ankle joint increase the odds of having a fall. Ankle musculature function is important to produce stabilizing moments during balance and other functional tasks. Thus, a multi-pronged approach to treatment focusing on decreasing glucose level and IR, as well as, ankle exercises directed at increasing muscle strength may increase the effectiveness of clinical and community interventions designed for improving balance and reducing falls in women with FM.

ACUTE EFFECTS OF CONTRACT-RELAX STRETCHING, STATIC STRETCHING AND ISOMETRIC CONTRACTIONS ON MUSCLE-TENDON MECHANICS

Anthony Kay [1,*] Jade Husbands-Beasley [1] Anthony Blazevich [2]

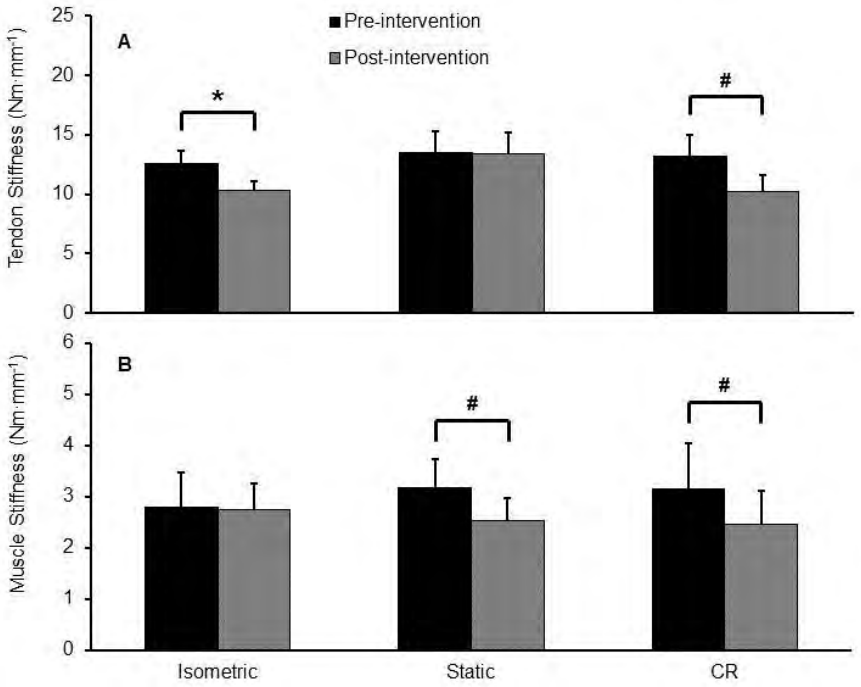
[1]Sport, Exercise & Life Sciences, The University of Northampton, Northampton, United Kingdom, [2]Centre for Exercise & Sport Science Research, Edith Cowan University, Joondalup, Australia

Introduction and Objectives: Maximum joint range of motion (ROM) and resistance to joint rotation within that range (i.e. resistance to stretch) are important physical characteristics that influence the capacity to perform activities of daily living and athletic tasks [1], and are affected considerably by aging and disease [2]. The loading characteristics of different muscle stretching techniques likely influence the specific mechanisms responsible for acute increases in range of motion (ROM). Identifying mechanisms allows the determination *a priori* as to whether these interventions might be useful in different clinical populations, why such stretch interventions elicit different responses in different individuals, and to optimize/improve the methodology of, and response to, the stretch technique. Therefore, the effects of contract-relax proprioceptive neuromuscular facilitation (CR) stretching, static stretching (SS) and maximal isometric contraction (Iso) interventions were studied in 17 healthy human volunteers.

Methods: Passive ankle moment was recorded on an isokinetic dynamometer with electromyographic (EMG) recording from the triceps surae, simultaneous real-time motion analysis, and ultrasound imaging recorded gastrocnemius medialis muscle and Achilles tendon elongation. The subjects then performed each intervention randomly on separate days before reassessment. The SS condition included 4 x 15 s plantar flexor stretches with 15 s rest between stretches, the CR condition included 10 s stretches followed immediately by a 5-s ramped maximal isometric plantar flexor contraction in a fully stretched position, repeated four times giving a total duration of 60 s; identical to the SS condition. The Iso condition included 4 x 5 s ramped maximal isometric plantar flexor contractions performed in the anatomical position, with 15 s rest between contractions.

Results: Significant increases in dorsiflexion ROM (2.5-5.3°; $P < 0.01$) and reductions in whole muscle-tendon stiffness (10.1-21.0%; $P < 0.01$) occurred in all conditions, with significantly greater changes detected following CR ($P < 0.05$). Significant reductions in tendon stiffness (see Figure 1, A) were observed after CR and Iso (17.7-22.1%; $P < 0.01$) but not after SS ($P > 0.05$), while significant reductions in muscle stiffness (see Figure 1, B) occurred after CR and SS (16.0-20.5%; $P < 0.01$) but not after Iso ($P > 0.05$). Increases in peak passive moment (stretch tolerance) occurred after Iso (6.8%; $P < 0.05$), CR (10.6%; $P = 0.08$) and SS (5.2%; $P = 0.08$); no difference in the changes between conditions was found ($P > 0.05$). Significant correlations (r_s = 0.69-0.82; $P < 0.01$) were observed between the changes in peak passive moment and maximum ROM in all conditions.

Figure:



Caption: Figure 1. Achilles tendon stiffness [A] and gastrocnemius medialis (GM) muscle stiffness [B] pre- and post-intervention.

Conclusion: While similar ROM increases occurred after isometric contractions and static stretching, changes in muscle and tendon stiffness were distinct. The concomitant reductions in muscle and tendon stiffness after contract-relax stretching suggest a broader adaptive mechanical response that likely explains its superior efficacy to acutely increase ROM. These are the first data to confirm that acute changes in tendon stiffness may contribute to PNF stretching's superior efficacy to increase ROM, above other stretching modes. However, while mechanical changes appear tissue-specific between interventions, significant correlations between the change in peak passive moment and the change in ROM were observed in all conditions, indicative of a neurological adaptation (i.e. increased stretch tolerance) also being important for the acute increases in ROM. The reduction in tendon stiffness and increase in ROM detected following the Iso condition have important methodological implications as these data indicate that the performance of contractions 'on stretch' during PNF stretching may not be needed. Modifying PNF stretching to perform the contraction phase in the anatomical, rather than highly stretched position, removes the need for partner assistance, decreases the likelihood of inducing pain, tissue damage and muscle strain injury during the technique, which may enhance PNF's suitability and practicality for athletic and clinical populations.

EXPLORING THE RELATIONSHIP BETWEEN LOCAL AND GLOBAL SPINE STABILITIES DURING REPETITIVE LIFTING TASKS.

Matthew Mavor [1,*] Ryan Graham [1]

[1]School of Physical and Health Education, Nipissing University, North Bay, Canada

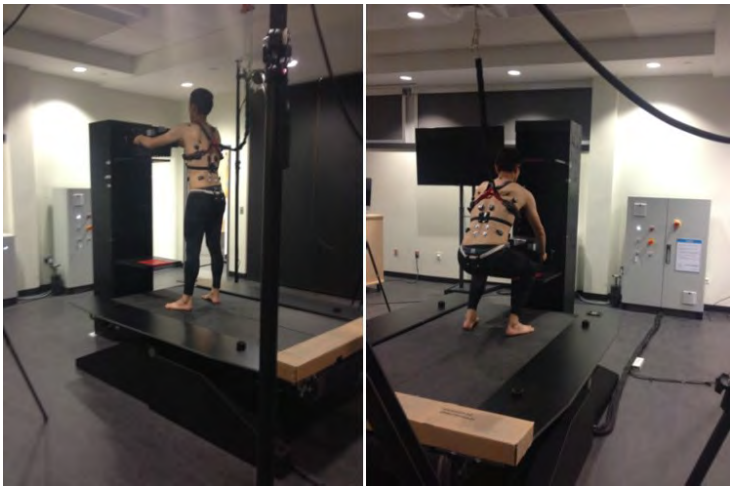
Introduction and Objectives: Lifting is a major occupational risk factor for low back injury. Lifters experience small continual perturbations, because moving a load provides a disturbance to the lifter's balance and equilibrium [1]. In healthy individuals, these perturbations are offset in order to maintain a stable trunk and spine during movement. However, lifters also experience larger perturbations due to a variety of factors such as loads shifting in boxes or unstable/slippery floors, which can cause slipping and/or tripping. With enough internal (local) stability the lifter can offset such an external (global) perturbation and return to their desired movement trajectory without injury to the spine system (i.e. passive tissues, muscles, nervous system) [2]. The goal of the present study was to examine the relationship between local and global spine stabilities during perturbations introduced at the foot-floor interface. It was hypothesized that there would be good agreement between both stability metrics, and that both local and global stabilities would be progressively increased as the lifted load in the hands was increased [3].

Methods: 12 healthy males were recruited to participate in this study. Mean age, height, and mass were 23.2 years (SD = 4.0), 178.2 cm (SD = 6.9), and 73.5 kg (SD = 10.7), respectively. Participants completed a freestyle lifting protocol on a perturbation treadmill, while wearing a harness that was secured to the ceiling (V-Gait, Motek Medical, Holland) (Figure 1). Participants lifted a box from knee to shoulder height under three load conditions (0, 4, and 8kg in a randomized order), at a rate of 6 cycles per minute to the beat of a metronome. Under each load condition participants performed a total of 40 lifts; the first 20 lifts were without any perturbations. Then, in the following 20 lift cycles (in blocks of 5), participants were randomly given perturbations by the treadmill in each of the four direction combinations (forward or backward tilt of 4° and left or right displacement of 5cm). Perturbations were programmed to not occur back to back, and were initiated when the box eclipsed 50% of the participant's height on the way up. During all trials, 3-D kinematic data were collected from the pelvis and spine at 100Hz (Oqus 400+, Qualisys, Sweden). 6-D state spaces (x,y,z linear and angular velocities of the trunk relative to pelvis) were created using data recorded from the first 20 unperturbed lift cycles (attractor), and local dynamic spine stability was quantified using the local divergence exponent, λ_{max} [4,5]. In addition, we analyzed the distance traveled from the unperturbed lifting pattern (B), the time to max distance (Tau), the relaxation distance (A), and the rate of return toward the normal lifting pattern (Beta) following each external perturbation [4,5]. Each global perturbation metric was then averaged across the four perturbations, and both local and global stability values were compared using repeated-measures ANOVAs in SPSS 22 (IBM Corporation, USA).

Results: An increase in load lifted lead to significantly increased local spine stability (decreased λ_{max}) during the unperturbed lifts ($p = 0.046$) (Table 1). Post-hoc testing revealed that the 8kg condition was significantly more stable than the 0kg condition ($p= 0.011$). Higher load also lead to decreased distance (B) traveled away from the unperturbed

trajectory (p = 0.023). Post-hoc testing revealed that both the 4 and 8kg conditions were more stable than the 0kg condition (p= 0.007 and 0.018).

Figure:



Caption: Figure 1. Experimental set-up. Under each load condition participants were required to repetitively lift between the targets placed at shoulder and knee height.

Conclusion: Results agree with our previous research that increasing the load lifted significantly improves local spine stability during non-perturbed lifting due to higher muscle activation that translates into greater lumbar spine rotational stiffness [3]. Here we have shown that these changes also translate into a greater ability to resist external global perturbations, which may reduce injury risk and should be explored in the future. The exact relationships between local and global stabilities are currently being analyzed in each individual subject using linear mixed modelling (repeated-measures regressions).

Table:

Stability Values		0 kg	4 kg	8 kg	Repeated-Measures ANOVA Results
		Mean (SD)	Mean (SD)	Mean (SD)	p-value
Local	λmax	1.09 (0.25)	0.99 (0.17)	0.96 (0.14)	**0.046**
Global	A	3.14 (0.77)	3.14 (0.97)	2.96 (0.54)	0.652
	B	38.6 (16.7)	31.0 (13.2)	27.7 (10.0)	**0.023**
	Tau	57.4 (21.3)	58.7 (21.6)	56.8 (19.3)	0.966

IN SEARCH OF THE UNDERLYING MECHANISMS RESPONSIBLE FOR IMPAIRED GAIT-RELATED POSTURAL CONTROL IN PEOPLE WITH PARKINSON'S DISEASE

Brook Galna [1,*] Chris Buckley [2] Aodhán Hickey [1] Silvia Del Din [1] Alan Godfrey [1] Claudia Mazzá [2] Lynn Rochester [1]

[1] Institute of Neuroscience / Newcastle University Institute for Ageing, Newcastle University, Newcastle upon Tyne, [2] MRC-Arthritis Research UK Centre for Integrated Research into Musculoskeletal ageing (CIMA) / Insigneo Institute for in silico medicine, Department of Mechanical Engineering, The University of Sheffield, Sheffield, United Kingdom

Introduction and Objectives: The ability to make small yet precise adaptations to step width is crucial for the coupling of postural control and gait. People with incident Parkinson's disease (PD) walk with a less variable step width, suggesting early changes in gait-related postural control [1]. Impaired postural control during gait puts people with PD at a high risk of falls. A better understanding of the underlying mechanisms responsible for reduced step width variability in PD may help facilitate earlier and better targeted interventions to prevent future falls. Previous analysis suggests reduced trunk accelerations during gait contribute to a less variable step width in PD [2]. Rigidity is one of the cardinal symptoms of PD and may affect trunk accelerations by resisting the counter rotation between the pelvis and trunk; hence we hypothesise that increased trunk rigidity indirectly influences step width variability in PD. However, there are important technical and clinical challenges in addressing this hypothesis. First, we do not know whether upper body trunk accelerations can be used as a proxy measure of trunk rigidity during gait in PD. Second, the relationship between trunk accelerations, rigidity and step width variability may vary between different PD phenotypes (subtypes). Therefore, the aims of this analysis were to: i) investigate the relationship between clinical measures of rigidity and trunk accelerations during gait; ii) examine whether step width variability correlates with rigidity and trunk accelerations; and iii) test whether these relationships are similar across different PD phenotypes.

Methods: Step width variability (within-person SD of step width) of 84 people with early PD (Mean (SD) Age:69 (9.6) years; 35 females; Unified Parkinson's disease rating scale (UPDRS) III:28(11), 18-22 months since diagnosis, tested at peak dose of their medication) was measured over 4 x 10m walks using an instrumented walkway (GAITRite). For sub-group analysis, participants were classified into postural instability and gait difficulty (PIGD, n = 31), indeterminate (n = 17, excluded from sub-group analysis) and tremor dominant (n = 36) phenotypes using established methods [3]. Anterior-posterior (AP) and mediolateral ML trunk accelerations were measured during gait using 3D accelerometers (100Hz, ±8g, 4th order Butterworth 20Hz low-pass filter) taped onto the chest (mid way between the xiphoid process and clavicular notch) and lumbar spine (L5). The following variables were calculated: root mean square acceleration (RMS), harmonic ratio (HR) and attenuation of acceleration from the L5 to Chest sensor derived from RMS accelerations [4]. Rigidity was assessed using the average response from 5 rigidity items incorporated into the UPDRS III (each item scored from 0 no rigidity to 4 severe). Partial correlations were used to assess the relationship between trunk accelerations, rigidity and step width variability correcting for age, sex, gait speed and step duration. A $p \leq .05$ was used to guide interpretation.

Results: There were no significant correlations between trunk accelerations and rigidity. Reduced step width variability was correlated with reduced ML RMS_{Chest} ($r = .237$, $p = .028$), with no other significant correlations being observed. This

correlation was stronger in the PIGD sub-group (r=.420, p=.021) whereas no correlations between trunk accelerations and step width variability were found in the tremor dominant sub-group.

Conclusion: Our findings suggest that impaired trunk motion is associated with reduced step width variability in people with early PD, especially in people with a PIGD phenotype. However, we found no support for the use of upper body trunk accelerations as a proxy measure of rigidity in people with PD, hampering our ability to test the hypothesis that trunk rigidity is associated with step width variability. The lack of correlation between trunk motion and rigidity may be due to: i) the lack of sensitivity of the UPDRS subscale to rigidity in our relatively mild PD group; and ii) the UPDRS III items focus primarily on peripheral and not axial rigidity features and may not be as sensitive as direct mechanical assessment [5]. Although our findings suggest altered trunk accelerations are related to reduced step width variability, more appropriate methodology is needed to assess trunk rigidity during gait to assess its contribution to the coupling of postural control and gait in early PD.

INDIVIDUALS WITH CHRONIC ANKLE INSTABILITY USE DIFFERENT PATTERNS OF MUSCULAR ACTIVATION TO MAINTAIN BALANCE WHILE KICKING A BALL IN SINGLE-LEG STANCE

Jaqueline Lourdes Rios [1 2,*] Josilene S Conceição [3] Ana Luiza Gorges [3] Felipe Gustavo S de Araújo [3] Marcio Jose dos Santos [4 5]

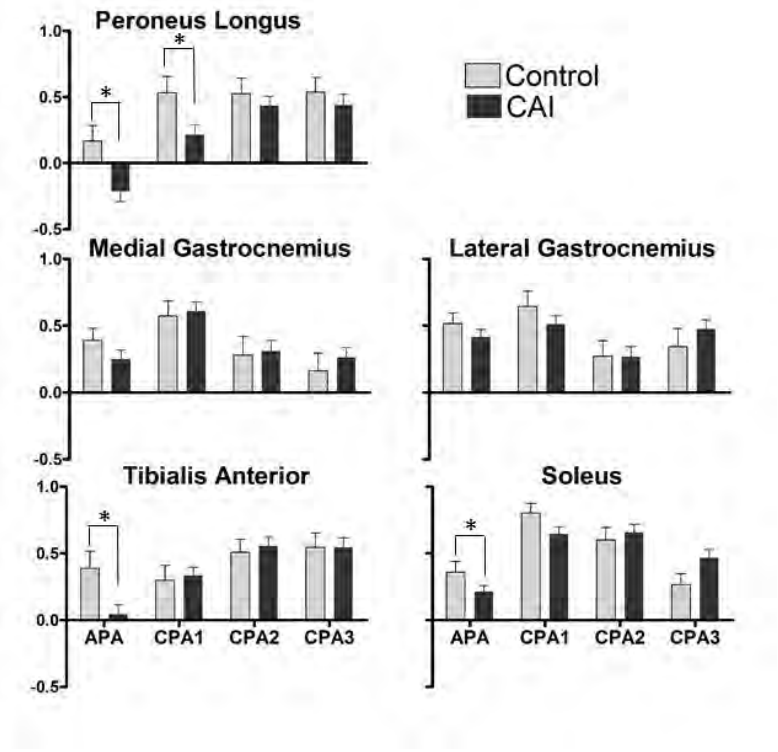
[1]Faculty of Knesiology, University of Calgary, Calgary, Canada, [2]Center of Sports and Health Sciences, [3]Physical Therapy, [4]Physical Therapy and Center of Sports and Health Sciences, Santa Catarina State University, Florianopolis, Brazil, [5]Physical Therapy and Rehabilitation Sciences, University of Kansas Medical Center, Kansas, United States

Introduction and Objectives: Kicking a ball is a task commonly used at athletic clubs and rehabilitation sites to train and rehabilitate individuals with chronic ankle instability (CAI), especially with athletes and soccer players [1]. Recent studies showed that, during this task, subjects with CAI exhibited reduced magnitude of electromyographic (EMG) activity at the ankle muscles in the supporting leg. However, it is still unknown which muscles around the ankle are driving the postural equilibrium of these individuals during this task. The aim of this study was to investigate the muscle activity patterns of the ankle joint during the kicking a ball task in individuals with CAI.

Methods: We used the principal component analysis (PCA) to identify differences in patterns of muscle activation between 60 individuals with CAI and 21 healthy controls while they performed the kicking a ball task standing in a single-leg stance. We registered the EMG activities of the ankle muscles of the supporting leg: soleus (SOL), medial and lateral heads of the gastrocnemius (GasM and GasL), tibialis anterior (TA) and peroneus longus (PL) as well as of the adductor (AD) muscle of the kicking leg. We calculated the magnitudes of the EMG activities (integrals: $\int$EMG) during the time intervals of anticipatory (APA) and compensatory (CPA1, CPA2 and CPA3) postural adjustments according to the AD activity onset. We performed the PCA analysis on the $\int$EMGs across these 4 time intervals.

Results: The first three principal components covered about 80% (41%, 23%, and 15%) of the spread of the data in the CAI group and 84% (46%, 19% and 18%) in the control group. The muscles seen significantly loaded (with the absolute value over 0.5 [2]) for the CAI group were: *PC1*: TA and PL; *PC2*: GasL and GasM; *PC3*: SOL while for the control group were: *PC1*: GasL and GasM; *PC2*: TA; *PC3*: SOL and PL (Table 1). The magnitudes of the SOL and TA $\int$EMG were smaller in the CAI than in the control group during the APA time interval. The PL $\int$EMG was smaller in the APA and CPA1 phases. **Discussion:** The dominant principal components differed between the control and CAI groups. For the CAI group, PC1 clustered the TA and PL muscles; while for the control group, this component included GasL and GasM. These results suggest that individuals with CAI primarily control the inversion/eversion muscles to maintain their balance during the kicking task. In contrast, the healthy control used predominantly the GasL and GasM, which is expected since kicking a ball involves an anteroposterior perturbation. It is possible that CAI factors such as ligament laxity, weakness, reduction in nerve conduction velocity [3] and decreased muscular activity (observed in this study) lead to increased instability in the frontal plane. This will make individuals with CAI employ a pattern of muscle activity with amplified control of mediolateral ankle stability during the kicking task.

Figure:



Caption: Fig 1. Mean normalized of the ∫EMG (arbitrary units) of muscles around the ankle for individuals with (CAI) and without (Control) chronic ankle instability, during the anticipatory (APA) and compensatory postural adjustments (CPA1, 2 and 3). * Indicate significant differences between groups at $p<0.05$.

Conclusion: CAI may alter the muscle control strategy during kicking to better stabilize the ankle mediolaterally. Further research is needed to determine whether rehabilitation interventions based on this or other balance perturbation trainings enhance this functional adaptation or reverse it to normal patterns of those without CAI.

INDIVIDUALS WITH KNEE OSTEOARTHRITIS USE DIFFERENT MUSCLE ACTIVATION PATTERNS THAN HEALTHY SUBJECTS DURING MAXIMAL ISOMETRIC KNEE EXTENSIONS

Jaqueline Lourdes Rios [1,2,*] Conrad Tang [1] Walter Herzog [1]

[1]Faculty of Kinesiology, University of Calgary, Calgary, Canada, [2]Coordenadoria de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), Brasília, Brazil

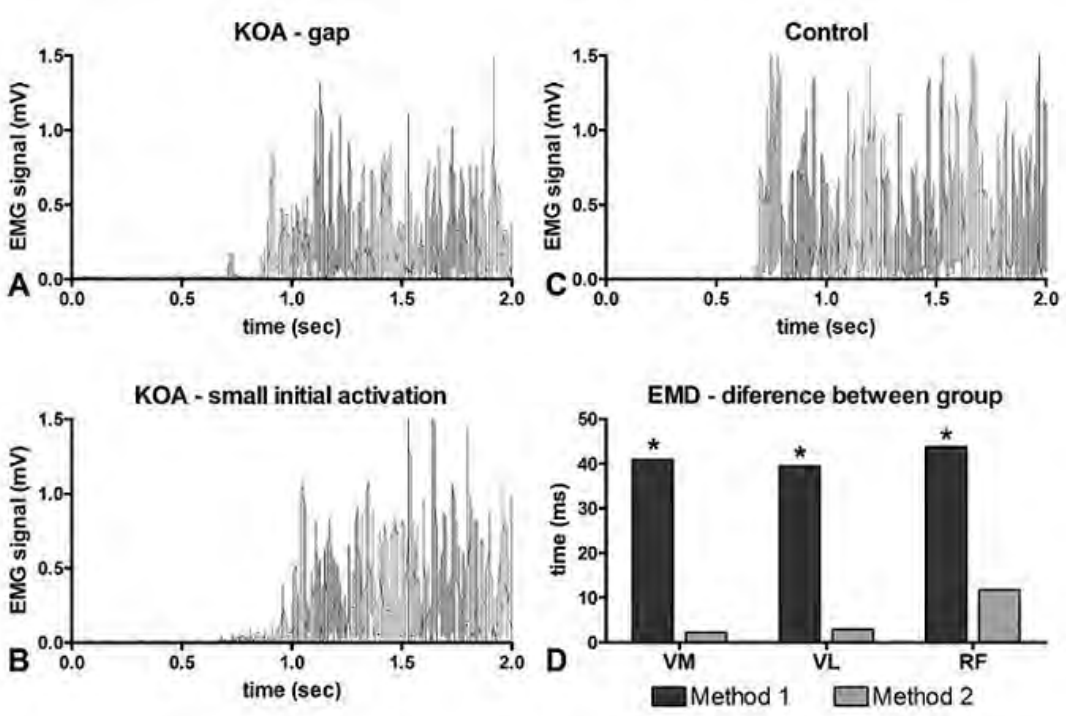
Introduction and Objectives: Patients with knee osteoarthritis (KOA) have demonstrated impaired postural balance, decreased medial knee compartment loading, increased stance times during walking, and muscle weakness. Furthermore, strength training has not been effective in reducing the progression of KOA, and muscle activation patterns in KOA have not been well defined under controlled conditions. Specifically, electromechanical delay (EMD), a key indicator of proper muscle function, has not been evaluated in patients with early KOA. Abnormal EMD might provide important insight into the loss of control of the knee extensor muscles which are crucial for optimal knee loading. Therefore, the aim of this study was to analyze EMD in KOA patients and age-matched controls during maximal isometric contractions.

Methods: Fifty-six patients with KOA (KOA group) and ten healthy individuals (control group), matched by age, performed three isometric knee extensor contractions at 60° of knee flexion. For the KOA group, the knee with the more severe OA symptoms was studied. For the control group, both knees were used for testing (20 knees). The vastus medialis, vastus lateralis and rectus femoris muscle activation onset (MO) and torque onset were identified. EMD was then calculated as the difference in time between MO and torque onset [1]. MO was defined as the instant when the EMG amplitude exceeded ± 2SD of baseline values and lasted for more than 50ms [2]. This assessment of MO was defined as method 1. Qualitative analysis of the EMG signals revealed a burst of EMG activity lasting less than 50ms that often preceded the regular EMG in KOA patients. Therefore, MO was also defined as the first burst of EMG activity independent of its duration (method 2). Differences between groups were analyzed using a one-way ANOVA (α=0.05).

Results: Using method 1, KOA patients had a significantly shorter EMD (40ms on average) than the healthy control subjects. However, using method 2, there was no difference between groups (Fig.1-D). 86% of the muscles from the control group subjects presented a MO pattern that is considered standard in the literature, that is EMG onset is clearly defined by a long burst of activity (Fig.1-C). For these trials, analysis method 1 and 2 gave the same result. However, for the KOA group subjects, 86% displayed a non-standard activation pattern in which a continuous burst of EMG activity was preceded by a short (about 25ms) burst that was followed by a distinct (46ms) silent period or a period of low activation not exceeding ±2SD of the resting EMG. For these trials, analysis methods 1 and 2 give distinctly different EMD values. 35% of muscles of KOA group subjects had this low activation (Fig.1-B), and 51% showed a silent period between the initial burst and the standard MO (Fig.1-A). This last pattern was responsible for most of the differences observed between KOA and control group subjects, since the mean difference in EMD was 71ms for the two analysis methods. These altered muscle recruitment pattern in the KOA patients could be associated with pain experienced by the KOA patients [3]. When recruiting the knee extensor muscles, knee pain may have triggered muscle inhibition that was

subsequently overcome by voluntary activation on order to fulfill the required knee extensor task. In addition, the low activation following the initial burst in some KOA patients could be an avoidance strategy adopted by KOA patients to dealing with the chronic pain. Since the first component of pain acceptance is a willingness to experience pain, and the second is the pursuit of goals and activities despite having pain, the current results might be explained within this framework [4].

Figure:



Caption: Fig.1.(A) Raw data from an exemplar trial for a subject with KOA, showing a gap between the first burst and the standard MO, and (B) decreased initial activation. (C) Healthy subject presenting typical MO. (D) Difference between EMD of subjects with KOA and healthy using method 1 and 2.

Conclusion: Individuals with KOA presented with distinctly different EMG activation patterns in the knee extensor muscles during an isometric task which resulted in a decreased EMD compared to control subjects. KOA patients also frequently had a distinct short initial burst of activation not seen in control subjects. Therefore, we conclude that knee extensor activation patterns in KOA subjects are impaired and result in shorter EMD. The mechanism underlying these altered activation strategies in KOA patients are not known. Therefore, these results set up potential investigations to examine the detailed activation mechanisms in patients with KOA.

MUSCLE SYNERGIES IN LEVEL AND INCLINED WALKING

Lars Janshen [1,*] Alessandro Santuz [1] Antonis Ekizos [1] Adamantios Arampatzis [1]

[1] Training and Movement Science, Humboldt-Universität zu Berlin, Berlin, Germany

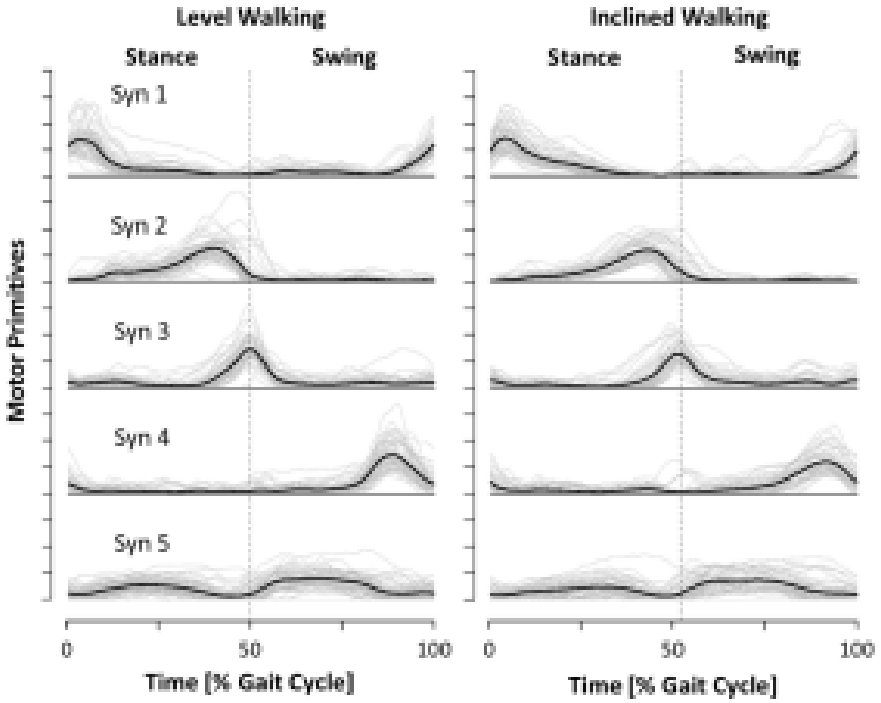
Introduction and Objectives: Neuromuscular coordination in human walking can be described by general patterns referred to as motor modules or muscle synergies [1]. There is evidence that muscle synergies are neurophysiological entities whose combination constructs a large set of movement [2]. The number of synergies and their structure resulting from the amplitude time courses of the contributing muscles are mainly consistent across individuals and different conditions in level walking, e.g. walking speed [3]. During inclined walking the characteristic of joint torques is different compared to level walking [4] and this may result in a different modular organization of the neuromuscular system. However, there is no knowledge about potential changes in the modular organization in non-level walking. The aim of this study was to compare the muscle synergies of level and inclined walking, hypothesising differences in neuromuscular organization between both conditions as a result of changes in the dynamic demands during inclined walking.

Methods: Surface EMG activity of 24 muscles [5] of the right body side of ten males and ten female participants was recorded over 50 cycles during level and inclined walking performed in a randomized order on a treadmill instrumented with a pressure plate. All participants performed each of two trials of level and inclined walking on the same day as well as in a second measurement at least 48 h (122±84 h) later. Walking speed was self-selected for level walking (1,4±0,2 m/s) and was 85% of this speed during walking at 10° incline. Gait cycles were determined from pressure plate data. EMG signals were band-pass filtered at cut off frequencies of 5 Hz and 400 Hz respectively by the recording system. The signals were high pass filtered, fully rectified and low pass filtered at 50 Hz and 20 Hz respectively using IRR 2nd order zero-lag Butterworth filters. EMG envelopes were time normalized to 200 data points per gait cycle [6] and amplitude normalized to one. To be comparable to the existing literature, muscle synergy extraction was performed using a customized Gaussian non-negative matrix factorization (NMF) algorithm [7]. A sufficient number of synergies was reached, when additional synergies did not increase the total explained variance represented by the rate of changes in the R^2 curve of reconstructed to original signal. To analyse the differences between level and non-level walking an ANOVA for repeated measures was used.

Results: No significant differences in gender as well as for both, the intraday and the inter-day measurements for each participant were observed. Level and inclined walking tasks could be reconstructed by 5±1 synergy with an R^2 of 0.92 and 0.90 respectively. The respective synergies majorly represented the muscular activity of (1) the hip and knee joint extensors attributed to foot strike, (2) the upper body muscles in the late stance phase, (3) the ankle joint extensors during push off, (4) the knee flexor and upper body muscles during late swing in preparation of the next stance phase and (5) the upper body muscles during stance and swing phase. However, during inclined walking in 32 % of all trials a sixth synergy shape for the upper body muscles during stance was observed. In 44 % this led to a total number of six synergies. Within five synergies, this resulted in a merge of synergy three and four or one and five. The flexor and extensor muscles of the

hip and ankle joint demonstrated higher weights for the respective synergies during inclined compared to level walking. These differences were predominantly significant ($p<0.05$).

Figure:



Caption: Motor primitives in level (left) und inclined walking (right).

Conclusion: The applied data acquisition methods seem to be robust against measurement artefacts occurring at multiple measurements even when repositioning the EMG electrodes. The congruence of synergies in the majority of the investigated trials (i.e. 5 synergies) during level and incline walking indicate a similar modular organisation of the neuromuscular system in both conditions. The observed higher weights of the flexor and extensor muscles of the hip and ankle joint could probably be attributed to the increased demands on the mechanical output of these muscles during inclined compared to level walking. However, the redistributions in muscle synergies in some cases may indicate changes in the neuromuscular control in inclined compared to level walking.

THE EFFECTS OF FATIGUE ARE INFLUENCED BY MUSCLE ACTION (ECCENTRIC VS CONCENTRIC) AND FORCE DEMANDS (SUBMAXIMAL VS MAXIMAL)

Chad A. Sutherland [1 2,*] Nicholas La Delfa [1] Jim Potvin [1]

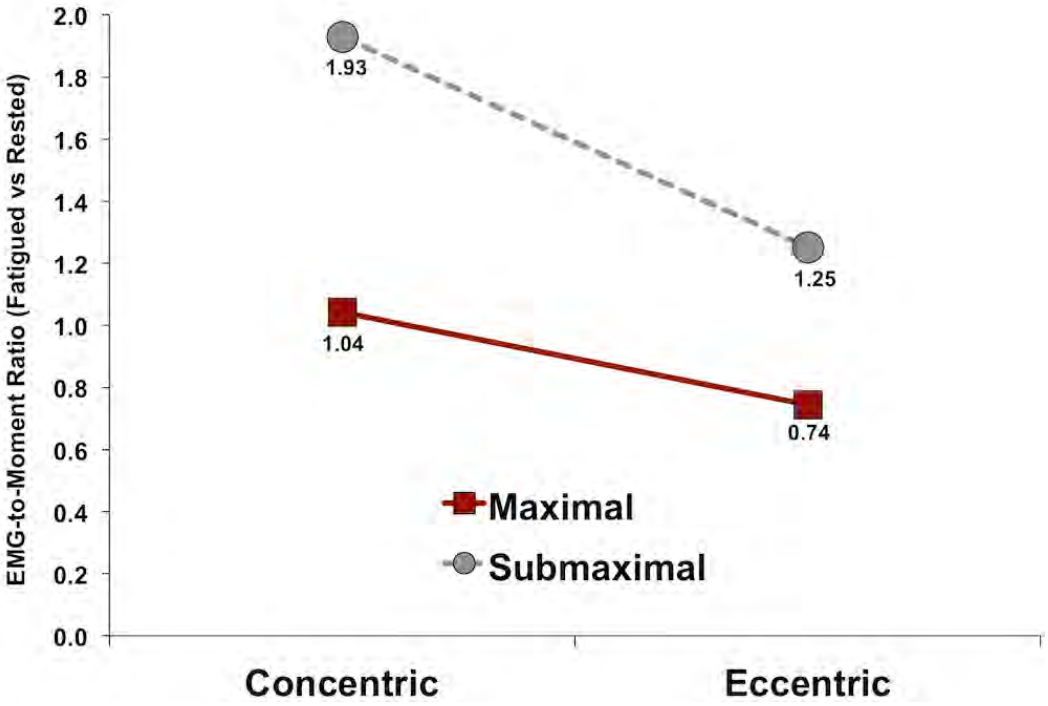
[1]Kinesiology, McMaster Univeristy, Hamilton, [2]Kinesiology, University of Windsor, Windsor, Canada

Introduction and Objectives: It is generally accepted that muscle fibers can generate more force during eccentric efforts, compared to both concentric and isometric efforts, under isotonic conditions. However, it appears that individuals are limited in their ability to produce maximal muscle activation during voluntary eccentric efforts. LaDelfa et al. (2014) termed this a "neural tension-limiting mechanism" (NTLM) and showed that processing the raw sEMG signal with alternative methods, such as extreme high pass filtering or whitening, allows for novel insights into the different neurophysiological control strategies used during fatiguing efforts. The purpose of the current study was to investigate the effects of fatigue on the agonists during the concentric and eccentric phases of repetitive knee extensor efforts that were either submaximal or maximal.

Methods: Sixteen male participants performed continuous maximal knee extension efforts on a Biodex dynamometer, concentrically (CON) at a velocity of 30°/s and eccentrically (ECC) at -30°/s, between 50-110° of knee flexion, until exhaustion. After a week of rest, fourteen participants repeated the protocol at a submaximal effort level of 33% MVC. We recorded the net knee extensor moment and raw sEMG signals from vastus medialis, vastus lateralis and rectus femoris. The sEMG signals were Butterworth filtered with a 6th order, extreme high pass cutoff of 140 Hz (see Potvin & Brown, 2004). A weighted average EMG value (EMG_{WA}) was calculated based on the PCSA of each of three quadriceps muscles, relative to their total PCSA. We then used a regression analysis to estimate the EMG_{WA}-to-Moment ratio at the start (rested) and end (fatigued) of each session, and then a ratio of fatigued/rested for the CON and ECC directions.

Results: Participants completed an average of 12.1±2.6 and 25.5±7.8 cycles, for the maximal and submaximal protocols, respectively. During both protocols, the increase in EMG_{WA}-to-Moment ratio was much more pronounced during the CON vs ECC efforts (Figure 1). These findings are in agreement with Gonzalez-Izal et al. (2014), who showed that fatiguing protocols cause a greater loss of force in CON efforts, compared to ECC efforts. Furthermore, we observed a larger effect of fatigue, on increasing the EMG_{WA}-to-Moment ratio, for submaximal vs maximal efforts. Consequently: 1) during the submaximal protocol, fatigue had the greatest effect on the CON efforts as it was associated with a 93% increase in activation, relative to the constant, submaximal moment (Figure 1), and 2) during the maximal protocol, fatigue had the least affect on the ECC efforts, as only a 26% decrease in activation was associated with a 56% decrease in the maximal extensor moment.

Figure:



Caption: Figure 1. The EMGWA-to-Moment ratio was calculated at the start and end of the fatiguing trial during both the CON and ECC efforts. This figure shows fatigued ratios relative to the rested ratios. The ECC values are much lower than CON, particularly with the submaximal effort.

Conclusion: During repeated, maximal and submaximal, dynamic knee extension efforts to exhaustion: 1) ECC efforts were less affected by fatigue than CON efforts and, 2) maximal efforts were less affected by fatigue, than submaximal efforts. Lastly, the use of alternative sEMG processing methods, specifically extreme high pass filtering, has enhanced our ability to interpret how the neuromuscular system modifies the NTLM in the presence of fatigue.

EXISTENCE OF MUSCLE SYNERGIES INCREASE LEARNING SPEED: SIMULATION STUDY BASED ON NEURAL NETWORK MODEL

Shota Hagio [1,*] Motoki Kouzaki [1]

[1] Graduate School of Human and Environmental Studies, Kyoto University, Kyoto, Japan

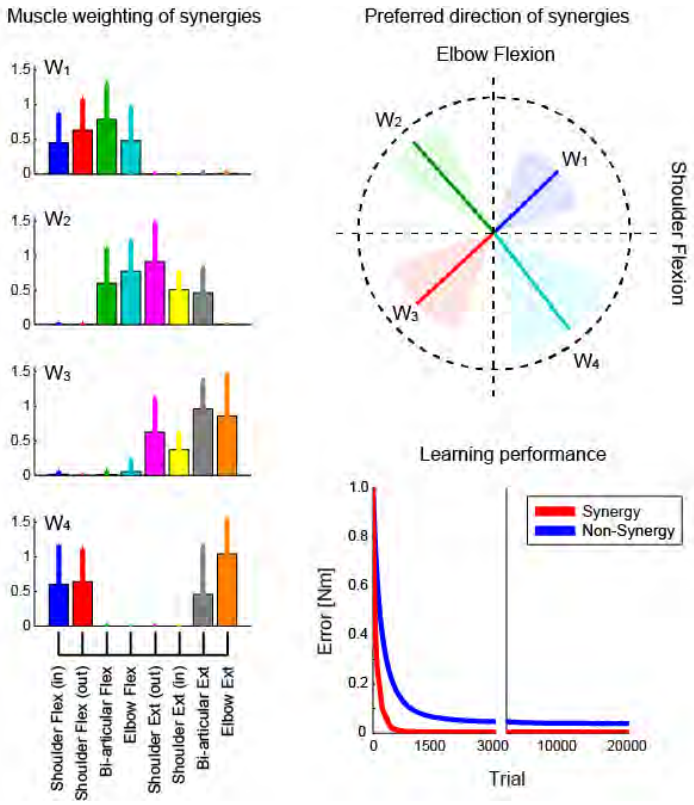
Introduction and Objectives: The concept of muscle synergies has been proposed to simplify redundant motor control by low-dimensionally organizing functionally similar muscles [1, 2]. Reduction of neuronal redundancy due to muscle synergies will contribute to upgrading learning performance as acquiring complicated movements. However, the functional roles of muscle synergies during motor learning remain unknown. The simulation analysis using neural network model makes it possible to specify the functional roles by evaluating leaning performance, such as learning speed, in the presence and absence of muscle synergies. The purpose of this study was to clarify the functional roles of muscle synergies during motor learning based on neural network simulation.

Methods: The descending neural network model including 3 intermediate layers (synergy model) was constructed based on the previously used model [3]. The neural network performed isometric force-generation around right wrist on a horizontal plane (elbow and shoulder joint flexion angles: 90° and 30°, respectively). The first intermediate layer contained 1000 neurons in primary motor cortex (M1). Each neuron received a desired shoulder flexion and/or elbow flexion torque vectors from the input layer with a synaptic weight (W_{neu}). These M1 neurons were connected to the second intermediate layer that indicated the muscle synergies as spinal interneurons [4, 5, 6, 7] with a uniformly distributed constant innervation. The number of muscle synergies was varied across continuous leaning. The muscle synergies controlled 26 muscles spanning elbow and shoulder joints with a synaptic weight (W_{syn}) in the third intermediate layer. The muscle mechanical pulling vector was determined by physiological parameter of each muscle. These muscles were then grouped into 8 muscle groups. W_{neu} and W_{syn} were modified using an error back-propagation algorithm [8] to minimize the error between output torque generated from muscles and randomly presenting desired 12 input torques, which were uniformly distributed on the two joint torque plane with the same intensity. The experiment was additionally conducted, which required the same task as above. We then extracted muscle synergies by measured muscle activities using non-negative matrix factorization [9]. Leaning performance in the presence and absence of muscle synergies was evaluated by comparing the synergy model with the previously constructed model, which didn't include the layer of muscle synergies (non-synergy model) [3]. When the state of the neural network was constant after leaning, we exposed the neural network to a force field: the output torque was rotated. During the adaptation period to the force field, W_{neu} was only modified [10].

Results: Four muscle synergies were required to appropriately produce the desired torques and to decrease motor redundancy. The synaptic weights (W_{syn}) between synergy and muscle layers after learning (Figure; left) were similar to the muscle weightings of the extracted synergies in the experiment. The simulated muscle synergies had specific preferred directions, which indicated the highest activations (Figure; right top). The synergy model increased learning speed and decreased the final error between the desired and output torques as compared with non-synergy model (Figure; right bottom). After adaptation to the force field, the preferred directions of muscle synergies were rotated to the

direction of the force field. In this case, the synergy model also increased learning speed, suggesting that the acquired neural basis as muscle synergies contributes to increasing adaptation speed against the changes of external environment.

Figure:



Caption: Simulated muscle synergies and leaning performance.

Conclusion: The neural network model including muscle synergies increased learning speed as compared with non-synergy model. These results suggest that one of the functional roles of muscle synergies is to increase speed of motor learning.

MALPOSITIONING OF THE PATIENT DURING X-RAY ACQUISITION CAN AFFECT THE ASSESSMENT OF SAGITTAL PELVIC PARAMETERS: EVALUATION IN ADULTS AND CHILDREN

Ayman Assi [1,*] Ziad Bakouny [1] Elie Saghbini [1] Nour Khalil [1] Lydia Chelala [1] Elias Naoum [1] Christophe Sauret [2] Wafa Skalli [2] Ismat Ghanem [1]

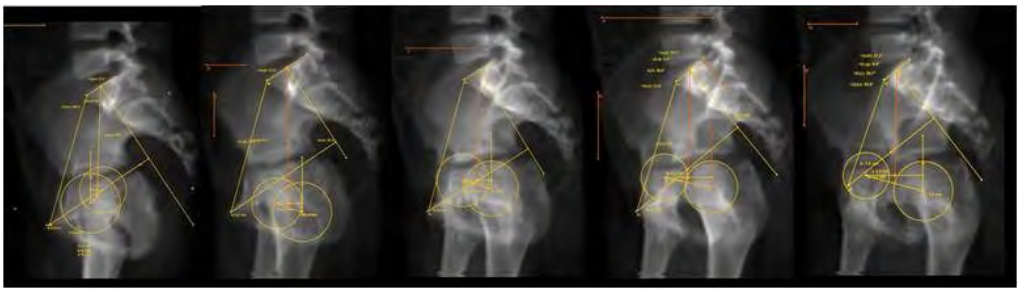
[1] Laboratory of Biomechanics and Medical Imaging, School of Medicine, University of Saint-Joseph, Beirut, Lebanon, [2] Laboratoire de Biomécanique, Arts et Métiers ParisTech, Paris, France

Introduction and Objectives: In order to assess sagittal balance, clinical parameters are measured on lateral X-rays of the pelvis [1,2]. These radiographs require standard positioning of the patient during acquisition. To our knowledge, there are no studies that have investigated the effect of pelvic axial rotation on sagittal clinical parameters. The aim of this study was to estimate the effect of erroneous positioning of patients, during pelvis lateral X-ray acquisition, on the reliability and validity of sagittal pelvic parameters.

Methods: Helical pelvis CT-Scans (slice thickness: 0.6mm) of 8 children (3 F and 5 M, age: mean 12 - SD 2.2) and 9 adults (5 F and 4 M, age: mean 51 - SD 26) were considered. Lateral Digitally Reconstructed Radiographs (LDRRs) were reconstructed from CT-Scans using a homemade software. Then, for each patient, axial rotation of the pelvis was simulated and the corresponding LDRRs were reconstructed at 5°, 10°, 15° and 20° of axial rotation. Clinical parameters were measured digitally on each radiograph using the SterEOS® 2D toolbox: sacral slope (SS), pelvic incidence (PI), pelvic tilt (PT), pelvic inclination (PIL), sagittal pelvic thickness (SPT), bifemoral distance (BFD) and pelvic depth (PD). Three trained operators repeated the measurements 3 times each, in each axial rotation position and for each radiograph (Figure 1). The Intraclass Correlation Coefficient (ICC) was evaluated for inter-observer agreement. The 95% confidence interval (95%CI) was calculated as 2SD of inter-observer reliability. The bias of each clinical parameter, in each axial rotation position, was calculated as the absolute mean difference relatively to the 0° position.

Results: Inter-observer agreement was shown to be very high (ICC>0.88) for all parameters and in all axial rotation positions. In the absence of axial rotation of the pelvises (0˚), the 95% CI of the SS and the PI were lower than 4°, lower than 2° for PT and PIL and lower than 1 cm for both SPT and BFD. The 95% CI increased with pelvic axial rotation; at 20° of rotation it exceeded 7° for SS and PI, 7° and 4° for PIL and PT respectively, and remained constant for SPT and BFD. All the parameters showed an increase in the bias during axial rotation of the pelvis, where PI showed the greatest bias by reaching 6° at 20° position. Only SPT and PD exhibited a bias which was minimal and constant (< 0.5cm) for all axial rotation positions. Even though insignificant (p>0.05), the bias on PI and SS was shown to be higher in children than in adults.

Figure:



Caption: Figure 1- Lateral radiographs of the pelvis at 0°, 5°, 10°, 15°, 20° of axial rotation with pelvic parameters measurements

Conclusion: Clinical parameters measured on lateral radiographs were shown to be less accurate and less reliable when pelvic axial rotation increased. The bias exceeded 10% of the normative values of each clinical parameter when the AR exceeded 10°. This bias could significantly affect orthopedic decision-making in patients with sagittal malalignment.

THE POSTPARTUM DIASTASIS RECTIS ABDOMINIS AND THE ABILITY OF THE ABDOMINAL MUSCLES TO STABILIZE THE PELVIS DURING THE DOUBLE-LEG LOWERING EXERCISE

Augusto G. Pascoal [1,*] Cristiana Vaz [1] Patricia Mota [1] Filipa João [1] António Veloso [1]

[1] University of Lisbon, Faculty of Human Kinetics, CIPER, LBMF, Lisbon, Portugal

Introduction and Objectives: Postpartum distasis rectis abdominis (DRA) refers to the separation of both recti abdominis (RA) muscles starting in the last trimester of pregnancy and extends up to 8-16 weeks postpartum. DRA is quantified by the inter-recti distance (IRD) measured around the umbilicus. Postpartum IRD vary between 20-50mm which may change the line of action of both RA muscles [1] compromising their ability to produce torque on thorax and/or on pelvis. Mostly postnatal women are encouraged to resume abdominal exercises, such as curl-ups and double-leg lowering (DLL) exercises, to restore their abdominal figure. The DLL involves the subject lying supine and starts with both lower extremities placed in a vertical position. Then both legs are lowered to the horizontal while knees are kept straight and low back flat [2]. Abdominal muscles contraction maintains the pelvis in a posterior-tilted position counteracting the anterior-tilted action produced by the hip flexors muscles [3]. A negative correlation was found between postpartum IRD and the abdominal muscles ability to perform a curl-up exercise [4, 5]. However no information is available about the implication of the postpartum DRA on the ability of the abdominal muscles to stabilize the pelvis in a posterior-tilted position against a resistance. The main purpose of this study was to investigate the relationship between the width of the IRD and the abdominal muscle function to stabilize pelvis against resistance during the DLL exercise. Additionally, the effect of pregnancy on IRD and pelvic tilt angle was also analyzed.

Methods: A convenience sample of 11 postpartum (age:32.9±3.5 years; postpartum weeks: 10.7±3.3) and 11 nulliparous (age:29.8±4.9 years) women was tested on 2 static positions of the DLL exercise: 1) starting flexion position (FPos), at 90º hip flexion and 2) final extended position (EPos) at 10º hip flexion. On each DLL position, the pelvis tilt angle was recorded by means of a motion capture system (13 Qualisys cameras;FR:50Hz). Pelvis position was tracked by means of 4 reflective markers (on both anterior-superior iliac spines and iliac crests) and a set of 10 reflective markers (on both acromion, lateral projections of the xiphoid, iliac crests, anterior superior iliac spines and lateral and medial femoral condyles) and two marker clusters (one at the thigh segment and other at the sternum region) was used to build and track the thorax and thigh segments position. The Visual 3D (Basic RT) software was used for segment 3D reconstruction and calculation of Euler angles describing pelvis and thigh position in global, pelvis and thorax coordinate systems. Simultaneously an ultrasound image was collected (GE Logic-e; 4-12 MHz,39mm) by placing the transducer transversely along the midline of the abdomen (2 cm below the umbilicus) allowing the measurement of DIR. A two-way repeated measure ANOVA was performed to determine whether any change in each dependent variables (pelvic tilt angle and IRD) was the result of the interaction between women's group (nulliparous and postpartum) and DLL positions (FPos and EPos).The relationship between IRD and pelvic tilt angles was examined using the Person product-moment correlation coefficients.

Results: A positive correlation was found between mean IRD values and the pelvic tilt angle, both in FPos (r=0.70;p=0.02) and in EPos (r=0.65; p=0.03) position. This relationship was in such a way that women with highest IRD were those that tended to place pelvis in a more anterior tilt angle. This finding suggests that in postpartum women the incomplete recovery of the abdominal wall integrity, revealed by the width of IRD, may lead to a certain mechanical deficit, resulting in a reduction in the ability of the abdominal muscles to stabilize the pelvis in a posterior-tilted position. However, no differences were found between groups with respect to the pelvic tilt angle on both DLL positions, despite the postpartum women exhibited a significantly greater IRD [$F(1,19)=12, p<0.05$]. Thus, the postpartum group had a significantly greater IRD (17,0±1,6mm;IC95:13,7-20,3mm) comparing to the control group (9,4±1,5mm;IC95:6,3-12,6 mm) with a difference of 7,6±2,2mm (IC95:3,0-12,2mm). These results are in accordance with previous studies [6, 7].

Conclusion: In postpartum women a negative relationship was found between IRD and the ability of abdominal muscles to keep the pelvis in a posterior tilt position on two positions of the DLL exercise. However, on both DLL position no differences were found on pelvic tilt angle between postpartum and nulliparous women.

A GOAL PROGRAMMING MODEL FOR ASSESSING SAGITTAL SPINAL CURVATURE UNDER BACKPACK CARRIAGE

Daniel H. Chow [1,*] Simon Li [1]

[1]Department of Health & Physical Education, The Hong Kong Institute of Education, Hong Kong, Hong Kong

Introduction and Objectives: Previous research established that load carriage would induce immediate changes in spinal curvature which was associated with spine disorders [1]. Neutral upright standing has been proposed as the healthy posture for minimizing spine loading [2]. It was hypothesized that the maximum load should be one that induced minimum changes to the spine curvature in neutral upright stance. In this study, a multi-objective optimization goal programming (GP) model [3] was developed and applied to determine the optimal limit of backpack load for upright standing.

Methods: This was a single factor randomized repeated measure design. Spinal curvatures [in terms of the angles of cervical lordosis (CVL), upper thoracic kyphosis (UTK), lower thoracic kyphosis (LTK) and lumbar lordosis (LBL)] were measured non-invasively using five sensors affixed to the middle of the back of head, C7, T7, T12 and pelvis [4, 5]. All subjects were instructed to maintain a standardized and relaxed barefoot erect stance without load and with a backpack loaded at 5, 10, 15 and 20% of their body weights. The four curvature angles among the five sensors were measured by a motion analysis system. The sequence of experimental trials was randomized. Three trials for each unloaded and loaded conditions were recorded. Regression equations predicting the four loaded curvatures were obtained. The deviations of loaded from unloaded curvatures and the target levels of the predicted mean loaded curvatures were formulated as the cost and constraint functions of the GP model respectively. The sequence of optimization process of the GP was prioritized with respect to the magnitude of the mean loaded curvature deviations. The optimal mean loading condition was determined by solving the sequential optimization problems.

Results: Ten young male adults (age between 20 and 29) were evaluated. The baselines of mean curvatures of CVL, UTK, LTK and LBL were 32.1^{o}, 32.9^{o}, 10.3^{o}, and 17.2^{o} respectively. The respective mean deviations under loaded conditions were -0.6^{o}, -5.0^{o}, 1.6^{o}, and -2.1^{o}. The r^2 of the 2nd order regressions were 0.97, 0.99, 0.91, and 0.91 respectively. The sequence of optimization process was UTKàLBLàLTKàCVL. On average, significant flattening of the CVL, UTK and LBL as well as significant increased curvature in LTK were observed ($p<0.05$). The mean allowable load limit was found to be 7.4% of body weight. The predicted mean curvatures of CVL, UTK, LTK and LBL were 29.6^{o}, 26.8^{o}, 13.1^{o}, and 14.8^{o} respectively.

Conclusion: A symmetric backpack load at 7.4% of body weight was recommended, in order to achieve an optimal standing posture with minimal spinal curvature deviations from the unloaded condition.

INTERVERTEBRAL DISC STRESS IN STANDING AND SITTING; MAGNETIC RESONANCE IMAGING BASED FINITE ELEMENT STUDY

Sahand Zanjanipour [1,*] Christopher Smith [2] C Peter Winlove [1] Jude Meakin [1]

[1]Physics, [2]Engineering, University of Exeter, Exeter, United Kingdom

Introduction and Objectives: The cause of disc degeneration can be attributed to mechanical loading, which varies in different postures. The effect of different daily postures such as standing and sitting for instance has previously been investigated by measuring the pressure within the discs (which is invasive) or by computational models (based on generic anatomical data which largely ignore differences between individuals).

The aim of this project was to non-invasively investigate the stress distribution in standing and sitting postures by incorporating magnetic resonance (MR) imaging data in subject-specific finite element (FE) models. Objectives were defined as:

- Create a FE model for each subject based on MR images;
- Determine boundary conditions of the standing and sitting postures with respect to reference posture (supine);
- Compare the stress distribution in standing and sitting postures.

Methods: Two-dimensional FE models of the lumbar spine (L1 to S1) were created for nine healthy individuals. The initial geometry of each model was based on MR images of the individual in the supine posture. Two types of FE model were investigated: a time-dependent model and a simple elastic model. In the time-dependent model, material properties of the disc were defined as poroelastic.

The disc was modelled with an annulus (Young's modulus, E=2.5 MPa, Poisson's ratio, v=0.4) and a nucleus (E=1 MPa, v=0.45). In the time-dependent model poroelastic properties were assigned to the annulus (Permeability, K=1.83E-12 ms^{-1}, void ratio, e=3.54), nucleus (K=2.06E-12 ms^{-1}, e=4.88) and the vertebral bodies (K=1E-23 ms^{-1}, e=0.02).

Boundary conditions were determined by considering the vertebrae as rigid bodies and applying the translation and rotation of each vertebral body in either the sitting or standing posture, with respect to the supine posture. In the poroelastic model, a fluid boundary condition was set to allow fluid movement across the interface between the vertebrae and discs.

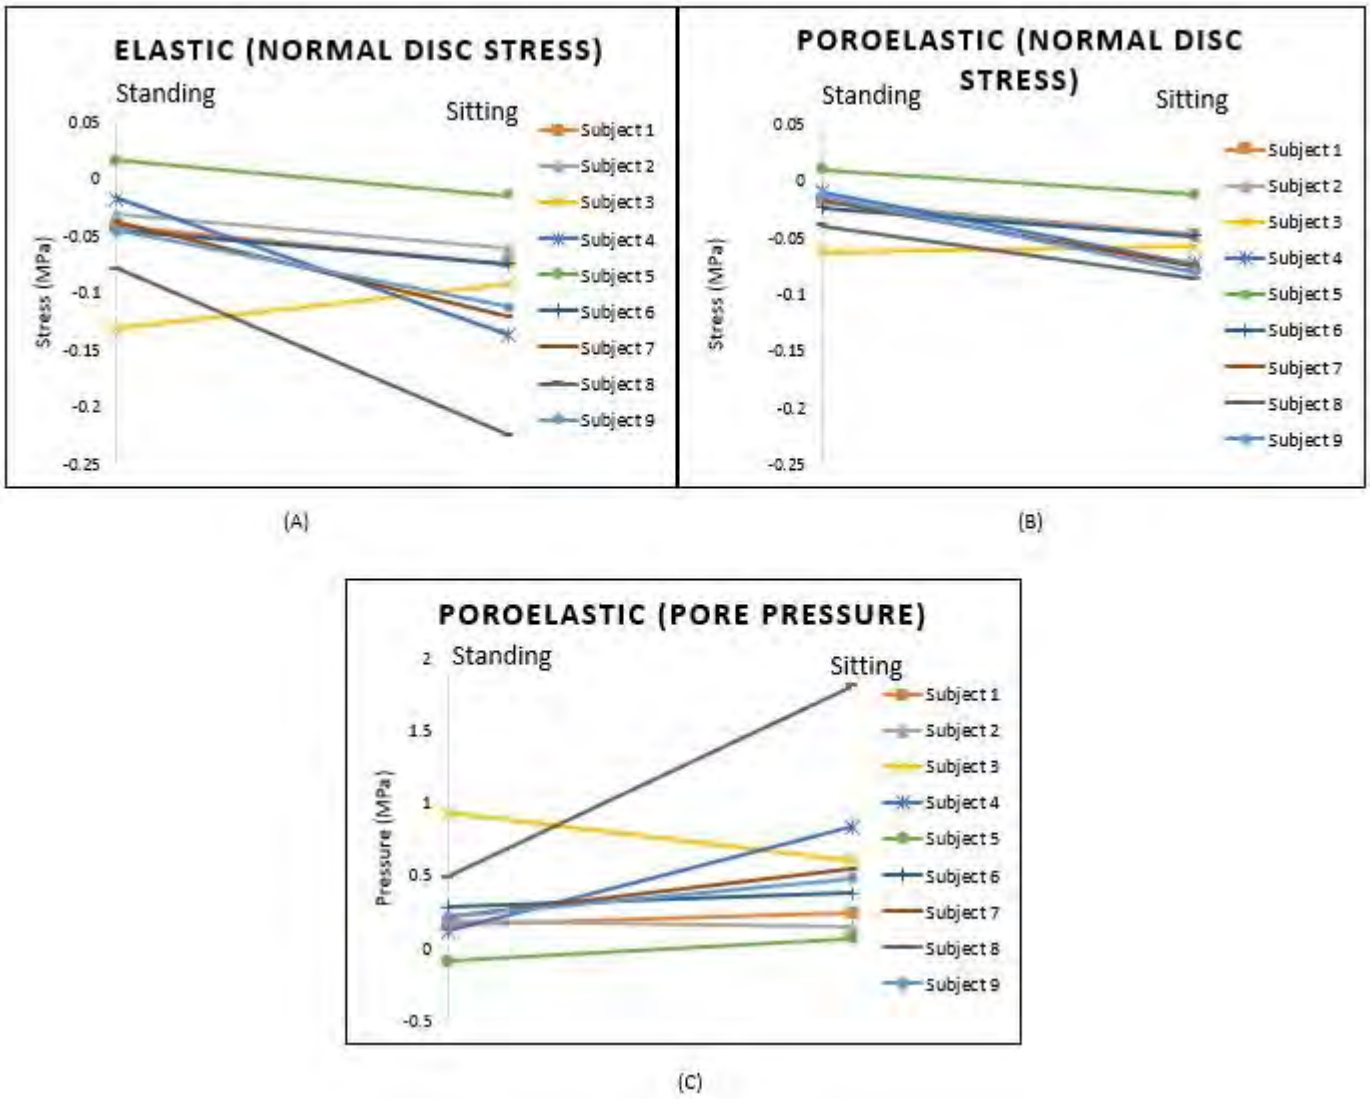
The resulting stresses in a central region of the L4/L5 disc were averaged and used to determine the normal disc stress (i.e. the stress acting perpendicular to the mid-plane of the disc). For the time-dependant model the results were taken at the time-point corresponding to the duration of the MR scan and comprised two components: the effective stress normal to the disc and the pore pressure.

Results: Figure 1 shows the normal disc stresses and the pore pressure on the L4/L5 disc in standing and sitting for each individual. In both the elastic and poroelastic models, the sitting posture created more normal disc stress than standing in all subjects except one. For the poroelastic model, the pore pressure was also more in sitting than standing except two subjects. These results are consistent with experimental measurements of disc pressure reported in the literature where sitting tends to produce a higher intradiscal pressure than standing. The absolute values of the disc stress are lower than

we would expect from experimental measurements, this is due to assumptions in the modelling (i.e. the two-dimensional modelling and the material properties assigned to the discs).

Further visual analysis of the models showed that in some individuals the highest disc stress occurred within other intervertebral discs along the lumbar spine.

Figure:



Caption: Figure 1: The normal disc (L4/L5) stress in standing and sitting for (A) elastic model and (B) poroelastic model. (C) Pore pressure within the disc in the poroelstic model.

Conclusion: Incorporating information from MR images in a displacement based FE model offers a non-invasive way of determining the relative intervertebral disc stresses induced by postural change. The results of elastic and time-dependent models are consistent with each other. This method may be useful in investigating other more extreme postures such as those experienced when lifting loads.

IS THERE A CHANGE IN THE ABILITY TO REACT TO A PERTURBATION FOLLOWING A BOUT OF PROLONGED SITTING?

Tara Diesbourg [1,*] Peter Sheahan [1] Geneviève Dumas [2] Steven Fischer [1]

[1]School of Kinesiology and Health Studies, [2]Department of Mechanical and Materials Engineering, Queen's University, Kingston, Canada

Introduction and Objectives: Standing rest-breaks are often recommended during seated work in order to mitigate the ill-effects of prolonged sitting on spine health [1]. These ill-effects include changes in the passive stiffness of the trunk, thought to be a result of the creep response of the trunk's passive tissues, and are hypothesized to decrease the body's ability to respond to a perturbation, which may increase an individual's risk for injury [2]. While evidence indicates that passive stiffness is affected by prolonged sitting, it is currently unknown whether the response to a perturbation (represented by the active trunk stiffness) is also affected. Therefore, the purpose of the current study was to examine changes in the active stiffness of the trunk following a 1-hour sitting task.

Methods: Twenty healthy subjects (10 male, 10 female: mean height – 174cm, mean weight – 72kg) were recruited from a university population. Trunk stiffness was estimated using a quick-release method described by Hodges and colleagues [3]. Subjects were asked to adopt a semi-seated position with their arms crossed over their chest. Using electromagnets on cables affixed to the anterior and posterior aspects of a chest harness, weights (15% body weight) were suspended from the subject. At a random time (0-5s) and in random order, either the front or the back weight was dropped (10 repetitions each), perturbing the subject in the opposite direction. A uniaxial load cell between the subject and the attached load was used to measure force. Acceleration was obtained from the force and was double-integrated to obtain displacement. It is assumed that the displacement of the load represents the linear displacement of the trunk. The maximum displacement (D) and the time required to achieve this maximum displacement (TMD) were used to determine the ability of the subject to respond to the perturbation. Increased TMD and increased D were assumed to represent a decreased ability of the subject to respond to a perturbation.

Trunk stiffness was estimated using a least-squares optimization algorithm which used time-varying force, acceleration, velocity, and displacement traces to estimate the system's effective mass, damping, and stiffness (TK) coefficients [3]. In the current study, only the TMD, D, and TK were examined.

This protocol was completed prior to and immediately following a seated 60 minute typing task. At 10 minute intervals, the subject was asked to complete a Visual Analog Scale (VAS) according to their level of low back discomfort. Subjects who showed an increase in VAS score of 10 or more units were classified as being Pain Developers (PD), those that did not were classified as Non-Pain Developers (NPD) [4].

The data from the first front and first back perturbations for each subject were collapsed and Repeated Measures (RM) ANOVAs were conducted to identify whether a main effect of time (pre vs post sitting task) existed. Additionally, interactions between time (pre vs. post sitting task) and PD/NPD were tested for all variables (TMD, D, and TK).

Results:

Due to malfunction within the load cells, the trials for 7 of the subjects were discarded from the analysis.

The mean (SD) for each variable is presented in Table 1. No main effect was identified for any of the variables of interest ($0.522 < p < 0.953$). There was no interaction of PD/NPD on any of the variables ($0.691 < p < 0.938$).

Conclusion:

The current study sought to identify if subjects altered their response to perturbations following a prolonged seated task. Previous research has shown a decrease in passive stiffness following prolonged sitting, where it was suggested that perturbation response may also be compromised [2]. The results of the current study suggest that 60 minutes of prolonged sitting does not affect the active stiffness of the trunk. While changes in passive stiffness have been attributed to a creep response of passive tissues [2], participants were able to maintain active stiffness despite potentially altered passive stiffness. This may be accomplished by increasing baseline muscle activity, as described by Brown and McGill [5]. In order to determine whether this effect is present, an analysis of the muscle activity throughout the perturbation is necessary.

Table: Mean (SD) for the variables of interest. TMD = Time to maximum displacement (ms), D = maximum displacement (mm), TK = Active Trunk Stiffness (N/m).

	Forward Perturbation		Backward Perturbation		Collapsed	
	Pre	Post	Pre	Post	Pre	Post
TMD (ms)	408 (67)	382 (61)	379 (98)	381 (97)	393 (17)	382 (16)
D (mm)	47 (12)	51 (9)	33 (10)	29 (8)	40 (3)	40 (3)
TK (N/m)	3997 (1455)	4913 (1977)	3748 (1143)	3748 (1143)	4188 (1520)	4330 (1690)

INTRA-TRUNK COORDINATION EXHIBITED DURING TREADMILL RUNNING BY INDIVIDUALS WITH SPINAL FUSION FOR ADOLESCENT IDIOPATHIC SCOLIOSIS

Yumeng Li [1,*] Rumit Kakar [2] Yang-Chieh Fu [3] Timothy Oswald [4] Cathleen Brown [1] Kathy Simpson [1]

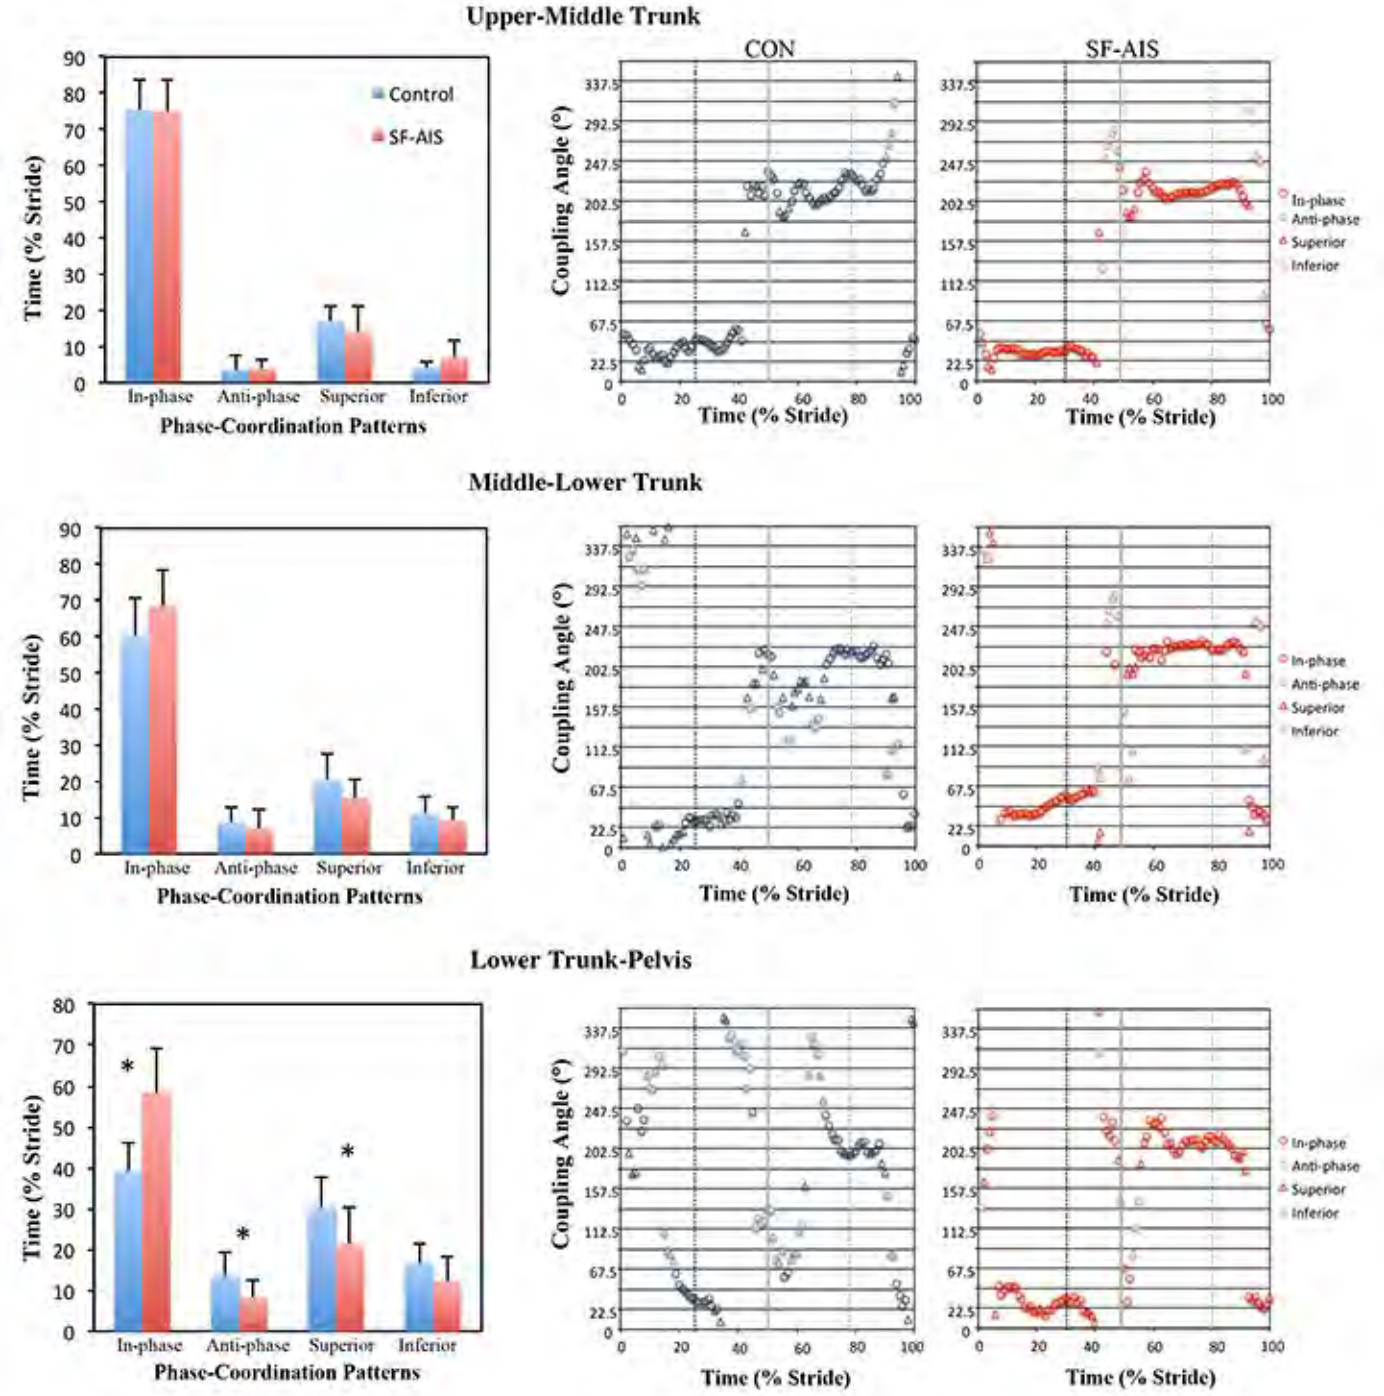
[1]University of Georgia, Athens, [2]Ithaca college, Ithaca, [3]University of Mississippi, Oxford, [4]Pediatric orthopedic associates, Atlanta, United States

Introduction and Objectives: Spinal fusion for adolescent idiopathic scoliosis (SF-AIS) largely corrects abnormal spinal curvature but limits motions among the fused vertebrae, decreases sensitivity of spinal proprioception[1]. Reduced spinal motions and proprioception may alter intra-trunk coordination during high-effort running; however, this has not been previously investigated. Therefore, the purpose of the present study was to compare intra-trunk coordination of axial-rotation between SF-AIS and healthy control individuals (CON) during high-effort treadmill running.

Methods: 11 SF-AIS (>1 yr postop, mid-thoracic to minimum of 1 lumbar intervertebral joint fused) and 11 CON (matched for mass, height, age, gender and physical activity level) ran on a treadmill with CON running at the SF-AIS matched speed (range: 2.2-3.8m/s, perceived-effort >14 on Borg scale). Locations of 24 reflective markers placed on the trunk, spine and pelvis were captured by a 7-camera Vicon system (240 Hz) for 10 strides. Axial segmental angles for the trunk segments (upper [UP]: C7 to T8; middle [MID]: T9 to T12; lower trunk [LOW]: L1 to L5), and pelvis (PEL) were used in cross-correlation analyses between adjacent segments to determine phase lag and in the generation of the coupling angle (CPA) using the vector coding method[2]. Each CPA was classified into a phase-coordination pattern[2]: in-phase, anti-phase, superior-segment dominant phase or inferior-segment dominant phase (Fig. 1). Phase lag and time spent in each phase-coordination pattern were scaled to % stride. A two-way, mixed model ANOVA with within-subjects effect of adjacent segments (UP-MID, MID-LOW and LOW-PEL) and between-subjects effect of group (SF-AIS and CON) was used to test phase lag (p<0.05). Independent t-tests were used to compare time spent in each phase-coordination pattern between the two groups (p<0.05).

Results: The main effect of group was significant $F(1, 20)=11.6$, $p<0.01$, indicating that the phase lag was significantly lower for SF-AIS (M=2.2, SE=0.6) compared to CON (M=5.0, SE=0.6). The main effect of trunk segment was significant $F(2, 40)=21.2$, $p<0.01$. Post-hoc analyses indicated that the intra-trunk phase lag was significantly increased from superior to inferior adjacent segments (Table 1). The interaction effect was non-significant $F(2, 40)=1.1$, $p=0.36$. Typically, the superior trunk segment led the inferior segment, although there were individual participant variations. For phase-coordination time, SF-AIS spent longer time in-phase and shorter time in anti-phase and superior-segment phase for LOW-PEL (Fig. 1). No other significant differences were observed.

Figure:



Caption: Figure 1. Intra-trunk coordination outcomes between adjacent segment pairs. Scatter plots: coupling angles of a representative CON and SF-AIS participant exhibited during each % of the stride (0% = rt foot touchdown) are displayed by phase-coordination pattern. Vertical lines: black = right foot, gray = left foot; solid = touchdown, dotted = toeoff. Bar graphs: total time spent in phase-coordination patterns; * indicates significant difference ($p < .05$) between groups.

Conclusion: Spinal fusion did allow some normalcy of typical phase-coordination patterns, as both groups displayed a pattern of increased phase lag and decreased in-phase coordination time at more caudal segment locations. However, the SF-AIS did not decouple their trunk motions to the same degree as healthy spines likely due to the intervertebral fusion. Group differences became significant between the most caudal adjacent segments, i.e., the LOW-PEL, whereby SF-AIS had lower phase lag and greater in-phase coordination time. Conversely, the phase lag and timing values between the most cephalic segments (UP-MID) of SF-AIS were more similar to CON. Previously, we reported that the maximum axial LOW-PEL displacements of SF-AIS were comparable to CON for running[3]. Hence, whether these more coupled LOW-PEL vertebral motions of SF-AIS influence running performance or affect lumbar mechanics is not known at present. In conclusion, the SF-AIS trunk displays similar patterns of phase lag and coordination as CON for axial rotation during treadmill running, but the spinal fusion hinders decoupling of intra-trunk motions, particularly between the lower back- pelvis motions.

Table:

	UP-MID		MID-LOW		LOW-PEL	
	CON	SF-AIS	CON	SF-AIS	CON	SF-AIS

THE EFFECT OF BREATHING ON ACTIVE DRAG WHILE SWIMMING

Pendar Hazrati [1,*] Peter Sinclair [2] Bruce Mason [1]

[1]Australian Institute of Sport, Canberra, [2]University of Sydney, Sydney, Australia

Introduction and Objectives: In competition, a swimmer must supply adequate oxygen to the muscles for continuing movement. For this to occur, the swimmer should perform the breathing phase while their body has adequate rotation which should be integrated into the stroke cycle without increasing resistive forces. Di Prampero et al. (1974) found that the breathing phase may increase the hydrodynamic drag of the body. It was also reported that the efficiency of stroke mechanics might be impeded by the breathing frequency (Stager et al. 1989). Town and Vanness (1990) reported that restricted breathing patterns (one breath every stroke, two, three or four strokes) may impede the efficiency of the stroke mechanics. Two main forces have a major effect on performance. The first is the propulsive force produced by the swimmer to propel their body through the water. The second is the drag force which is exerted by the water on the swimmer. Hence, it is essential for swimmers and coaches to understand the effect of breathing on each of these forces. The aim of this research is to determine the effect of breathing on active drag using resisted method, and how the breathing phase influences the swimmer's technique.

Methods: Nine international male swimmers completed all testing protocols each day over two alternate days. Two maximum effort free swim trials were performed over a 25 m distance (one without and one with breathing), with the mean velocity computed over six full strokes. Then, two trials were performed using a resistive dynamometer to achieve a velocity which was 5% to 8% slower than the mean maximum swim velocity over six full strokes (one without and one with breathing). The swimmers had five minute rest between each trial to eliminate fatigue on their performance. Using velocities from free swimming and tethered trials, together with the belt force that was slowing the swimmers, active drag was calculated using the formula developed by Kolmogorov and Duplischeva (1992). Active drag was calculated separately for breathing trials and non-breathing trials.

Results: Slower swim velocities were obtained for breathing trials than non-breathing trials ($p=0.022$), however no change was observed in active drag ($p=0.258$)(Table). No difference was observed between days of testing.

Conclusion: The mean active drag values of breathing and non-breathing found in this study were similar to those previously reported by Kolmogorov & Duplischeva (1992) (97.1±42.3 N at 1.83 m/s). Although, no statistically significant difference was found between the active drag values of breathing and non-breathing, there was inconsistency in the results of individual swimmers. Some swimmers who had a slower speed during the breathing trials than the non-breathing trials had a correspondingly greater active drag value for the breathing trials. The slower mean velocity during breathing trials was likely caused by a greater resistive force exerted on the swimmers due to the breathing technique. Extra rotation of head and trunk could have been increasing their active drag. Swimmers having extra rotation of the head and trunk would encounter a greater surface area. Also, the head rotation could affect form drag as well, because; a cavity is created behind the head during the breath.

Some swimmers had similar active drag values in both breathing and non-breathing trials. It is likely that these swimmers performed their breathing in a more efficient manner and therefore spent less energy to overcome active drag moving through the water. Hence, as performing breathing is more important for mid to long distance swimmers, practice is required to perform with greater efficiency while spending less energy.

Table:

	Day one		Day two	
	No breathing	Breathing	No breathing	Breathing
Active drag (N)	109.4±23.1	100.3±25.7	101.8±31.8	93.7±22.1
Swim velocity (m/s)	1.83±0.08	1.82±0.07	1.84±0.08	1.82±0.08

UTILITY OF VOLUMETRIC FLOW ULTRASOUND INDICES IN PREDICTING INTRAUTERINE GROWTH RESTRICTION FETUSES

Shier Nee Saw [1] Dawn Chia [2] Citra Nurfarah Zaini Mattar [3] Arijit Biswas [3] Choon Hwai Yap [1,*]

[1] Biomedical Engineering, National University of Singapore, [2] Fetal Care Centre, National University Hospital, [3] Department of Obstetrics and Gynaecology, National University of Singapore, Singapore, Singapore

Introduction and Objectives: Intrauterine Growth Restriction (IUGR) is a disease where the placenta experiences vasculopathy and high vascular resistance to blood flow, preventing the fetus from receiving enough nutrients and oxygen to meet growth potential. Its prevalence is approximately 3% in developed countries [1] and up to 10-15% in developing countries [2]. There is current no treatment or prevention for IUGR, but with detection, early delivery can be induced to reduce *in-utero* malnutrition and hypoxia to improve outcome [3]. It is thus important to evaluate and improve IUGR detection techniques. Currently, IUGR is detected using umbilical ultrasound Doppler indices such as Resistance Index (RI) and Pulsatility Index (PI), which were shown to correlate with increase vascular resistance of blood flow in the placenta [4]. However, mathematically, these indices measures flow pulsatility instead of resistance, and experimentally, it has been shown that RI describes compliance better than resistance [5], leading to our question of their theoretical applicability to high-resistance detection, and motivating our current study. In this study, we performed numerical modelling of umbilical-placental circulation and analysed clinical human fetal ultrasound scans to review the reliability of various Doppler indices as surrogate for placental vascular resistance, and to propose indices and quantification techniques for improved accuracy.

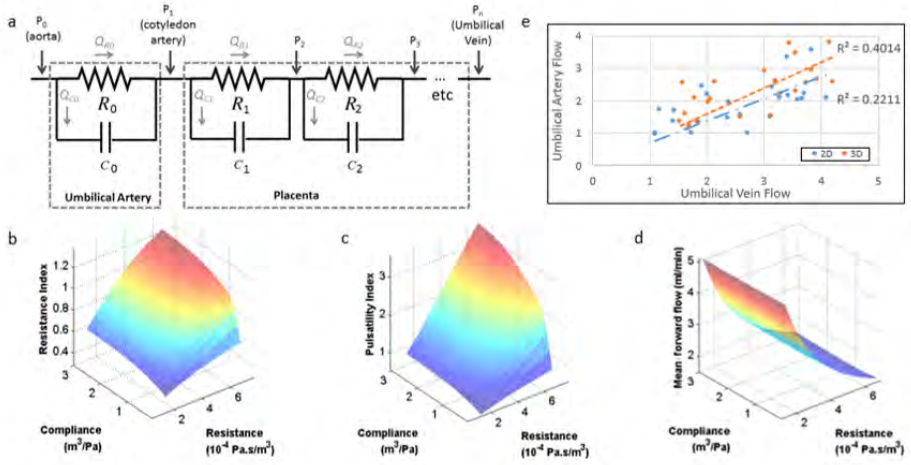
Methods: Lumped-parameter numerical modelling (Figure 1(a))) was performed to study flow in the umbilical-placenta circulation. Various umbilical Doppler indices were evaluated for their reliability in detecting high placenta vascular resistance. Clinical Doppler ultrasound scans of 537 normal and 13 IUGR human fetuses from GUSTO study [6] were investigated for their capabilities for distinguishing IUGR from normal fetuses.

To improve the quantification accuracy of indices involving umbilical vascular cross-sectional areas, we employed 3D reconstruction of vessels in the quantification and examined the improvement in accuracy.

Results: Numerical results showed that the RI and PI showed significant dependence on both placenta vascular resistance and compliance, and could not be unique representations of vascular resistance and of placenta insufficiency. Mean forward flow through the umbilical arteries, on the other hand, is independent of compliance, and dependent only on resistance, indicating improved ability to represent placenta insufficiency. Clinical data showed that mean flow parameters such as UATAV and UVVF may be more useful in distinguishing IUGR fetus compared to pulsatility indices (RI and PI), having lower p-value and higher area under receiver operating characteristic curve (Table 1).

QMean flow parameters, however, require the measurement of vascular cross-sectional area on top of velocity. Our results showed that 3D method can quantify cross-sectional areas better than 2D methods can, allowing arterial inflow to match vcenous outflow with a higher correlation coefficient. 3D methods of vascular size quantification can thus aid in more accurate quantification of mean umbilical vascular flow rates.

Figure:



Caption: Figure 1. (a) Schematic of the lumped-parameter model. The umbilical-placenta circulation is modeled as electrical circuits equivalents. Ri – ith resistance; Ci – ith compliance; Pi – pressure at i; QRi – Flow through the ith resistance; QCi – rate of fluid going into compliance storage. (b-c) Results of modeling the dependence of RI, PI and mean forward flow on vascular resistance and compliance. (e) Comparison of 2D and 3D methods in quantifying umbilical vascular flows.

Conclusion: Our computational work suggests that mean forward flow is a better parameter in gauging IUGR and clinical results corroborate this notion. 3D quantification of blood flow is more accurate compared to conventional 2D quantification method.

Table:

Doppler Indices	Area Under ROC Curve	P-value
Umbilical Artery Time-Averaged Velocity (UATAV)	0.617	0.012
Pulsatility Index (PI)	0.616	0.025
Resistance Index (RI)	0.612	0.059
Umbilical Vein Area (UVA)	0.600	0.024
Umbilical Vein Velocity (UVV)	0.582	0.175
Umbilical Vein Volumetric Flow (UVVF)	0.582	0.049

EFFECT OF PULSATILITY RATE ON THE HEMODYNAMICS OF BILEAFLET MECHANICAL PROSTHETIC HEART VALVES (ST. JUDE MODEL) FOR THE AORTIC POSITION IN THE OPENING PHASE; A COMPUTATIONAL STUDY

Mehdi Jahandardoost [1,*] Guy Fradet [2] Hadi Mohammadi [1]

[1]Biomedical Engineering, [2]Department of Surgery, University of British Columbia, Kelowna, Canada

Introduction and Objectives: Bileaflet mechanical heart valves (MHVs) designs are known for providing a uniform flow profile and a lower incidence of structural complications. However, thrombus formation on the hinges, valve failure and leaflet escapement have been reported in certain designs. To date, to the best of the authors' knowledge, almost in all of the studies performed around the hemodynamics of the bileaflet MHVs, a pulsatility rate (PR) or a heart rate (HR) of 70-72 beats per minute (bpm) has been considered. In fact, the HR of ~72 bpm does not represent the entire normal spectrum of physiological conditions under which the native or prosthetic aortic valves function. The HRs of 60 bpm or 120 bpm may lead to hemodynamic complications such as plaque formation and/or thromboembolism in patients. The objective of this study is to assess the hemodynamic performance of the bileaflet MHVs in a wide range of normal and physiological HRs, i.e., 60-150 bpm in the forward flow phase.

Methods: We applied an idealistic computational platform in this study which was recently developed in our laboratory [1]. Also, a similar model was developed for benchmarking of our results in which the SJM bileaflet mechanical valve was replaced by a native aortic valve. The flow around the bileaflet MHV (SJM model) is considered pulsatile and encompasses the three regimes of laminar, transient, and turbulent. To predict the salient features of flow around the bileaflet MHV, the shear stress transport (SST) low-Re two-equation turbulence models were applied.

Results: The hemodynamic performance of the SJM valve such as the regions of high shear stress, recirculation zones, vortex shedding and velocity profiles were assessed. Results suggest that the peak values of the velocity profile downstream of the valve increase as the HR increases but the location of the maximum velocity changes with HR. Results also indicate that the maximum values of shear stress and the wall sheer stresses (WSS) downstream of the valve are proportional to the HR values. Interestingly, the increase rate of WSS in the model with the SJM valve is remarkably higher than that in model with the native valve. More importantly in the model with the SJM valve, when the range of the HR is 90 bpm and higher, the threshold of the platelet activation is met in multiple locations of the aortic root which in turn may lead to thrombogenic complications.

Conclusion: Lack of adequate studies in the hemodynamic assessment of the MHVs at a variety of normal and physiological HRs was the motivation for the present study. Our results suggest a high risk of thrombogenicity associated with the hemodynamic performance of MHVs when the HR is high (90-150 bpm). The high value of shear stress in the areas around the valve housing and leaflet leading edges and wakes meets the threshold for platelet activation. These findings may be of importance in the hemodynamic performance of bileaflet MHVs and may play an important role in the design improvement of conventional prosthetic heart valves and the design of the next generation of prosthetic valves.

MODELLING EXPIRATION USING VISCOELASTIC PRESSURE DEPENDANT RECRUITMENT MODELS – IS IT THE SAME AS INSPIRATION

Daniel Redmond [1,*] Jörn Kretschmer [2] Yeong Shiong Chiew [1] Christopher Pretty [1] Knut Möller [2] J Geoffrey Chase [1]

[1]Department of Mechanical Engineering, University of Canterbury, Christchurch, New Zealand, [2]Institute for Technical Medicine, Hochschule Furtwangen University, Villingen-Schwenningen, Germany

Introduction and Objectives: Viscoelastic Pressure Dependent Recruitment Model (VEPRM) models recruitment, over-distension and viscoelastic effects under various ventilation manoeuvres [1]. This model improves understanding of respiratory pathophysiology in complex lung diseases such as Acute Respiratory Distress Syndrome (ARDS) and allows accurate model predictions of patient response to differing ventilator settings which can be used in a clinical setting to improve patient care.

Methods: VEPRM [1] is based on the pressure recruitment model which uses the alveolar recruitment mechanism proposed by Hickling [2], where viscoelastic effects are assigned to each layer of the recruitment model. This results in pressure dependant compliance and resistance. Passive expiration can be modelled by the analysis of the VEPRM with a reverse in the direction of the flow, and the addition of an expiratory resistance, which represents the resistance to expiration due to the ventilator tubing. Expiratory resistance can be estimated by simple linear regression of the airway pressure and flow [3].

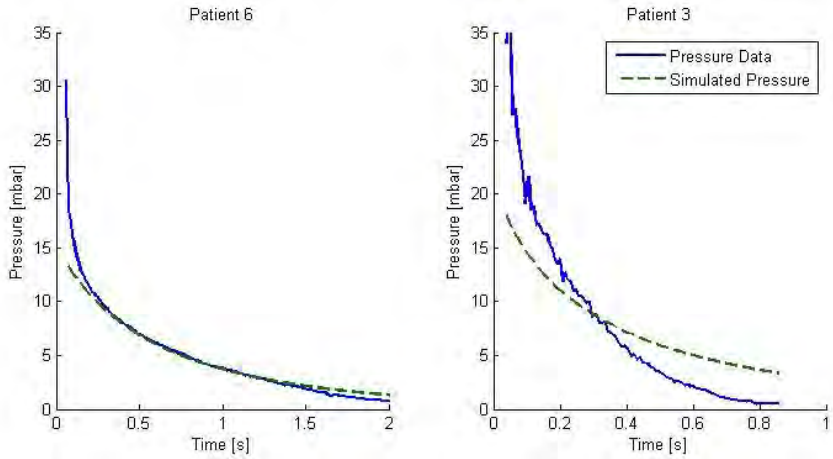
During expiration, to determine the recruitment status of a layer of lung units, threshold closing pressure (TCP) is required in addition to threshold opening pressure (TOP) used in inspiration as stated by Hickling [4]. During expiration, an opened lung unit remains open if the alveolar pressure is greater than the sum of superimposed pressures and TCP. Thus, if the VEPRM is successfully fitted to inspiration, the only free parameter required for fitting the model to the expiration is TCP. This identification is performed by a simplex search, using TOP as an initial estimate of TCP.

Airway pressure and flow data, sampled at 125Hz were measured from 12 mechanically ventilated ARDS patients. The study was approved by the local ethics committees of participating hospitals. The expiration data used comes from dynamic slice manoeuvres. The dynamic slice is an inspiration of 600mL/s for 2 seconds followed by free expiration. Data from low flow and static compliance automated single step manoeuvres are used for identification of inspiratory parameters, as explained in [1]. See [5] for a detailed description of the experimental setup. A hierarchical individualisation process is used to identify the VEPRM model parameters for inspiration. In this process, the simpler models are identified first, and then used as initial guesses for the more complex models [1,6].

Results: When fitting to the dynamic slice data, there was a very good fit on inspiration for 12 patients, coefficient of determination CD > 0.9. 4 patients had their inspiration parameters fitted well (CD > 0.9) to the expiration data with median [Interquartile range (IQR)] CD of 0.912[0.905-0.919]. 8 remaining patients had poor model fits with median [IQR] CD of 0.711[0.654-0.770].

In 6 patients, the identified TCP is greater than TOP which is not physiologically plausible and does not follow the recruitment model assumptions [4,7] where TOP is always higher than TCP. An identified TCP greater than TOP is an artefact of the numerical method for model fitting or a sign of mismatch between the model and the dynamics of reality. While some patients have poor model fits, it is of particular importance that there is systematic error, with pressure being underestimated at the beginning of expiration, and overestimated at the end of expiration as shown in Figure 1. This poor fitting suggests that some parameters that have been assumed constant for inspiration and expiration are actually different. It is likely that the resistance parameters used are not the same during inspiration and expiration. This difference is due to the flow having different geometry during inspiration, where the airways are bifurcating, from expiration, where airways are joining [8].

Figure:



Caption: The VEPRM model fitted to expiration for two different patients. The expiration of Patient 6 fits well to the model, whereas the model does not capture the behaviour exhibited by Patient 3.

Conclusion: The viscoelastic pressure dependent recruitment model can only be used to model expiration in 4 of 12 patients. In most patients, the parameters identified from inspiration no longer describe the pressure response of the lung during expiration. In order to use expiration data for respiratory mechanics models and to better understand respiratory processes, further studies are required to investigate which model parameters are the same in inspiration and expiration, and which are different.

A COUPLED HUMAN LEFT VENTRICLE AND SYSTEMIC ARTERIES MODEL

Weiwei Chen [1,*] Hao Gao [1] Xiaoyu Luo [1] NA Hill [1]

[1]Mathematics & Statistics, University of Glasgow, Glasgow, United Kingdom

Introduction and Objectives: Cardiovascular disease leads to over 17 million deaths worldwide per year, which makes it the single greatest cause (48%) of motality. Understanding how the disease develops and relationships between each part in the cardiovascular system are very important for reducing motality and morbidity. Computational simulation is effective in studying the cardiovascular system, but modelling a detailed three-dimensional description of a left ventricle (LV) combined with a dynamic systemic arterial circulation remains a major challenge.

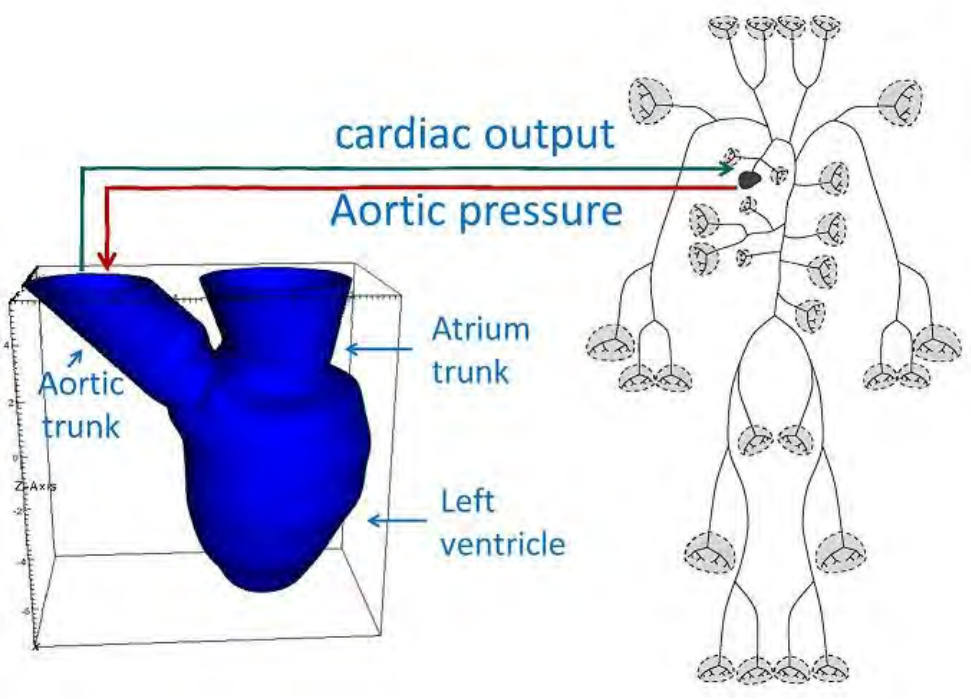
Methods: Two advanced independent mathematical and computation models for the LV and the systemic arteries are coupled to study the interactions in the systemic arterial circulation. The coupled model consists of a dynamic three-dimensional finite-strain structure-based LV, and a one-dimensional dynamic physiologically-based model for the systemic arteries. The fluid-structure interaction (FSI) is described by an Immersed Boundary (IB) approach, in which an incompressible solid is immersed in a viscous incompressible fluid, and solved by a Lagrangian Finite Element (FE) method. The passive and active material parameters in the LV model are determined by fitting the end-diastolic and end-systolic volumes to measurements of the left ventricular volume. The systemic circulation model consists of two groups of arteries, large arteries and small arteries (vascular beds). The large arteries model uses a Lax-Wendroff scheme to compute the cross-sectional area-averaged flow and pressure based on physiological parameters of the arterial tree, such as length, radius and compliance, which are measured and using MRI. The small arteries are modelled as asymmetric structured trees to give outflow boundary conditions at the end of each large arteries. The coupling is achieved by matching the pressure and flow rate at the aortic root, i.e. the circulation model feeds back the pressure as a boundary condition to the LV model, and the flow rate from the LV is used as the input for the circulation model. An explicit method is used. Among the four phases during one cardiac cycle in the LV, the coupling only happens during systole; two models are separate during all the other phases, i. e. diastolic filling, iso-volumetric contraction and relaxation. The coupling starts when the pressure in the LV is higher than the end-of-diastolic pressure in the ascending aorta, and it ends when backflow occurs at the interface.

Results: The results of this coupled model (normal case) show good agreement compared with measured data (less than 5% in peak flow rate). Three disease-related cases are studied in the coupled model, i. e. stiffening of arterial wall, changing end-of-diastolic pressure and simulating functional rarefaction. Results of the disease-related cases are compared with the normal case.

Increasing the stiffness of the large arteries by 50% and 100% result in increased pulse pressure (3.8% and 8.0%) and decreased trough pressure (4.1% and 8.0%) in the ascending aorta, while increasing the stiffness of small arteries has less effect on the pressure or the flow rate during systole. Increasing the degree of vascular rarefaction (5.8%, 13% and 20%) increases both peak and mean pressure in the aorta (2.6%, 8.6% and 17.6% for peak pressure), but the peak flow rate barely changed. Increasing the EDP from 8 mmHg to 10 mmHg leads to an 4.1% increase of the end-of-diastolic

volume and 9.76% increase of the cardiac output as well as a 5.9% increase of the peak LV pressure, while decreasing the EDP has the opposite effects on these characteristics.

Figure:



Caption: Coupling the 3-D LV model and the 1-D systemic circulation model

Conclusion: We have developed a dynamic left ventricle and circulation model, which contains a dynamic FE/IB LV model and a cross-sectional area-averaged systemic circulation model. The model provides insight into the roles of the physiological parameters, as well as predictions of blood flow and pressure at any position in the systemic arteries. The coupled model can be used to analysis the interactions of the LV and the systemic arteries during systole as well as to explore the causes and development of cardiovascular diseases.

NUMERICAL INVESTIGATION OF DESIGN PARAMETER EFFECTS ON HEMODYNAMICS IN A NOVEL SPIRAL-INDUCING BYPASS GRAFT

Andres Ruiz-Soler [1,*] Amir Keshmiri [1 2]

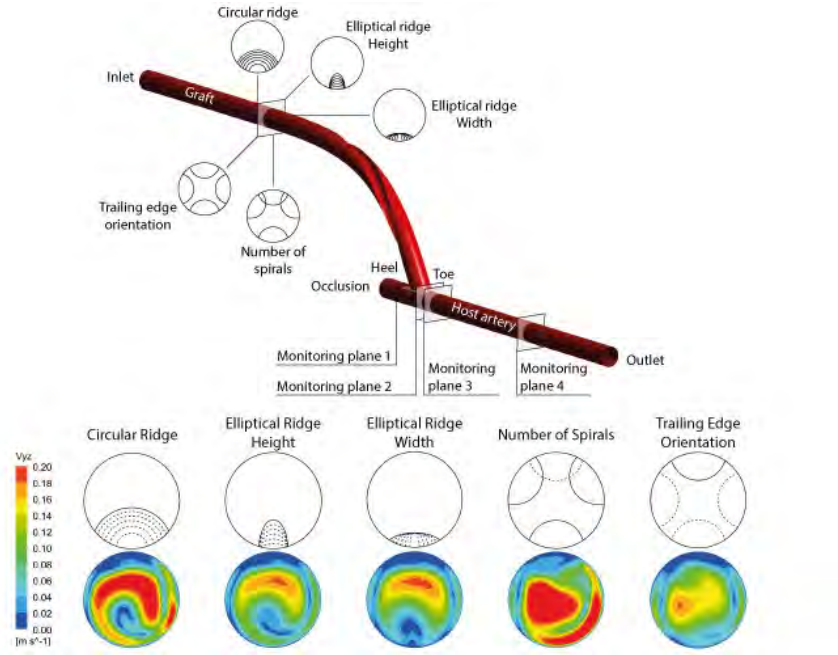
[1]School of Engineering, Manchester Metropolitan University, [2]School of Mechanical, Aerospace and Civil Engineering (MACE), The University of Manchester, Manchester, United Kingdom

Introduction and Objectives: In the present work, a numerical investigation has been conducted to analyse the blood flow in an End-To-Side (ETS) distal graft anastomosis. The aim is to evaluate the hemodynamic effects of different geometrical parameters involved in the design of a novel spiral-inducing prosthetic graft [1], the performance of which is based on the identification of the blood motion as a swirling flow in the whole arterial system [2]. The relevance of spiral and helical configurations of prosthetic graft lies in the physiological benefits of the swirling flow as a natural phenomenon for the stabilisation of the blood flow with the inhibition of stagnation and flow separation points [3]. It is known that the hemodynamic parameters play an important role in the development of stenosis at the junction due to thrombosis, atherosclerosis and intimal hyperplasia, which are the main causes of graft failure [4].

Methods: Computational Fluid Dynamics (CFD) has been used to simulate the blood flow through a peripheral bypass graft anastomosis that engenders a spiral flow by means of a helical ridge in the internal wall of the graft. The effects of different design parameters have carefully been studied including the ridge cross-sectional area, position and number of ridges. All the three-dimensional simulations were conducted for different Reynolds numbers (570, 1140 and 1700) and the blood flow was assumed as laminar, incompressible and Newtonian fluid. The walls were considered as rigid with no-slip condition.

Results: The results show that changing the orientation of the trailing edge as well as increasing the height of the elliptical ridge and the cross-sectional area of the circular ridge have significant influence on producing secondary flow in the lumen. Furthermore, the effects of such design parameters are observed in the distribution of Wall Shear Stress (WSS) that represents a fundamental hemodynamic factor in the enhancement of bypass graft patency rates. By contrast, changing the width of the elliptical ridge was found to have marginal effects.

Figure:



Caption: Top: Schematic of the computational model. Bottom: Secondary velocity magnitude contours at the monitoring plane 2 for different geometrical parameters. The results correspond to the schematics of ridges with solid lines.

Conclusion:

In this work, the physiological importance of secondary flow motion produced by spiral ridges on peripheral bypass graft anastomosis has been studied using CFD in order to determine the qualitative influence of different design parameters. In addition, the effects of pulsatile inlet flow and the non-Newtonian behaviour of the blood will also be analysed using different haemodynamic metrics (e.g. Oscillatory Shear Index and Relative Residence Time) to present a more physiologically-accurate prediction.

OPPORTUNITIES FOR MEASURING WHEELCHAIR KINEMATICS IN MATCH SETTINGS; RELIABILITY OF A THREE INERTIAL SENSOR CONFIGURATION

rienk V. D. slikke [1 2,*] monique berger [1] daan bregman [2] dirk jan veeger [2]

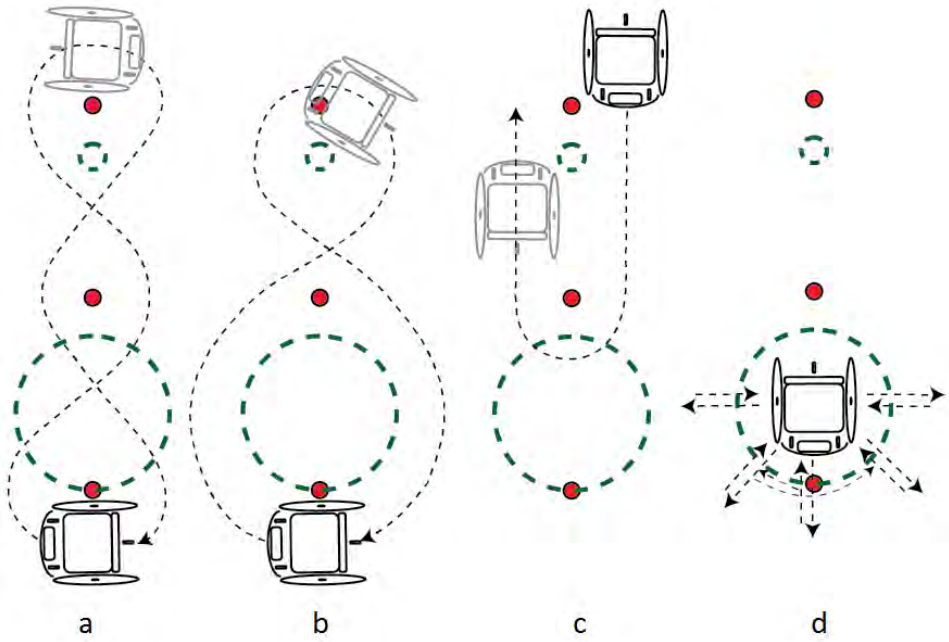
[1]Faculty of Health, Nutricion and Sports, The Hague University of Applied Sciences, The Hague, [2]3ME, Delft University of Technology, Delft, Netherlands

Introduction and Objectives: *:* Increased professionalism in wheelchair basketball has raised the need for scientific input into optimizing performance. Knowledge of wheelchair kinematics during a match is prerequisite for this performance improvement [1]. Unfortunately, no measurement system providing key kinematic outcomes has proven reliable in competition. A method for measurement of wheelchair kinematics in match play would allow for applied research into athlete-wheelchair interaction by determining the relation between wheelchair settings, kinematics and performance. That knowledge could provide basis for more precise and faster optimization of individual wheelchair settings and thereby support existing experience-based expertise. In this study, the reliability of acquiring wheelchair kinematics based on a three inertial measurement unit (IMU) configuration was assessed in match-like basketball conditions.

Methods: Twenty participants performed a series of tests reflecting different motion aspects of wheelchair basketball, such as a straight 5m sprint; a slalom; a U-turn; moving back and forth while rotating; collide and spin (see Figure 1). During these tests wheelchair kinematics were simultaneously measured using IMU's on wheels and frame, and a 24-camera optical motion analysis system serving as gold standard. Calculated outcomes of wheelchair kinematics based on IMU and gold standard were compared to test the reliability of the IMU sensor configuration.

Results: Results show only small deviations of the IMU method compared to the gold standard. As expected, kinematics derived from wheel rotation showed increased errors in wheel skidding conditions. Therefore newly skid correction algorithms were developed, using multiple sensor information. Once these algorithms were applied, calculated Root Mean Square Errors (RMSE) showed good estimates for frame displacement (RMSE≤ 0.05m) and speed (RMSE≤ 0.1m/s), except for three truly vigorous tests (during collisions and an evoked skidding stop). Estimates of frame rotation in the horizontal plane (RMSE<3°) and rotational speed (RMSE<7°/s) were very accurate in all tests. Differences in calculated instantaneous rotation centres (IRC) were small, but somewhat larger in tests performed at high speed. At normal speed the error in calculated distance between IRC and frame centre stayed below an RMSE of 0.1m, but at high performance speeds it reached up to an RMSE of 0.19m. For linear speed (ICC's > 0.90), rotational speed (ICC>0.99) and IRC (ICC> 0.90) average outcomes showed high correlations between IMU data and gold standard. So, even estimates with higher RMSE values, showed small errors once averaged per test.

Figure:



Caption: Test track lay-out and example tests: a) Slalom test; b) Figure eight test; c) U-turn (left & right); d) Star twist (moving back and forth, combined with rotation)

Conclusion: The developed method provides a valuable tool for wheelchair athletes, coaches and researchers to perform ambulant measurements and applied research in the field of wheelchair sports. Wheelchairs can easily be equipped with cheap lightweight IMU sensors, providing reliable wheelchair kinematics if wheel diameter and track width are known. In future research, the use of this method might allow for a more detailed profile of wheelchair kinematics during a match. Combined with measurement of additional quantities, such as exerted force or observed game performance information, this allows for composition of an athlete specific performance profile. Such a profile could be used to determine the effect of sport specific training or wheelchair setting adjustment.

MODIFICATIONS OF PROPULSION MECHANICS WITH INCREASES IN SPEED ALTERS DISTRIBUTION OF MECHANICAL DEMAND IMPOSED ON THE UPPER EXTREMITY

Ian M. Russell [1,*] Philip S. Requejo [1] Sara Mulroy [2] Carmen Muller-Karger [3] Mary M. Rodgers [4] Jill L. McNitt-Gray [1]

[1]Biomedical Engineering, University of Southern California, Los Angeles, [2]Rehabilitation Engineering, Rancho Los Amigos National Rehabilitation Cen, Downey, United States, [3]Department of Mechanical Engineering, Simon Bolivar University, Caracas, Venezuela, Bolivarian Republic Of, [4]Physical Therapy & Rehabilitation Science, University of Maryland School of Medicine, Baltimore, United States

Introduction and Objectives: Preservation of shoulder function is important for manual wheelchair (WC) users with spinal cord injury (SCI). Manual WC propulsion is an effective form of low-cost wheeled mobility as it preserves upper body strength, cardiovascular conditioning as part of daily activities, and community participation. Repetitive mechanical loading of the upper extremity often leads to physical impairment (e.g. shoulder pain) that affects activities of daily living.[1,2] Current experimental research and clinical guidelines promote improved interaction between the individual and the WC as a means to mitigate detrimental mechanical loading of the shoulders.[3]

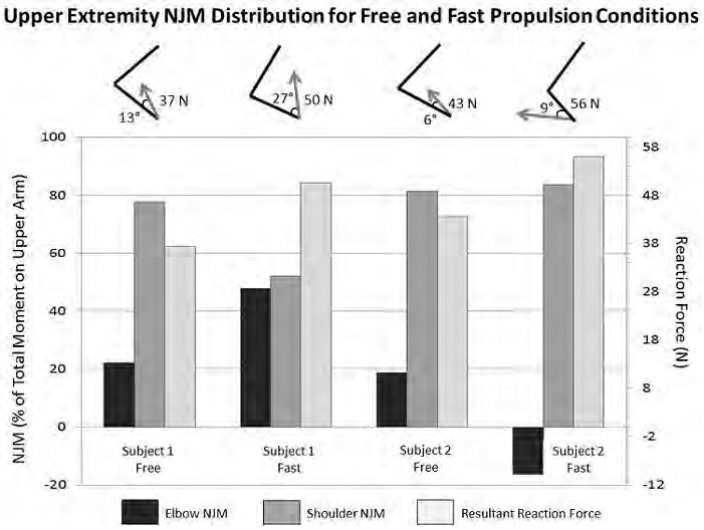
Manual WC propulsion requires generation of a reaction force (RF) at the handrim with a component tangential to the wheel. The mechanical demand (Net Joint Force (NJF), Net Joint Moment (NJM)) imposed across the upper extremities, however, is affected by orientation of the resultant RF relative to the body segments.[4,5] Model simulation results indicate a 2-fold increase in RF magnitude can result in minimal changes in shoulder NJM magnitude without decrements in performance if the orientation of the RF relative to the upper extremity segments is modified.[4] The aim of this study was to determine if individuals with SCI modify mechanical load distribution imposed on the upper extremity by reorienting the RF relative to the forearm and upper arm when manually propelling their WC under free as compared to self-selected fast conditions.

Methods: Forty-one experienced manual WC users (8 Females, 33 Males) with paraplegia (8 ± 6 yrs post SCI) from the Rancho Los Amigos National Rehabilitation Center volunteered to participate in accordance with the Institutional Review Board. Individuals were excluded from participation if they reported a history of shoulder pain that altered performance of daily activities. Kinematics (VICON, 50Hz) and pushrim RFs (SmartWheel, 240Hz) were collected during manual WC propulsion on a stationary ergometer at self-selected free and fast conditions. Joint kinetics (NJM, NJF, Visual 3D) and mechanical load distribution represented as a percent of the total NJM (e.g. NJM elbow/(|NJMshoulder| + |NJMelbow|)) were used to characterize within subject differences in propulsion mechanics during the push phase at self-selected free and fast conditions.

Results: Within-subject analyses revealed that over a third of the participants in this study modified the mechanical load distribution imposed on the upper extremity during the push phase by more than +/-10% when manually propelling their WC under free as compared to self-selected fast conditions. The median mechanical load distribution imposed on the shoulder was 77% for both free and fast conditions. Participants with a load distribution exceeding the median under the free condition demonstrated increased elbow and reduced shoulder contributions to NJM during the fast condition. In

contrast, participants with a load distribution less than the median under the free condition exhibited mixed results. In this group, redistribution of mechanical load was achieved by redirecting the reaction force, modifying forearm and upper arm orientation, or some combination of both. Figure 1 illustrates how two exemplar participants, with similar increases in RF magnitude with speed, modified the orientation of their RF relative to the upper extremities and, as a result, redistributed the mechanical demand. Exemplar Subject1 increased the mechanical demand imposed on the elbow by 28% when shifting from free to fast conditions, resulting in a decrease in rotational demand imposed on the shoulder. Note however that more vertically oriented reaction forces associated with reduced contribution of the shoulder NJM are likely to add to the upward component of the shoulder NJF. In contrast, exemplar Subject 2 generated similar increases in RF at the faster speed, yet the RF force acted posterior to the forearm thereby changing the elbow NJM from an extensor to a flexor moment and thereby increasing the demand imposed on the shoulder.

Figure:



Caption: Fig 1 NJM distributions for 2 participants with comparable increases in RF during push between free and fast propulsion conditions.

Conclusion: Knowledge of how experienced manual WC users regulate increases in mechanical demand imposed on the shoulder joint in response to increased speed requirements provides an important step in identifying effective propulsion strategies for individuals to maintain and improve performance while mitigating the repetitive loading associated with the development of shoulder pain.

EVALUATION OF A WHEELCHAIR TRICYCLE ATTACHMENT FOR PERSONS WITH DISABILITIES IN DEVELOPING COUNTRIES

Rodrick Shangali [1,*] Harold Shangali [2]

[1]Engineering Department, [2]TATCOT, TATCOT, Moshi, Tanzania, United Republic of

Introduction and Objectives: The design was done in reference to need, opportunity identification, brainstorming within groups, visiting search field, making observation and interviews to identify the existing needs and evaluation to select design opportunities. The use of the attachment will allow the user (disabled persons) to access the daily socio-economic activities for personal development and income generation. The attachment can provide large distance coverage as compared to the manual wheelchair which is mostly for indoor activities.

The main objective of this project was to develop a wheelchair tricycle attachment for easier accessibility and increased performance to the wheelchair users in Dar es Salaam and Kilimanjaro regions (Tanzania).

Methods: The design was done in reference to need, opportunity identification, brainstorming within groups, visiting search field, making observation and interviews to identify the existing needs and evaluation to select design opportunities. Each wheelchair user will have his/her unique set of needs which the wheelchair should cater for. The wheelchair should take into account the wheelchair users as: Home environment, Disability, Lifestyle and Economic situation. This was done by investigating the existing driving systems for both wheelchairs and tricycles. Literature review, survey, information analysis, observations, manufacturing, design testing, evaluation and interviews was carried out. Conceptual design was done followed by embodiment design and detail design The evaluation was done by looking through the following criteria; i.e. easy to manufacture, low production cost, reasonable product price, easy to operate, simple design, efficiency, ergonomics, aesthetics and weight.

Detail and assembly drawings of various components and manufacturing were carried out at Tanzania Training Centre for Orthopaedic Technologist (TATCOT). Thirty disabled people were interviewed. Finally we were able to manufacture five units. From these units we were able to test on 5 wheelchair users tested as shown as one of them in (Figure.1) with the consideration of Operating efficiency, Conformance to standards, Torque transmitted, Power transmitted and Conformance to ergonomics requirements.

From the evaluation point of view, we began by identifying the static loads on the wheelchair and attachment when the attachment is in use. We made the conservative estimate that the center of gravity of the user will be at the center of the seat. Using equations from summing moments about the rear wheel axle and summing the vertical forces in the device. The reaction forces at both wheels could be obtained for a predetermined human load. In order to make a simple calculation of the moment on the device at the place the attachment connects to the wheelchair.

The Clip-on Tricycle Attachment is a quick release clip-on, clip-off attachment which can be fitted to the Motivation Rough Terrain wheelchair. It converts the wheelchair into a tricycle allowing the user to travel greater distances more effectively. After attaching to the main frame of wheelchair, need to lock it so as to avoid twisting and dismantle of the front attachment. The mounting / junction part to the main beam of the wheelchair need to be clamped so as the castor wheel

to inclined at an angle. For longer distance accessibility, the user can use the attachment by altering/changing gear depending with topographic of the land. For indoor activities such as office, home, hospital and other places, user will remove the attachment easily and park lock on the security area.

Results: The results of the majority of the wheelchair users interviewed became disabled early in life with a birth defect or polio, of which most had to resort to crawling as a means of mobility before obtaining a wheelchair or tricycle. Most of the interviewed needed to travel multiple kilometers per day. For long distance a tricycle required less much power than a wheelchair. One major problem observed during the assessment was the inability of many people to purchase their own mobility aid. As a result, the tricycles attachment was observed to be a proper solution for wheelchair users and also for environmental concerns (Indoor & Outdoor).

Figure:

Conclusion: The attachment during attaching/detaching on the wheelchair was agreed to be a better solution for wheelchair users.

Table:

TESTING CRITERIA	WHEELCHAIR USER RESPONDS(N=5)
Operating efficiency	80%
Conformance to standards	85%
Power transmitted	90%
Conformance to ergonomics requirements	88%
Aesthetics	90%

INFLUENCE OF THE MANUAL WHEELCHAIR SETTINGS WHEN ROLLING ON A CROSS-SLOPE : A THEORETICAL STUDY

Joseph Bascou [1,*] Christophe Sauret [2] Fanni Li [1] Coralie Villa [1] Francois Lavaste [2] Hélène Pillet [2]

[1]Institution Nationale des Invalides / CERAH, Créteil, [2]Institut de Biomécanique Humaine Georges Charpak, Paris, France

Introduction and Objectives: The manual wheelchair (MWC) allows disabled people to retrieve both mobility and autonomy. However, it can induce overload on the upper body [1], which can be amplified by some daily situations, such as cross slopes. This specific situation requires additional efforts to counterbalance the MWC tendency to roll the hill down [2], [3], [4].

This additional load could be limited by appropriate adjustments of the MWC. Unfortunately, MWC has a large panel of geometrical and material settings, making the selection of the best combination for propelling on a cross-slope difficult. If the effect of the fore-aft location of the user's center of mass was rapidly identified [4], the effects of other settings such as tire type, swiveling resistances, etc, are not yet defined.

So, the aim of this study was to evaluate, by means of a theoretical model, the effects of a large panel of MWC settings on the counterbalancing braking moment required to maintain the straightforward displacement on cross slopes.

Methods: : A static mechanical model of a subject and the wheelchair on cross-slope was defined with a three wheeled MWC, to fulfill iso-static conditions (Figure 1). This model allowed linking the braking moment Ms->w applied by the subject at the center of rear wheel axle on the wheelchair, to 10 geometrical and mechanical parameters of the MWC, the cross slope and the subject, leading to the following expression:

$$Ms\text{->}w = (ns * Ps + nw * Pw) * \sin\theta - C * d/d1 - frf * \cos\theta * (ns * Ps + nw * Pw) * (1/d + 1/d1) - frr * \cos\theta * (Ps * (d-ns)/d + Pw * (d-nw)/d) \quad \text{(equation 1)}$$

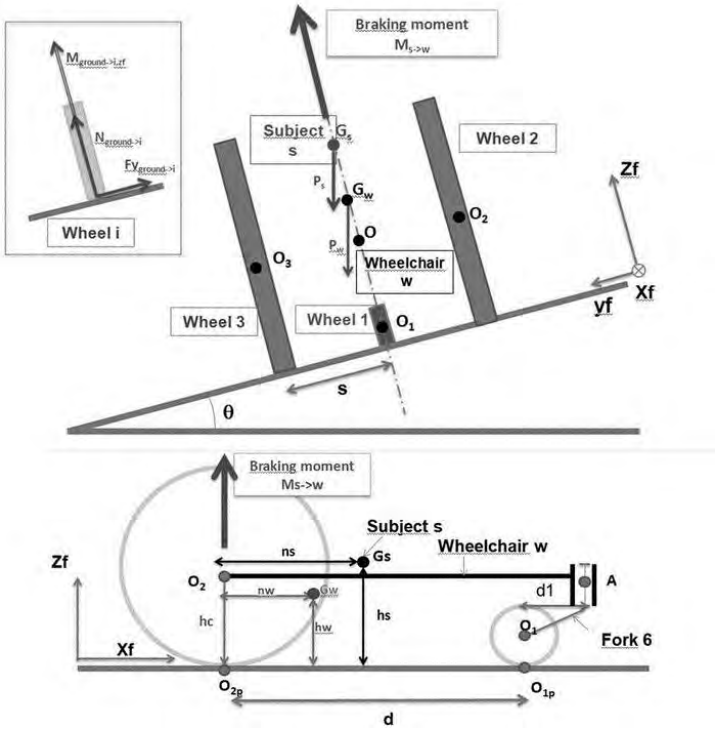
Ranges of variation of each parameter were defined according to the literature as follows : ns / nw are the distances between the subject (s) / the wheelchair (w) centers of mass and the rear wheel axle, both ranging from 0.05 m to 0.3m; ms / mw are the subject / wheelchair masses, ranging from 50kg to 90kg for the subject and from 7 kg to 20 kg for the wheelchair ; C is the fork pivot resistance, ranging from 0.02 Nm to 0.1 Nm; d is the wheelbase, ranging from 0.3 m to 0.45m, d1 is the horizontal length of the fork, ranging from 0.03m to 0.06m; frr / frf are the front / rear wheel swiveling resistance parameters, both ranging from 0.001m to 0.002m. In this study, the inclination of the cross slope (θ) was chosen equal to 6°.

A 2-level *in-silico* experimental plan was designed to cover every possible wheelchair parameter sets, each parameter taking the minimal or the maximal value of its variation range, resulting in 1024 parameter sets. For each set, the resulting braking moment was calculated according to equation 1.

Results: Relatively to the averaged braking moment Ms->w of 7.4 Nm, the variations – named "effects" – due to a change between medium and maximal value of the tested parameters were expressed in table 1.

With respect to the range of their individual variations, parameters with the greatest effects were the fore-aft distance of the subject's center of mass (ns), but also the horizontal length of the fork and the swiveling resistance of the front wheel, for instance.

Figure:



Caption: Figure 1: free body diagram of the static wheelchair on a cross slope

Conclusion: This study allowed quantifying the effects of manual wheelchair parameters on the counterbalancing braking moment required during propulsion on cross slopes. As found in the literature, the fore-aft distance between the subject center of mass and the rear wheel axle is the major lever to limit load on upper limbs during cross slope propulsion [2]: placing the total center of mass above the rear wheel axle should cancel the effect of the cross slope. Unfortunately, this setting would increase the MWC backward tilting risk. However, this study demonstrates that reducing the length of the fork or increasing the swiveling resistance of the front wheel, for instance, could also help in limiting the users' efforts. Further experimentations need to be conducted to confirm the results of this theoretical study.

Table:

Effect / Interaction	Label	Effect (Nm)
n_s	Distance subject center of mass / rear axle [m]	5,77
fr_f	Front wheel swiveling resistance parameter [m]	-1,98
d_1	Horizontal length of the fork [m]	1,97
m_s	Subject mass [kg]	1,86
n_w	Distance wheelchair center of mass / rear axle [m]	1,40

m_w	Wheelchair mass [kg]	0,70
C	Fork pivot resistance [Nm]	-0,38
fr_r	Rear wheel swiveling resistance parameter [m]	-0,35
d	Wheelbase [m]	-0,19

Caption: Table 1: Effects of the parameter variation from medium to maximal value on braking moment for a 6° cross slopes.

SPINAL POSTURE AND BALANCE IN INDIVIDUALS WITH SPINAL CORD INJURY IN RESPONSE TO WHEELCHAIR SEAT CHANGES

Beth A. Cloud [1,*] Kristin D. Zhao [2] Kai-Nan An [3]

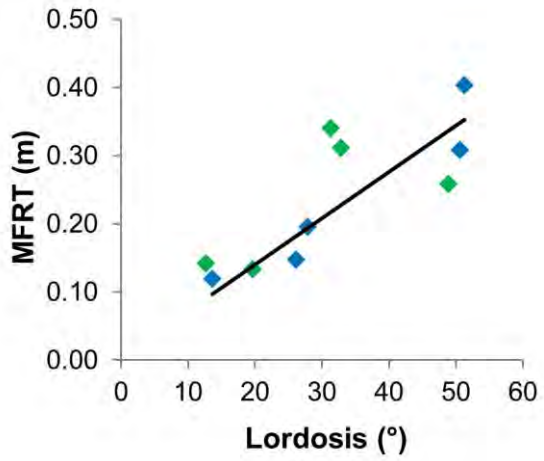
[1]Mayo Graduate School, Center for Clinical and Translational Science, [2]Rehabilitation Medicine Research Center, Department of Physical Medicine and Rehabilitation, [3]Biomechanics Laboratory, Division of Orthopedic Research, Mayo Clinic, Rochester, United States

Introduction and Objectives: Seating parameters have been shown to affect how one functions from a manual wheelchair (MWC) base. This includes effects on upper extremity kinematics during propulsion in response to axel position [1] as well as effects on vertical reach distance and possible influences on postural parameters in response to seat angle changes [2]. Positioning in one's MWC is a means by which to optimize function. This is imperative considering the amount of time individuals spend in their MWC and the high prevalence of upper extremity pain and pathology in this population [3]. The purpose of this study was to investigate the effects of a seat dump angle change on postural and functional parameters, including sagittal plane spinal curvature and balance, in MWC users with spinal cord injury. We hypothesize that increased seat dump angle (created by increasing the height of the front of the seat relative to the back) will increase lordosis in the thoracolumbar region of the spine and increase balance as measured by a seated reach test.

Methods: Chronic MWC users (>1 year from onset of MWC use) with spinal cord injury (SCI) or disease were recruited. Each participant's MWC was modified with custom wedges to create 0° and 14° seat dump angles (relative to horizontal) with a vertical backrest. Spinal posture was measured with a fiber optic system overlying spinous processes from the first sacral to seventh cervical vertebral level. Spinal curvature was defined as regions of kyphosis and lordosis quantified as the angles created from the normal to the curve at the endpoints of each region [4]. Posture was captured with participants looking straight ahead, hands in their lap. Balance was assessed with the modified functional reach test (MFRT), previously validated for use with individuals with SCI [5]. Electromagnetic sensors were used to track thorax and humerus segments. The excursion of the sternal notch in the global coordinate system was used to determine forward reach distance while the dominant arm was held parallel to the ground. Five trials were completed in each seat condition. The minimum and maximum distances were excluded and the mean of the remaining three were used to determine MFRT values. Lordosis, kyphosis, and MFRT values were compared between each condition using a Wilcoxon signed-rank test. All data was combined, to plot a correlation between MFRT and curvature (lordosis or kyphosis) values.

Results: Six participants (3 male; age: 34-52 years; duration MWC use: 2.83-19.25 years; SCI level C6/7-T10) participated in the study to date. Changes in seat dump angle did not have a consistent, statistically significant effect on lordosis, kyphosis or MFRT values. Kyphosis value did not have an association with MFRT. Lordosis, when present, was correlated with MFRT values ($R^2 = 0.66$, $p < 0.01$).

Figure:



Caption: Figure 1: Correlation between lordosis values for all participants with detectable lordosis, data from both seat positions combined (R2= 0.66, $p < 0.01$). Black line indicates fit; blue diamonds indicate values in 0° seat dump angle condition; green diamonds indicate values in 14° condition.

Conclusion: The seat dump angle changes evaluated in this study had different effects on amount of lordosis in MWC users with SCI. These differences may be due to SCI level as individuals with higher level injuries (T4 and above) tended to experience an increase in lordosis (when present) with increased seat dump angle. Those with lower level injuries had less lordosis in the larger seat dump angle condition. Larger values of lordosis, regardless of seat dump angle, were associated with increased reach distance. The relationships observed will continue to be assessed as additional participants are recruited. Seat dump angle did not have a consistent effect on participant posture in this study. However, increased spinal lordosis may be associated with enhanced balance and function from a MWC base.

Wheelchair

AS-0048

ESTIMATED ATHLETE'S BASKETBALL MATCH PERFORMANCE BASED ON MEASUREMENT OF WHEELCHAIR KINEMATICS USING INERTIAL SENSORS.

R.M.A van der Slikke, M.A.M. Berger, D.J.J. Bregman, H.E.J. Veeger

Introduction & Objectives: Since wheelchair basketball events have become more and more competitive, there is a need to optimize all factors contributing to team performance. One of these factors is individual kinematic performance of the athletes, yet to date limited kinematic match information is available. Knowledge of wheelchair kinematics during a match is prerequisite for further performance improvement [1]. In this study wheelchair kinematics profiles of athletes on different competition levels are measured during a match, using a newly developed inertial sensor based measurement method [2]. Measurement outcomes provide an impression of typical match characteristics and show which characteristics seem sensitive to discriminate between performances based on classification and competition level.

Methods: Twenty nine participants were measured in their own wheelchair during basketball competition matches at top national as well as international level, with twelve male first division players (National), nine female internationals (NL & UK) and eight male internationals (NL, ISR & AUS). Field positions (guard, forward and center), as well as athletes' classification points were evenly distributed over the different groups (Table 1).

Each wheelchair was equipped with three inertial sensors, one on each wheel axis and one on the rear frame bar, providing key aspects of wheelchair kinematics: displacement, speed, acceleration, rotation, rotational speed and rotational acceleration. Additionally, the time to reach a certain displacement (2, 4 or 6m) or rotation (90° or 135°) was calculated. Data were compared at competition level and at the level of athletes' classifications, with one group class 2.5 or less and one group class 2.5 over.

Results: For all 29 measurements a kinematic profile could be made, although in seven measurements partial data loss occurred due to vast collisions. During movement time (frame center speed>0.05 m/s) an average speed of 1.22 m/s and rotational speed of 47.3 °/s was measured, with minor (not significant) differences between competition level groups and classification groups. The average time to reach a certain distance or rotation, was based on sprints as well as on movements where no maximal performance was required, such as wheeling to a free throw. Therefore, the average of the 10 fastest sprints and rotations are displayed in the graph (Figure 1). Analysis of competition level revealed only significant ($p<.05$) differences for the time to a rotation (90° and 135°), between the national players and both international male and female players. When grouped by classification, the differences in time to a certain distance or rotation showed all significant ($p<.05$).

Figure: Average time (± stdev.) from standstill to a certain distance (2, 4 or 6 meter) or rotation (90° or 135°), grouped by competition level (left chart) and classification (right chart).

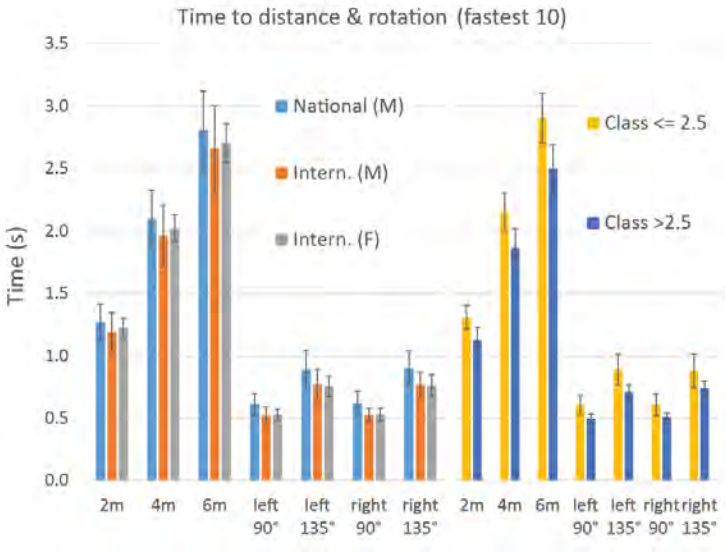

Table: Wheelchair athlete (n=29) data, grouped by classification and by competition level.

Group		*Min*	*Max*	*Mean*	*SD*	*N*	*Level*	*Freq.*	*%*
Class <= 2.5	Class	1.0	2.5	1.7	0.6	17	National (M)	7	41%
	Age	15	42	28.6	7.4		Intern. (M)	5	29%
							Intern. (F)	5	29%
Class >2.5	Class	3.0	4.5	4.0	0.6	12	National (M)	5	42%
	Age	14	46	28.6	9.4		Intern. (M)	3	25%
							Intern. (F)	4	33%
National (M)	Class	1.0	4.5	2.5	1.4	12			
	Age	14	46	27.9	9.4				
Intern. (M)	Class	1.0	4.5	2.8	1.1	8			
	Age	22	42	30.0	6.0				
Intern. (F)	Class	1.0	4.5	2.8	1.3	9			
	Age	15	39	28.3	8.8				

Conclusion: Average speeds, accelerations, rotational speeds and rotational accelerations, do not discriminate between groups based on either competition level or classification. To determine best match performance only the ten fastest forward movements and rotations are included in the analysis, discriminating well between different classification groups. Competition level based comparison only showed significant differences between national and international players for the time to rotation. Although the average time to a certain distance also shows noticeable differences between national and international level, these differences were not statistically significant due to the large standard deviation. Future enlargement of the measurement population would allow for classification based division *within* competition level groups, most likely reducing performance outcomes standard deviations.

Further data analysis and additional research is needed to identify the most sensitive performance measures as well as its stability over consecutive matches. Once established, this method provides a valuable tool for wheelchair athletes,

coaches and researchers to perform ambulant measurements and applied research in wheelchair sports. Combined with measurement of additional quantities, such as exerted force or observed game performance, this allows for composition of an athlete specific performance profile. Such a profile could be used to determine the effect of sport specific training or wheelchair setting adjustment.

SOFT TISSUE ARTIFACT DESCRIPTION USING TRIANGULAR COSSERAT POINT ELEMENTS

Dana Solav [1,*]MB Rubin [1]Andrea Cereatti [2]Valentina Camomilla [3]Alon Wolf [1]

[1]Mechanical Engineering, Technion, Haifa, Israel, [2]POLCOMING department, Information Engineering Unit, University of Sassari, Sassari, [3]Department of Movement, Human and Health Sciences, University of Rome, Rome, Italy

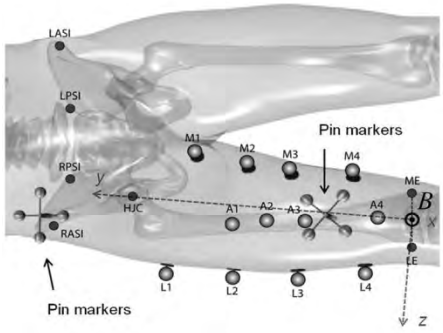
Introduction and Objectives: Accurate estimation of the position and orientation (pose) of a bone from the motion of skin markers is limited mostly by the relative motion between the markers and the bone, which is known as the Soft Tissue Artifact (STA). Various methods have been proposed that employ clusters composed of a redundant number of skin markers (>3) to minimize the effect of the STA on the bone pose estimation, but no satisfactory solution yet exists. The objective of this paper is to propose a method for the description of the non-rigid kinematics of marker clusters within a theoretical framework of continuum mechanics. The method entails the definition of time-variant parameters for the description of the marker cluster strain and the relative rotation and translation between clusters due to the presence of STA. The latter exercise may provide new insights for the development of novel methods aimed at compensating for the STA effects.

Methods: The cluster of markers on the skin of the analysed bone is characterized by Triangular Cosserat Point Elements (TCPEs) defined by all combinations of three markers. The kinematics of each TCPE is evaluated in terms of its translation vector and deformation gradient tensor [1]. Subsequently, three instantaneous scalar TCPE parameters $\{E,\Phi,T\}$ are defined, to characterize the magnitude of strain in each TCPE, and the relative rotation and relative translation between pairs of TCPEs, respectively.The proposed method was evaluated using previously collected *ex-vivo* data [2] on the motion of the lower limbs of three cadavers measured simultaneously from skin markers and bone pins, as shown in Fig. 1. The cluster of twelve skin markers was used to construct 220 TCPEs. The instantaneous femur position error $\Delta\theta$ and orientation error Δt, and the parameters $\{E,\Phi,T\}$ were obtained for each TCPE. The bone pose errors were also calculated by applying the Procrustes Superimposition (PS) approach on the entire cluster of markers, for comparison.

Results: Statistics of the values of the parameters $\{E,\Phi,T\}$ and the pose errors $\{\Delta\theta, \Delta t\}$ for all the TCPEs are shown in Table 1. The maximum values of $\Delta\theta$ and Δt obtained by a single TCPE were 36 degrees and 95mm, respectively. When selecting the TCPE with the smallest error at each time step, the maximum values were reduced to 5.2 degrees and 7.5 mm, respectively. In particular, it is noted that a number of TCPEs exhibited errors smaller than those estimated by the PS approach applied on the entire cluster of markers (on average, 31% of the TCPEs had smaller orientation errors and 21% had smaller position errors). This suggests that the pose errors could be reduced if selection of quality TCPEs, which best represent the underlying bone pose, is feasible.To examine the ability of the parameters $\{E,\Phi,T\}$ to predict the quality of the TCPEs' pose estimation, Spearman's rank correlation coefficients (R_s) between the errors $\{\Delta\theta,\Delta t\}$ of the TCPEs and each of the parameters $\{E,\Phi,T\}$ were calculated at each time step. Statistics of the values of R_s are also shown in Table 1. The results revealed mostly poor to moderate correlations between E and the errors, suggesting that the strain magnitude may not be a good parameter for selection of quality TCPEs to estimate bone pose. The strongest correlations were found

between Φ and $\Delta\theta$ and between T and Δt. This suggests that TCPEs with smaller Φ should more accurately represent bone orientation and TCPEs with smaller T should more accurately represent bone position.

Figure:



Caption: Fig. 1. Pin and skin markers configuration

Conclusion: The TCPE method proposes a number of physical parameters that can be used to describe the deformation of the body segment under analysis. It has been shown that some of these parameters correlate well with femur pose errors measured *ex-vivo*, which suggests that they can be used to select, at each instant, subset groups of TCPEs which are more likely to accurately estimate the underlying bone pose. It has been proved that, if an effective method for the selection of optimal subset groups of TCPEs is devised, the bone pose accuracy can be highly improved. It is expected that the operational framework provided by the TCPE method can be used to describe the body segment deformation and to lay the foundation for the compensation of the STA in *in-vivo* measurements of different populations, motor tasks and body segments when a high number of observation points are recorded.

Table:

	Min	Max	Median	IQR
E (%)	0	61.3	5.9	8.5
Φ (deg)	0	6.8	40.9	6.2
T (mm)	0	87	15	14
$\Delta\theta$ (deg)	0	36.2	5.2	6.6
Δt (mm)	0	95.8	9.7	14.4
R_s (E, $\Delta\theta$)	-0.49	0.79	0.40	0.26
R_s (Φ, $\Delta\theta$)	-0.19	1.00	0.70	0.31
R_s (T, $\Delta\theta$)	-0.44	0.90	0.56	0.20

HUMAN PERFORMANCE IN SIMULATED REDUCED GRAVITY ENVIRONMENTS

Matt Cowley [1,*]Lauren Harvill [1]Sudhakar Rajulu [2]

[1]Human Health and Performance, NASA / Lockheed Martin, [2]Human Health and Performance, NASA, Houston, United States

Introduction and Objectives: NASA is currently designing a new space suit capable of working on the moon and Mars. Designing a suit is very difficult and often requires trade-offs between optimal human performance, cost, mass, and system complexity. To design the suit for optimal human performance, we need to first understand human performance in a non-earth planetary environment.

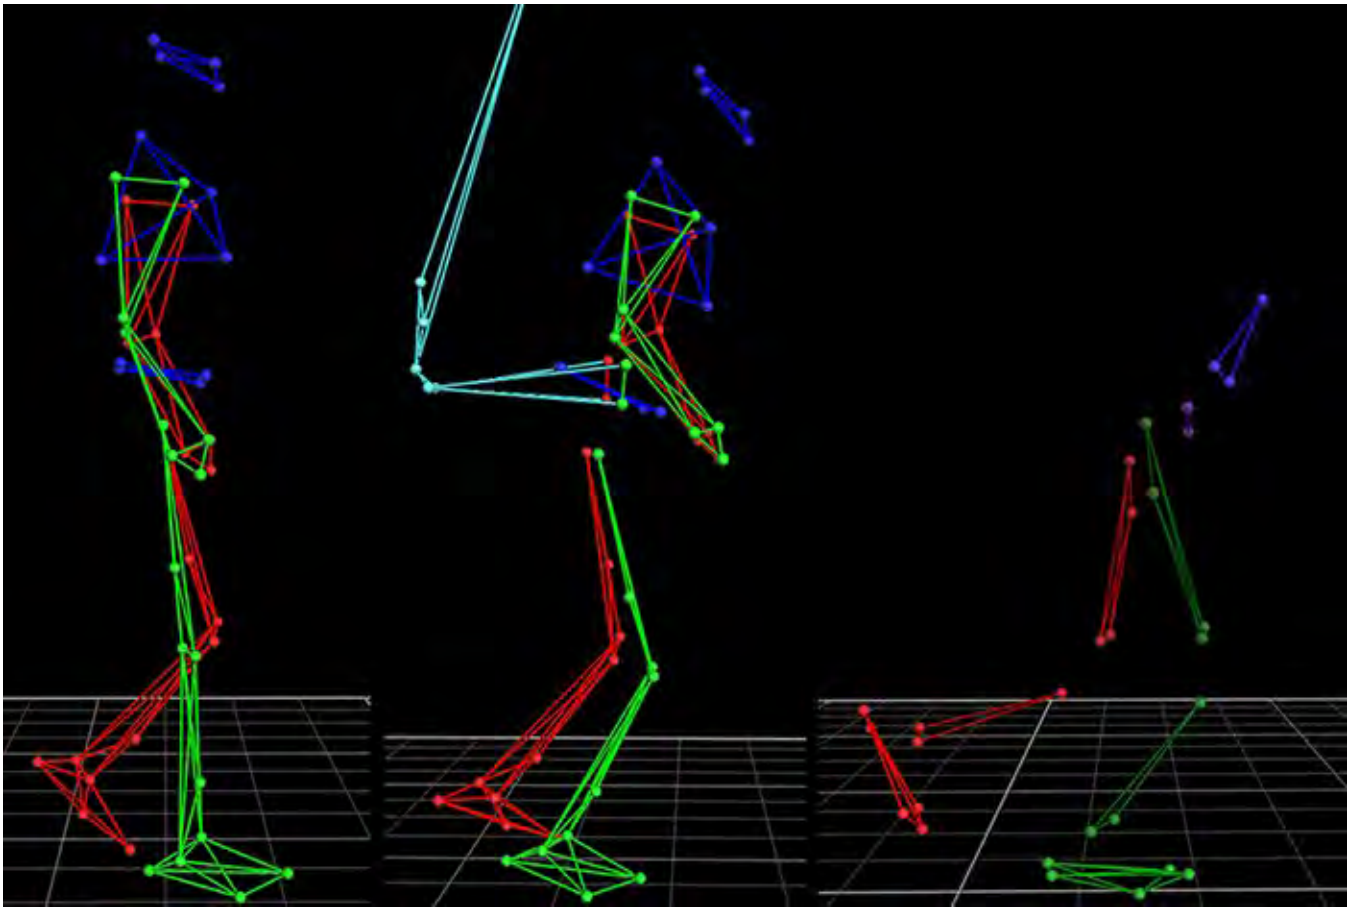
Our current understanding of human performance in reduced gravity environments (the moon or Mars) is limited to lunar observations, aided by studies from the Apollo program and other reduced gravity analogs [1-3] and from recent studies conducted at JSC using state-of-the-art reduced gravity simulators. This study will look at ambulation in our most recent reduced gravity simulator, the Active Response Gravity Offload System (ARGOS), compared to both the C-9 reduced gravity plane (gold standard) and ambulation in Earth gravity.

Methods: Subjects ambulated in reduced gravity analogs to obtain a baseline for human performance. Subjects were tested in lunar gravity (1.6 m/s^2) and Earth gravity (9.8 m/s^2) in minimal clothing. Subjects ambulated over ground at prescribed speeds on the ARGOS, but ambulated at a self-selected speed on the C-9 due to time limitations of the flight parabolas. Subjects on both systems were given time to acclimate to the gravity environment before data was collected. Nine subjects were tested in the ARGOS (6 males, 3 females, 79.5 ± 15.7 kg), while six subjects were tested on the C-9 (6 males, 78.8 ± 11.2 kg).

Data was collected with an optical motion capture system (Vicon, Oxford, UK) and custom and commercial force-platforms (AMTI, Watertown, MA, USA) and was analyzed using customized analysis scripts in BodyBuilder (Vicon, Oxford, UK) and MATLAB (MathWorks, Natick, MA, USA).

Results: In both reduced gravity environments, variation between subjects and within subjects increased compared to Earth gravity. Kinematics in the ARGOS at lunar gravity resembled earth gravity ambulation more closely than in the C-9 (see fig 1). Toe-off occurred 10% earlier in both reduced gravity environments compared to earth gravity, shortening the stance phase. Likewise, ankle, knee, and hip angles remained consistently flexed and had reduced peaks compared to earth gravity, especially on the C-9. Peak ground reaction force in lunar gravity were 0.4 ± 0.2 (mean ± SD, normalized to Earth body weight) on the ARGOS, but only 0.2 ± 0.1 on the C-9 plane.

Figure:



Caption: Figure 1. Over-ground ambulation shown in mid-stance for Earth gravity (left), lunar gravity (ARGOS), and lunar gravity (C-9 plane).

Conclusion: Kinematic and kinetic analysis demonstrated noteworthy differences between the tested reduced gravity environments and Earth gravity, as would be expected. Although most of the subjects chose a somewhat unique gait style as a result of learning to ambulate in a new gravity environment, all but two subjects in the ARGOS were consistent with keeping an Earth-like gait. The analysis showed a trend to change the ambulation style in an offloaded environment to a rolling-loping walk (resembling cross-country skiing) with increased swing time. The general uniformity of the modified ambulation styles would indicate that the subjects are using similar optimization strategies to maintain gait efficiencies. Benchmarking the differences between the ARGOS (and other offloading systems) and the C-9 reduced gravity plane are imperative to all future reduced gravity studies for NASA and will allow NASA to continue to use less expensive earth-bound reduced gravity simulators while maintaining the integrity of the study results and conclusions.

PREGNANCY-RELATED CHANGES IN CENTRE OF PRESSURE DURING GAIT

Jeanne Bertuit [1,*] Clara Leyh [2] Véronique Feipel [1] Marcel Rooze [1]

[1]Laboratory of Functional Anatomy, [2]Laboratory of Anatomy, Biomechanics and Organogenesis , Université Libre de Bruxelles, Brussels, Belgium

Introduction and Objectives: During pregnancy, physical and hormonal modifications occur. These changes can lead to an increase in postural instability and to a higher risk of falls during gait [5, 7]. To evaluate gait and balance of subjects, the centre of pressure (COP) is commonly used. The aim of this study was to describe the evolution and variability of COP parameters during the four last months of pregnancy and in post-partum. A comparison with nulliparous women was conducted in order to assess the changes during pregnancy.

Methods: We used an electronic walkway (GAITRite system). Fifty-eight pregnant women (four last months of pregnancy), 9 post-partum women and 23 healthy non-pregnant women participated in this study. Women performed three gait trials at each of three different speeds (preferred, slow and fast) following standardised instructions. The order of speeds was randomized. COP path was extracted for each stance phase. Excursion, velocity and length of COP path were computed and averaged. COP parameter variability was computed for each subject as the standard deviation over all sampled stance phases. Gait speed and stance phase duration (stance time) were also computed. COP characteristics for pregnant and non-pregnant participants were compared using ANOVA.

Results: Pregnancy was marked by a significantly slower gait speed (-20%) and increased stance time (+12%). During the four last months of gestation, COP parameters did not change significantly.

COP excursion decreased by 5% ($p=0,003$) for all speeds as compared to control group.

COP velocity differed significantly from that of the control group ($p<0,001$) with a decrease by 16% and from that of the post-partum group ($p=0,022$) by 3% along the postero-anterior (PA) axis.

For the medio-lateral (ML) axis pregnant women differed from the control group ($p<0,001$), with a decrease of 20%%, and from the post-partum group ($p=0,030$) of 9%.

COP inter-individual variability was different between pregnant women and the control group: variability was greater for the control group.

Conclusion: The COP parameters appear slightly influenced by pregnancy, which suggests that pregnant women establish very specific and individual strategies:

COP velocity along PA and ML axes was slower. A longer stance time indicates some difficulty in balance during gait [8]. The changes observed here are consistent with this statement and may aim at increasing the stability of pregnant women. During pregnancy foot length and width were reported to remain unchanged [1, 3]. This can explain the observation that AP COP displacements were not found to evolve during pregnancy in our study. Medio-lateral COP displacement also remained unchanged. Pregnant women compensate with an increase in step width to maintain or increase during gait [2]. We may think that pregnant women develop very specific strategies such as step widening, alteration of spine posture, and centre of gravity to maintain stable COP displacements during gait as compared to nulliparous women. These types

of strategies provide a stable and safe gait. The variability was in general larger for frontal plane COP parameters, confirming previous observations [6]. This suggests that pregnant women establish specific control strategies along the ML axis, such as an increase step width. Nevertheless, low variability in gait parameters, as found here, were previously shown to be correlated with greater stability and a lower risk of fall [4].

Table: Mean (SD) COP parameters at all speeds (slow, S; preferred, P; fast, F) during pregnancy, Post Partum (PP) and for Control Group (CG).

	Speed	Pregnancy	PP	CG	P value Groups	P value Velocity	P value Months

QUANTIFYING VARUS AND VALGUS THRUST IN INDIVIDUALS WITH SEVERE KNEE OSTEOARTHRITIS

Lauren Sosdian [1,*]Rana Hinman [1]Tim Wrigley [1]Kade Paterson [1]Peter Choong [2]Michelle Dowsey [2]Kim Bennell [1]

[1]Department of Physiotherapy, The University of Melbourne, [2]St. Vincent's Hospital, Melbourne, Australia

Introduction and Objectives: Varus and valgus thrust are of interest in knee osteoarthritis (OA) as they indicate dynamic instability and varus thrust has been associated with an increased risk of OA progression (1). They have been previously defined as the visualized dynamic bowing-out/bowing in of the knee (1, 2), or the abrupt worsening of existing varus/valgus during the weight bearing phase of walking. While varus thrust has generally been assessed using visual observation, only one study has attempted to quantify varus thrust using 3-dimensional gait analysis and measured the change between the varus angle at heelstrike to the peak varus angle (3). However, this measurement did not examine valgus thrust, or any movements that might occur before the peak knee varus angle. Another study has related visual varus thrust to peak knee varus angle and peak knee angular velocity (4), but did not quantify thrust or consider valgus thrust. Other measurement parameters that quantify thrust need to be investigated.

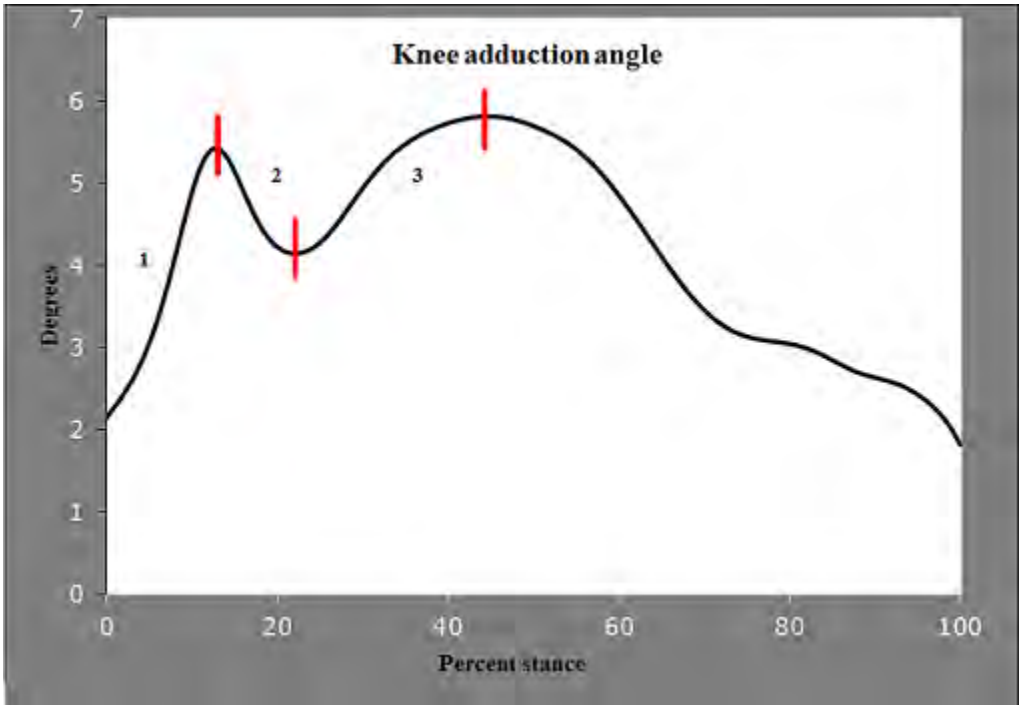
The aims of this study using 3-D gait analysis were to 1) determine the prevalence of varus and valgus thrust in a severe knee OA population compared to a healthy, asymptomatic control group and 2) quantify varus and valgus thrust and compare frontal plane dynamic movement quantitative parameters between the OA and control groups.

Methods: 35 patients with severe knee OA (46% M 54% F, mean (SD), age = 69.9 (7.7) years, BMI = 30.7 (4.0) kg/m2) awaiting total knee joint replacement and 31 healthy control participants (35% M 65% F, mean (SD), age = 59.7 (6.0) years, BMI = 24.9 (2.5) kg/m2) were recruited and underwent 3-dimensional gait analysis. Kinematic data (120 Hz) were acquired using a Vicon motion capture system (Vicon, Oxford, UK) and Nexus software with 12 MX cameras. A custom seven-segment, marker-triad-based lower limb direct kinematics model written in BodyBuilder (Vicon, Oxford, UK) was used (5). Knee frontal plane dynamic motion variables of interest included: overall, early, and mid-stance peak knee varus Cardan angles, maximum and minimum knee angular velocities, and maximum thrust (varus and valgus thrusts were labelled as positive and negative, respectively) and absolute value of the maximum thrust during stance loading phase. Thrust was extracted as the maximum angular excursion of the first three frontal plane knee movements within stance phase in the varus and valgus directions (Figure 1). These varus or valgus movements were classified as thrusts if the maximum or minimum knee angular velocities occurred at the same time. Prevalence of thrust between groups was compared using Chi square tests while student t-tests and Kruskal-Wallis tests were used to compare normally and non-normally distributed frontal plane parameters between groups. OA and control participants were then divided into varus and valgus groups for further analysis based on the direction of their maximum thrust.

Results: There was no difference in the prevalence of varus and valgus thrust between groups with 21 (70%) and 13 (30%) of the OA groups having a maximum thrust in the varus and valgus direction respectively compared with 16 (52%) and 15 (48%) of the control group ($p>0.05$).The minimum knee angular velocity and the absolute value of the maximum thrust were both significantly higher in controls when compared to the OA group. The same differences remained when comparing the varus thrust OA group to the varus thrust control group. The OA varus thrust group also had a higher varus

angle in early and mid-stance. No significant differences were found between groups when comparing the valgus thrust OA and valgus thrust control groups.

Figure:



Caption: Example of first three thrusts

Conclusion: This study introduces a new method that quantifies both varus and valgus thrust. It is the first to compare differences in thrust and frontal plane dynamic motion variables in individuals with severe OA and healthy controls. Although no difference was found in the prevalence of varus and/or valgus thrust between OA and control groups, the control group demonstrated a larger thrust magnitude, likely due to a faster walking speed. The OA varus thrust group walked with a higher varus knee angle in early and mid-stance than the controls with a varus thrust. No significant differences were found between OA and control valgus thrust groups, indicating that valgus thrust may not have as much effect on frontal plane dynamic motion variables. Future work in this cohort includes investigation of the effect of a total knee replacement on these variables.

KINEMATIC AND MUSCULAR CHANGES IN THE GAIT PATTERN DURING CROSS-SLOPE WALKING WITH MINIMAL SHOES AND BAREFOOT

Lea Nösberger [1 2,*] Anna Estermann [1 2] Lukas Stammler [2] Beat Göpfert [3 4]

[1]Health Division, Bern University of Applied Sciences, Bern, [2]BZG, Bildungszentrum Gesundheit Basel-Stadt, Münchenstein, [3]Center of Biomechanics, University of Basel, [4]Laboratory for Movement Analysis Basel, Children's University Hospital Basel (UKBB) Basel, Basel, Switzerland

Introduction and Objectives: Walking on cross-sloped surfaces occurs often in our daily activity. Very little is known about the changes in the movement and muscular activation pattern wearing different shoes. The goal of this study was to analyse the changes in the kinematics and the wavelet-transformed surface-electromyogram (WT-EMG) while overground walking on flat and cross-sloped surface within 2 footwear conditions: barefoot and minimal shoes (Aapa, Feelmax, Finland).

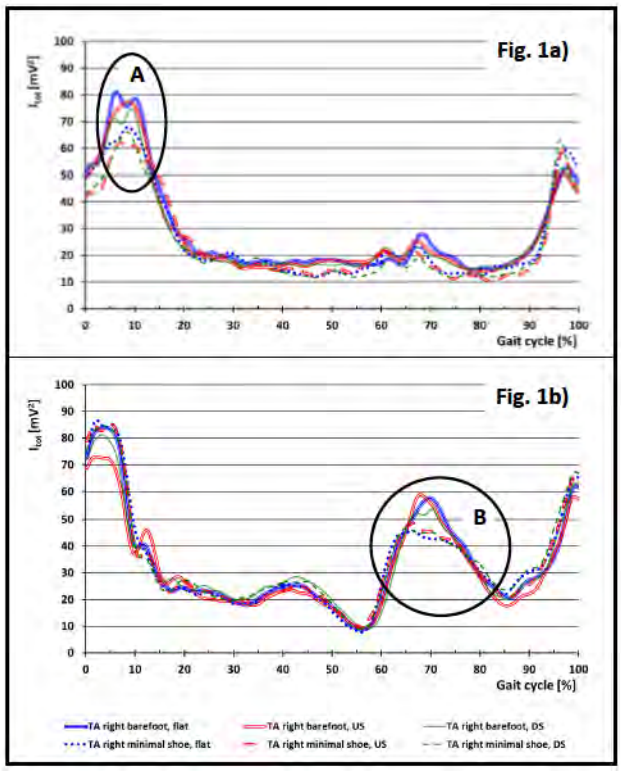
Methods: A whole body 3D-gait-analysis (Vicon, 12 Cameras T20, 240Hz) with a synchronous EMG (Myon, 2400Hz) of the following right leg muscles was done: Tibialis anterior (TA), Peroneus longus (PL), Gastrocnemius medialis (GM) and lateralis (GL), Vastus medialis (VM) and lateralis (VL), Rectus femoris (RF), Semitendinosus (ST), Biceps femoris (BF). 10 subjects (f, 22-25y) walked at a self-selected speed on flat and on a cross-sloped surface (6°). 10 trials of each condition and surface were measured: flat (F), cross-slope up-side-leg (US), cross-slope down-side-leg (DS). The time was normalised over a gait-cycle, the averaged kinematic data and the normalized WT-EMG-Total-Intensity (I_{tot}) was analyzed within a gait-cycle for each subject and overall subjects while walking under different conditions.

Results: Around 26 gait-cycles were collected per subject and footwear condition.

The average knee flexion is significantly 3° to 4° higher for the minimal shoes compared to barefoot. Furthermore, the up-side-leg showed the highest flexion in the ankle, knee and hip joint while the down-side-leg had the lowest flexion in general. During the stance phase no significant changes occurred in the flexion angles barefoot vs. with shoes, but variations were seen between the surface conditions. Additionally, the down-side-foot had in the terminal stance and swing phase a significant lower internal rotation than up-side-foot independent of the footwear condition. In the frontal plane occurred a significant higher lateral pelvis tilt barefoot vs. with shoes on the cross-slope, but not in the thorax.

The averaged I_{totMAX} overall subjects showed for all muscles a time shift during the stance phase between the three surface conditions within the same footwear condition and a more pronounced time shift between the footwear conditions. Additionally the shape of I_{totMAX} changed for e.g. VL in the loading response phase from barefoot flat and down-side-leg with a double-peak to single-peak with shoes (A, Fig.1a) or the TA in the early swing phase from a sharper to more rounded peak (B, Fig.1b).

Figure:



Conclusion: The results show a kind of parallel shift in the kinematic movement pattern between the different conditions with an increased range of motion with the minimal-shoe. The changes in the angular values are small but are reliable, because the measurements for all conditions were taken in one session. Only the markers on the foot had to be new placed between the two footwear conditions. The increased range of motion with the minimal shoes might be related to a slightly bigger size and different shape of the foot. Therefore it can be expected that the shape and design of the shoe has to be considered as a substantial factor in changing the loading conditions. They may alter the “preferred movement path” [1].The I_{tot}-patterns of the different muscles show often a two-dimensional shift between the different conditions, once in time and another shift in the intensity. The overall intensity changes are more depending on the footwear as on the surface conditions. The effect of the surface is more seen in anatomical function of the muscles. Like muscles located on the lateral side of the loading axis have a higher activity in the up-side-leg condition while the medial ones are more active in the down-side-leg. The temporal variation might also be linked to slightly different foot size and shape within the different setups. These temporal adaptions may be needed to balance and adjust the small variation in the different loading conditions and may follow the preferred movement pattern [1].

Our results show that cross-slope walking influences the movement pattern in all joint axes and has a detectable effect on muscular balancing and interplay especially in the frontal plane. Therefore it would be interesting to measure the effect of cross-slope walking in subjects with a total joint replacement. In such a setup muscular adaptions are more difficult due to the changed proprioception in the joint.

THE INFLUENCE OF WALKING ON A SLOPED INCLINE AND DECLINE SURFACE ON LUMBAR-PELVIC COORDINATION: A DYNAMICAL SYSTEMS APPROACH

Robert Needham [1,*] Nachiappan Chockalingam [1]

[1] Sport & Exercise, Staffordshire University, Stoke-on-Trent, United Kingdom

Introduction and Objectives: Optoelectronic motion capture is widely used in the study of human gait. Normal activities of daily life regularly require individuals to walk on slopes at varying gradients, yet the investigation of gait has primarily focused on the analysis of walking over-ground on a level surface.

Recently, Gallagher et al. [1] investigated the effect of prolonged standing on a sloped surface on an individual's perception of LBP. Altered spinal posture from standing on a sloped surface was associated with a reduction in the perception of LBP. Therefore, an understanding of changes in spinal posture and to the coordinated interaction between the pelvis and lumbar spine during sloped waking could provide support for gait re-training and rehabilitation programs. Nevertheless, one study to date has provided 3D motion analysis of the lumbar region during incline slope walking [2]. Also, the influence of decline slope walking on lumbar motion is restricted to the sagittal plane [3].

Vector coding (VC) is a non-linear technique employed by dynamical systems theorists to quantify coordination and variability. Although non-linear techniques have been used for the purpose of understanding the differences in pelvis-trunk coordination in healthy individuals to those with LBP [4,5], information on lumbar-pelvic coordination during gait is limited to a single study [6].

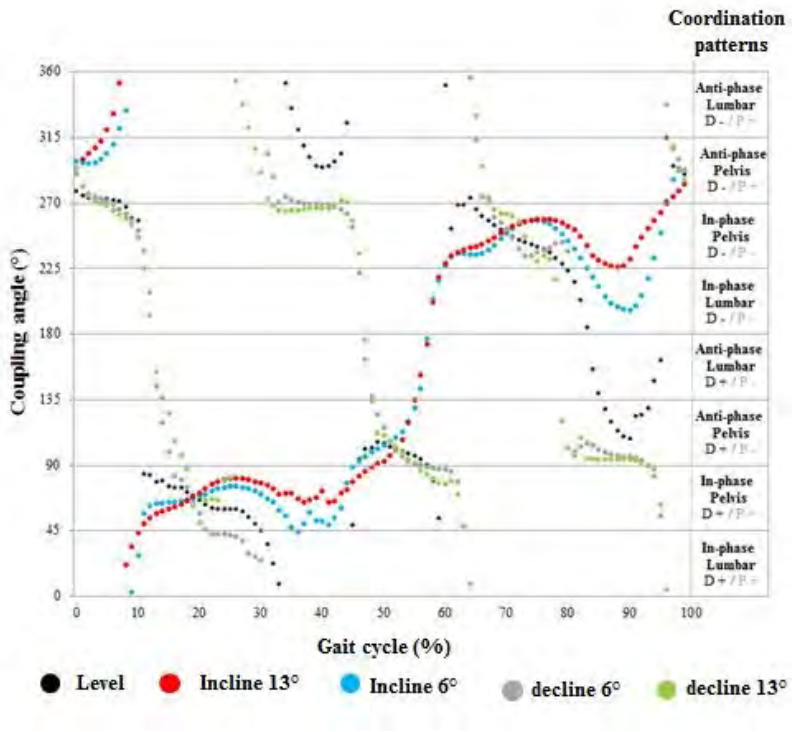
Therefore, this study aimed to investigate pelvis and lumbar spine kinematics during incline and decline walking at various gradients by applying a modified VC technique to quantify lumbar-pelvic coordination.

Methods: Eight male participants with no history of musculoskeletal impairments participated in the study. Ethical Approval was sought and received from the University Research Ethics Committee. An eight camera motion capture system (VICON, UK) was used to collect pelvis and lumbar spine kinematic data [6] over five trials for each walking condition; level over-ground, incline (6° and 13°) and decline (6° and 13°). Data was processed using a low-pass Butterworth filter with a cut-off frequency of 6Hz and normalized for time to 100% of the gait cycle (GC). Angle–angle diagrams were created with the proximal oscillator (lumbar) on the horizontal axis and the distal oscillator (pelvis) on the vertical axis. A VC technique was applied to quantify lumbar-pelvic coordination and circular statistics calculated the mean coupling angle (CA) between trials and across all participants. The CA is the outcome measure of the VC technique and represents the vector orientation between two adjacent time points on an angle-angle diagram relative to the right horizontal [6]. Mean coupling angles were classified into one of four coordination patterns; in-phase pelvis, in-phase lumbar, anti-phase pelvis, anti-phase lumbar.

Results: Figure 1 represents the mean CA across all eight participants for level ground (LG), incline (6° and 13°) and decline (6° and 13°) walking and corresponds to frontal plane movement of the pelvis and lumbar spine. Between 0-5% of the GC, an anti-phase pelvis coordination pattern between all walking conditions is noted. The decline walking (DW) conditions follow a similar coordination pattern to LG walking up to 10% of the GC. Between 10 and 30% of the GC which

represents mid-stance for LG walking, there is an in-phase coordination between the two segments with the pelvis being the dominant segment. The same coordination pattern is shown for the incline walking (IW) conditions but unlike LG walking this in-phase pelvis phase extended until approximately 50% of the GC. Between 30-45% of the GC the CA orientation was approximately 270° which suggests pelvis dominancy with little contribution of the lumbar spine to relative movement. During the latter stages of the swing phase an in-phase coordination pattern is highlighted for the IW conditions, yet during walking on an incline of 6° the lumbar spine was the dominant segment in comparison to walking at an incline of 13° where pelvis dominancy was noted. During the swing phase, the DW walking conditions revealed an anti-phase coordination pattern similar to LG walking.

Figure:



Caption: Mean coupling angle for all eight participants

Conclusion: The coordination patterns for LG walking corresponded to a previous investigation [6]. Although there is currently no research to compare the results regarding the incline and decline walking conditions, this abstracts presents novel data on pelvis and lumbar coordination in healthy young males during slope walking. This baseline information could be useful for future studies involving patients with lumbar–pelvic pathologies and other related clinical conditions.

ASSESSMENT OF LIMPING DURING GAIT BY ACCELEROMETERS

Ligia C. S. Fonseca [1,*]Kathrin Koch [1]Jorge Gooding [1]Thomas Claus [2]Catherine Disselhorst-Klug [1]

[1]Department of Rehabilitation & Prevention Engineering, Institute of Applied Medical Engineering, Aachen, [2]Dr. Becker Rhein-Sieg-Klinik, Nümbrecht, Germany

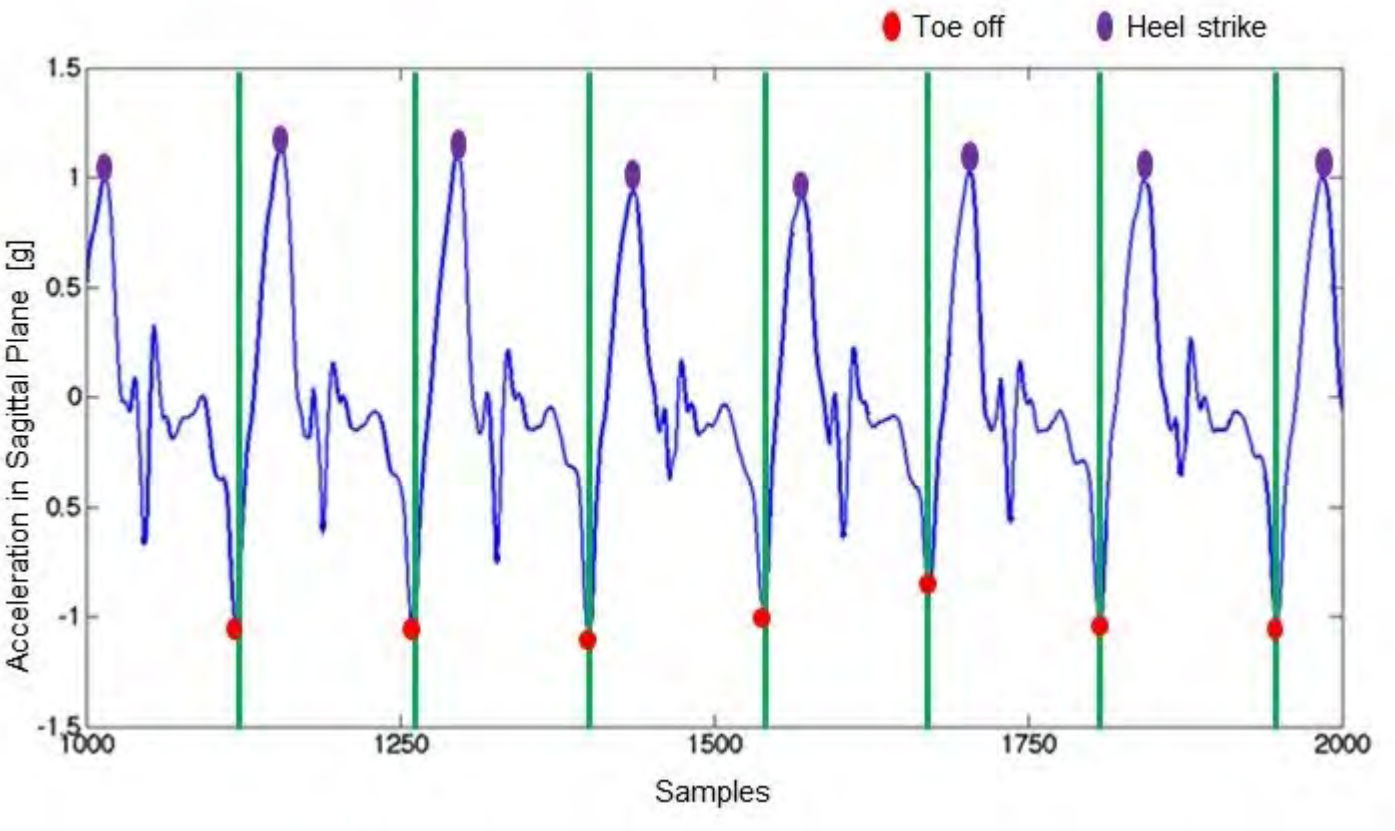
Introduction and Objectives: Knee osteoarthrosis (OA) is a common chronic joint disease with cartilage loss that results to increased stiffness and joint deformity leading to pain and loss of physical function, subsequent in significant limitation in daily life activities and reduction in quality of life. The conventional therapy includes information, exercise, and weight loss and when necessary even a prescription of pain-reducing pharmacologic agents. It can be positive for many young patients, but with increasing age, cartilage repair becomes more complex and the outcome is less predictable, been necessary an arthroplasty and intensive rehabilitation after the surgery to minimize pain and postoperative limping severity. Although patients are able to walk in a normal pattern after this intensive rehabilitation, they fall back into their limping patterns unintentionally. Limping may be caused by general fatigue or pain. However, walking in a pathological movement pattern means additional stress to the already damaged tissues. The goal of this study is to present a portable, wearable assistance system which can be used autonomously and provides a direct feedback about the quality of the gait and occurrence of limping to the patient.

Methods: Triaxial-accelerometer based sensor unit was integrated into commercially patellar tendon straps and used in the limping leg of the patient. The unit measured the acceleration of the knee and transmitted the digital data wireless through an integrated ANT sender module. On the receiver's end, an iOS device equipped with an ANT dongle receives and processes the data for being able to evaluate the quality of the gait. To calculate the gait events, the signals of the three channels of the sensor were used. The gait is divided into two different phases: swing and stance. To detect that gait phases, the extraction of the characteristics events toe off, heel strike and toe strike is necessary. These events were represented by extrema in the acceleration signals and could be extracted. The acceleration in the sagittal plane provides the information about the toe off by the minimum values of the signal and about the heel strike by the maximum values of the signal (see Figure 1). In order to describe the quality of the gait several parameters (see Table 1) were calculated for each step from the measured signals. For this stage 15 healthy subjects were evaluated for the development of the Norm collective. Ten parameters were extracted and used for the development of a scale within 0-10 points used to classify the gait in four different categories: normal gait (NG≤2), light limping (LL= 3 to 5), strong limping (SL= 6 to 8) and very strong limping (VSL≥9). From each parameter the patient can have a score from 0 to 1 and in the end a simple addition was made to give a final result (see the example in Table 1). However, in order to minimize the effect of single outliers, as may be the case with a sudden change of direction while walking, the features of single steps were averaged every five seconds during gait.

Results: A sample of 10 patients aged 41 to 75 years (mean 59.8 ± 10.0) in rehabilitation after knee or hip replacement surgery were recruited for the measurements. They were asked to walk over a straight, 10 m-long path, four times, in a comfortable speed. The patients were evaluated by the portable system and by a physical therapist. The system classified

the patients using the parameters and the professionals should classify the gate from a visual analogue scale from 0 to 10 based in their own expertise. The system classified eight patients in the same category as a physical therapist evaluation. The professionals classified the two other patients as a normal gait but the system could detect a light limping. The mean score of the patients was 5,2 ± 0,78 points at the system and 4,6 ± 1.5 points evaluated by the physical therapist.

Figure:



Caption: Figure 1: Detection of toe off and heel strike

Conclusion: The developed system demonstrated ability to quantify the quality of gait providing a valuable, easy to use tool for the objective assessment of gait during the rehabilitation. Additional tests series are being carried out to later quantify more precisely the gait quality, allowing not only the detection of pathological gait, but also providing valuable information regarding the severity of the abnormality, which should give insights into the effect of the rehabilitation phase in the clinic, as well in the residential setting, where the system can be used to provide a direct feedback to the patient regarding the quality of the gait in daily living situations.

MUSCLE AND JOINT CONTACT LOADING DURING ASSISTED UPPER-EXTREMITY MOVEMENTS PERFORMED WITH A ROBOTIC EXOSKELETON

Wen Wu [1] Justin Fong [1] Denny Oetomo [1] David Lloyd [2] Thor Besier [3] Mark Halaki [4] Karen Ginn [5] Peter Lee [1] David Ackland [1,*]

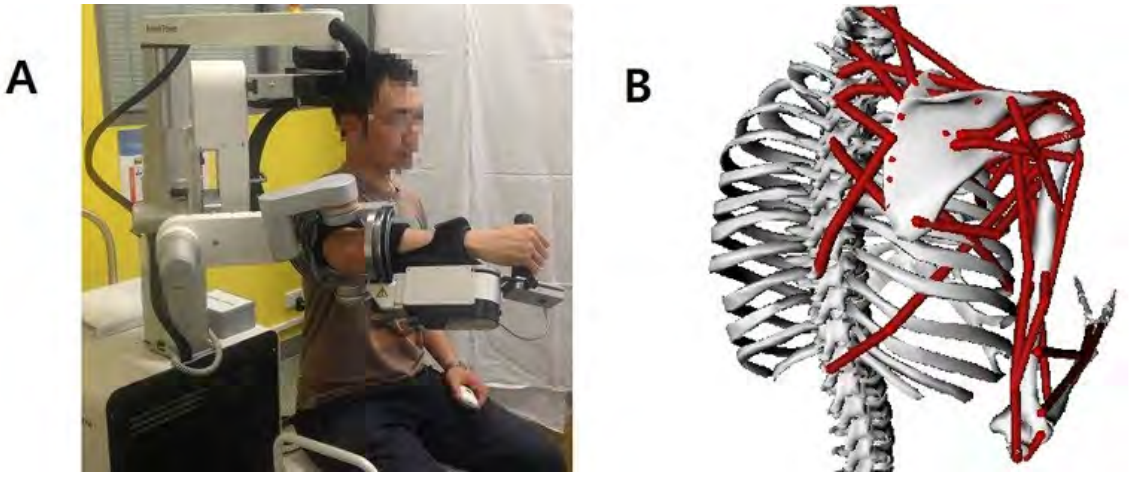
[1] Mechanical Engineering, University of Melbourne, Parkville, [2] School of Allied Health Sciences, Griffith University, Gold Coast, Australia, [3] Auckland Bioengineering Institute, Auckland University, Auckland, New Zealand, [4] Faculty of Health Sciences, [5] Biomedical Sciences, School of Medical Sciences, University of Sydney, Sydney, Australia

Introduction and Objectives: Assistive technologies for stroke patients, including exoskeletons and robotic-assistive devices, are receiving increasing attention in neurorehabilitation as these strategies may complement physiotherapy, resulting in more efficient motor relearning and mobility both at home and in the clinic. Developing a strategy to evaluate neuromuscular control of upper limb movement will improve our ability to diagnose neuromuscular impairments, and aid in development of robot-assistive rehabilitation strategies. Since no non-invasive muscle force measurement strategies are available, computational simulations are widely used to infer muscle and joint function. The objective of this study was to use musculoskeletal modelling to quantify muscle and joint-contact loading during upper limb movement, and evaluate the influence of an assistive robotic exoskeleton on muscle and joint behaviour during simulated weightless motion.

Methods: Two healthy male adults, P1 (age 35 yrs, weight 82 kg) and P2 (age 24 yrs, weight 77kg), were recruited. Subjects were seated and asked to perform an upper-limb reaching task from an initial neutral position (30º shoulder abduction, 0º elbow flexion) to an extended reach position (90º shoulder flexion, 0º elbow flexion). Reaching tasks were performed at each subject's self-selected speed. Six repetitions of the tasks were performed synchronised to a metronome, while three-dimensional shoulder and elbow kinematics were recorded with a magnetic motion tracking system (G4TM, Polhemus, USA). The reaching task was then repeated while the subject was interfaced with a 6 degree-of-freedom robotic upper-limb exoskeleton (ArmeoPower, Hocoma, Switzerland) (Fig. 1A). The anatomical joint coordinate systems for the upper limb were aligned with those of the robotic exoskeleton. The reaching task was performed under two conditions: (1) 100% weightlessness, i.e., with the robotic exoskeleton compensating for entire mass of the upper extremity and its own weight and inertia; and (2) 0% weightlessness, i.e., with the robotic exoskeleton only compensating for its own weight and inertia. A musculoskeletal model describing 9 degrees of freedom of motion at the clavicle, scapula, humerus, radius and ulna was developed (Fig. 1B) (OpenSim, SimTK). The model was actuated by 35 Hill-type muscle-tendon units representing the major upper-limb muscle groups. Muscle-tendon parameters and muscle moment arms were taken from the literature [1, 2]. Anatomical shoulder and elbow joint torques were calculated using inverse dynamics. Torques applied by the robotic exoskeleton to the upper limb joints during weightless motion were obtained by subtracting the measured exoskeleton torques at 0% weightlessness from those at 100% weightlessness. The resultant net internal anatomical joint torques were then obtained by subtracting the torques applied to the subject's shoulder and elbow joints by the robotic exoskeleton from the anatomical torques calculated using inverse dynamics. Muscle and joint-contact forces were then calculated for the assisted and unassisted upper limb motions using static optimisation.

Results: There were no substantive differences in shoulder and elbow joint kinematics between the unassisted reaching task and the robotic-assisted reaching task. Robotic-assisted upper limb motion under simulated weightless conditions substantially affected each subject's muscle recruitment patterns. The middle deltoid muscle force was an average 81% smaller under simulated weightless conditions (Table 1). The infraspinatus and subscapularis muscle force was an average 47% and 55% smaller, respectively. The magnitude of the glenohumeral joint reaction force decreased by 42% under the robotic-assisted upper limb motions.

Figure:



Caption: The ArmeoPower robotic-assistive rehabilitation device (A), and posterior view of the musculoskeletal upper extremity model (B)

Conclusion: The results of the present study demonstrate that a robotic-assistive upper extremity exoskeleton has the potential to significantly influence muscle and joint-contact load patterns at the shoulder. During weightless motion, finite deltoid muscle activity was still observed in the upper limb, most likely due to arm resistance against the robotic exoskeleton. The quantitative modelling framework in this study may be useful for targeted intervention in stroke patients using robotic assistive rehabilitation technology. Future studies will employ parameter-optimization approaches to evaluate muscle-tendon parameters, and electromyography-informed methods to derive muscle excitations.

Table:

	Subject P1		**Subject P2**	
	Unassisted	Assisted	Unassisted	Assisted
Deltoid	0.14	0.00	0.17	0.06
GHJF	0.40	0.27	0.33	0.15

ANALYSIS AND SIMULATION OF VARIOUS STEWART PLATFORM CONFIGURATIONS FOR LOWER LIMB REHABILITATION

Alireza Rastegarpanah [1,*] Mozafar Saadat [2] Hamid Rakhodaei [2]

[1]School of Mechanical Engineering, Doctoral researcher - University of Birmingham, [2]School of Mechanical Engineering, University of Birmingham, Birmingham, United Kingdom

Introduction and Objectives: The aim of physiotherapy by robots is to move paralyzed and disabled organs because of diseases such as cerebral apoplexy. Using the mobile platform under the patient's foot in order to create movement is a mechanism which is used in the rehabilitation of the ankle. In this mechanism, by programming the movement of the mobile platform, the entire foot or some parts of the foot are impelled to move. Parallel robots are closed loop mechanisms that have high mobility and accuracy [1].

With respect to different arrangements of the joints on platforms and the shape of the platforms, there are different structures with varying levels of stability. In this study three platforms of different structures were investigated; one of them is the PSRH structure (a platform with semi-regular hexagons); all of its base joints and all its mobile joints are coplanar and the distance between the actuators is so much greater than in other structures. Another structure is that of the TSSM (Triangular simplified symmetric manipulator); the mobile platform in this structure is triangular and the joints of the upper platform are close to each other. The last configuration, called the MSSM (Minimal simplified symmetric manipulator), combines the TSSM with a 3-3 platform, and its mobile and fixed platforms have a similar triangular shape [2].

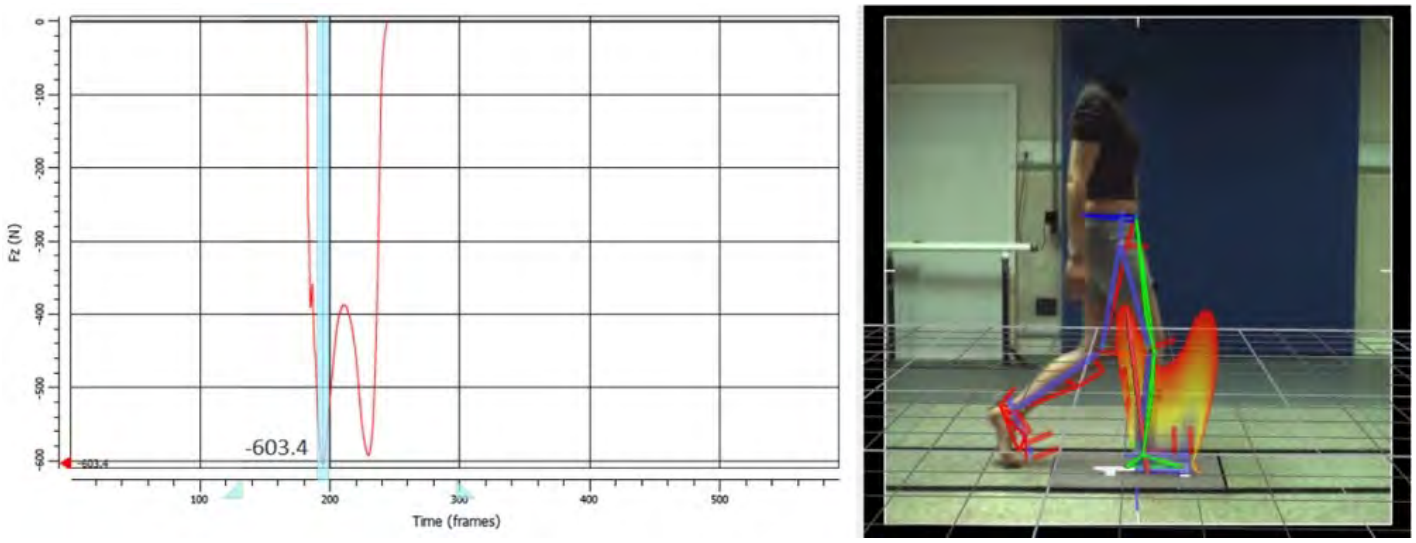
According to the performed gait analysis in the West Midland rehabilitation centre, the foot trajectories of healthy volunteers were analysed during a gait cycle and this trajectory was used as a desired motion for movement of Stewart platform. To choose the most suitably structured Stewart platform for rehabilitation applications, one must consider the anatomy of the ankle and the stability of the three different Stewart platform structures, as analyzed by Solidworks software. Next, the kinematic of the Stewart platform for all configurations was considered and on this basis the maximum workspace of the selected robot was examined.

Methods: To define an accurate path motion for rehabilitation of ankle, gait analysis was performed in West Midland Rehabilitation Centre (WMRC), UK. Twenty able-bodied participated in this experiment with age (year) of 24.34±4.83, weight (kg) of 73.41±5.2, height (cm) of 172.74±4.2.Laboratory was equipped by 16 Vicon cameras, two digital cameras and a Kistler force plate. After anthropometric measurements, reflective markers were attached to the lower limbs based on Oxford foot model. Barefoot participants were asked to walk along the walkway in self-speed and for each participant 6 trials were recorded. All three structures were designed and analyzed statically in the home position, while the maximum ground reaction force was measured and applied to the end-effector. Finally, length of actuators and workspace of robot during trajectory were calculated based on kinematics of hexapod.

Results: Based on gait analysis, the mean value maximum ground reaction force Maximum force of 603.4 N was exerted on the end effector and the maximum displacement and maximum stress for each structure were measured. By exerting a force of 603.4 N, the PSRHs structure had the maximum displacement of 6.628× mm and maximum stress of 21 (Mpa).

The primary stress analysis shows that the maximum displacement for MSSM and TSSM were 5.84× mm and 2.21× mm. PSRH had the highest factor of safety (1.31) and stiffness 26619 (N/mm) of all structures and these results lead to the choice the PSRH structure as the most stable one for manufacturing application.

Figure:



Caption: The profile of ground reaction force

Conclusion: Different configurations of parallel robot have been modelled and with respect to FEA analysis, their stability compared with each other. Platform of semi regular hexagons showed more stability in compare with other structures and it was found that the stability of different structures completely depends on the position of the joints and actuators and the shape of the platforms. With respect to kinematic analysis and gait analysis, the motion of ankle during a gait cycle was defined as a rehabilitation exercise and based on kinematic analysis and defined path motion, the workspace of robot was calculated. With respect to FEA analysis, Kinematic analysis and range of motion of lower limb`s joints, it was found that PSRH structure is a suitable choice for rehabilitation purposes.

REHABILITATION ROBOT PATH PLANNING AND TRACKING USING KINECT

Alireza Rastegarpanah [1,*] Mozafar Saadat [2] Jack Foxcroft [2] Guanqi Zhang [2]

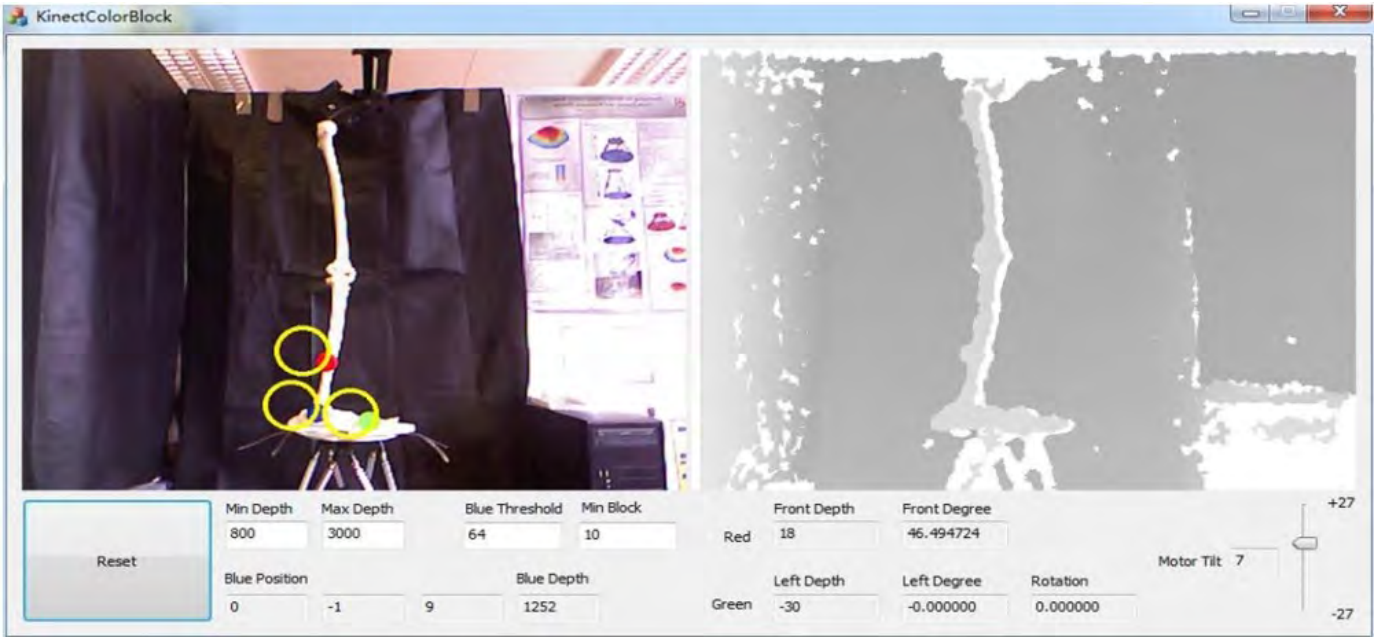
[1]School of Mechanical Engineering, Doctoral researcher - University of Birmingham, [2]School of Mechanical Engineering, University of Birmingham, Birmingham, United Kingdom

Introduction and Objectives: The accuracy position of a leg rehabilitation robot needs to be detected by independent measurement system to help reduce possible errors of controller and optimize the tracking of robot. Due to cheap price and high accuracy of kinect camera as a depth camera device, it uses in different applications such as robotics, gait assessment, gesture tracking and Image data capturing [1]. In this study, ability of utilizing of 6 degree of freedom Hexapod, consisting of a moving platform supported by six actuators, was investigated during a rehabilitation exercise

Methods: Based on Gait analysis, the path motion of walking for 30 healthy subjects have been analysed and extracted .Then, a Hexapod with universal joints at both ends was used in this experiment and three different colour markers were attached on moving platform and skeleton model of leg. As it shows in figure1, Kinect camera was placed on sagittal plane of Hexapod to detect the movements of end-effector and skeleton model during a gait cycle of skeleton model based on obtained trajectory of right leg during a gait cycle. Based on control system of Hexapod, mentioned movement performed and position error of Kinect camera was calculated. The principle of detection of pixel position and distinguishing different color markers have been addressed clearly and Clustering algorithm method was utilized to calculate the center position of target color. Primary colors; green, red and blue were detected by kinect camera at each pixel and they were translated into binary numbers. To find the minimum diameter of markers which can be detected by Kinect, different marker diameters have been tested ranging from 8mm-30mm .

Results: The minimum diameter of 12mm marker was detected by the camera and based on obtained results, the minimum diameter of 12mm detected by Kinect and the position error of 1.65mm, 1.63mm and 1.16 mm were observed, during movement of end-effector in X, Y and Z axis respectively.

Figure:



Caption: Kinect camera in sagittal plane

Conclusion: Kinect measurement system detected the robot plate's positions with an average error around 2mm for every 100ms. The advantages of this system are the low price, simple installation. In particularly, it can be used for detect under 6 freedoms machine's position, the output data of this system, as a feedback value, can be used to check the condition of this machine to reduce the position error. According to accuracy, cheap price and easy installation of Kinect, it can be used for path tracking and position detection of robots in different applications.

EVALUATION OF INDIVIDUAL MOVEMENT PERFORMANCE BASED ON MOVEMENT ANALYSIS USING INERTIAL SENSORS

Catheriene Disselhorst-Klug [1,*] Michael Hennes [1]

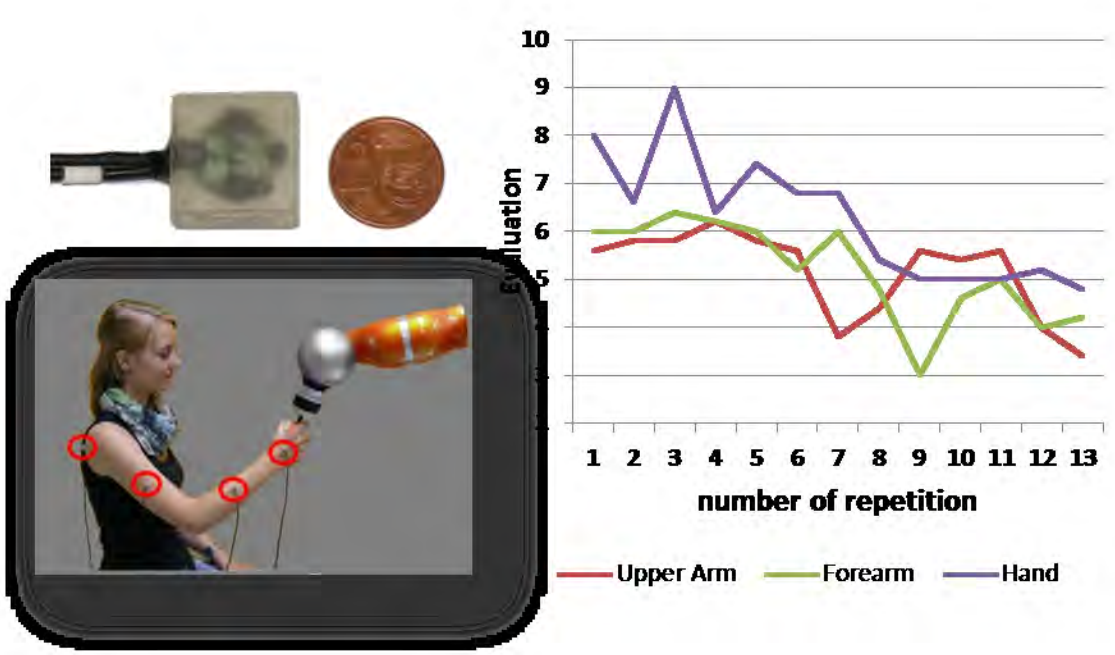
[1] Rehabilitation and Prevention Engineering, Applied Medical Engineering, RWTH Aachen University, Aachen, Germany

Introduction and Objectives: Due to the growing number of patients with musculoskeletal and neurological disorders, individualized physiotherapeutic rehabilitation becomes increasingly relevant. The challenges involved can only be solved, if the patients will do their exercises autonomously. Different assistive systems have been developed during the last years encouraging the patients to do self-motivated training. However, most of them permit compensation movements if the patients have problems in executing the movement tasks. Consequently, patients' movements have to be monitored during the exercise to detect harmful compensation movements and to give individual feedback. Conventional movement analysis systems are suitable but in general too complex to be used autonomously by the patient and available more elementary systems, like e.g. the Microsoft Kinect, are frequently not applicable in pathological movements.
The aim of this paper is to introduce a method based on inertial sensors, which allows the detection as well as a patient-tailored evaluation of the executed movements.

Methods: Since in some disorders additional masses put on the patients' body influence the individual movement performance, very small (2x2x0.5 mm) and lightweight (5 g) inertial measurement units (IMU) have been developed. Each IMU consists of a 3D accelerometer, a 3D magnetomer and a 3D gyroscope (figure 1). One IMU is mounted on every segment of the joint chain (e.g. scapula, upper arm, forearm and hand) to detect the movement of the patient.
Since noise is a general problem when using IMUs, the orientation of each body segment in the lab-coordinate system has been estimated by an unscented Kalman filter and initially represented in quaternions. Afterwards the quaternions have been transformed to Euler angles representing the orientation of each body segment. The variations of these Euler angles with time are used for the following evaluation of the performed movement.
To evaluate the exercise performed autonomously by the patient a reference movement has been detected during a so called teaching phase, which respects the needs and potentials of each individual patient. Therefore, the physiotherapist guides the patient to perform the desired movement while the IMUs record the Euler angles as a function of time.
The time course of the Euler angles of the teaching phase and the time course of the Euler angles of each repetition of the exercise are compared to each other by using a set of features describing the difference between nominal (teaching) and actual (exercise) values. Fuzzy logic which represents the individual movement performance by a number between 0 (bad movement performance) and 10 (perfect movement performance) has been used to evaluate the performed exercise on the basis of the features.

Results: To demonstrate the feasibility of the approach, five healthy subjects and one subject suffering from a hemiparesis after stroke were asked to repetitively perform a "hand from knee to mouth" movement. Movement performance during each repetition has been evaluated by the introduced method. Figure 1 shows exemplarily the movement behavior of the patient. Decreasing movement performance can be found after 7 repetition associated with compensation movements.

Figure:



Conclusion: Inertial sensors are suitable to evaluate the performance of an exercise executed autonomously by the patient. Using an unscented Kalman filter the orientation of the body segments can be expressed in Euler angles. Based on these Euler angles an evaluation of movement performance becomes possible when using fuzzy logic. This information can be used to detect compensational movements and to give feedback to the patients during self-motivated training.

FALL RISK MONITORING: FROM LABORATORY TO PORTABLE DEVICE, INFLUENCE OF SAMPLING FREQUENCY.

Paola Tamburini [1,*]Rita Stagni [1]

[1]DEI - Department of Electrical, Electronic and Information Engineering, University of Bologna, Bologna, Italy

Introduction and Objectives: Falls represent a major community and public health problem, with large clinical and economic consequences. The understanding of locomotors stability is a critical issue in clinical assessment procedures. Clinicians use clinical rating scales for fall risk assessment; but this approach highly relies on the clinician's subjective judgment [1].

Several variability and stability measures were proposed in the literature for the subject specific assessment of fall risk. Although promising, the assessment of fall risk without any indication of the subject specific factors leading to it, can not provide indication for the design of any effective clinical intervention for its effective reduction. Recent work [2,3] demonstrated that clustering appropriate selected indexes can provide indication regarding the specific subject alterations increasing fall risk. The effective exploitation of this approach is meant in its implementation on a portable device for the continuous monitoring of subjects at risk, either pathological (e.g. stroke subjects) or elderly subjects. The ideal device to maximise the exploitation, and subject acceptance is a mobile phone. Although the IMUs mounted on standard smart phones have nothing to envy to other commercially available devices, but sampling frequency at 100 or 200 Hz is not compatible with the computational characteristics. The influence of reduced sampling frequency on the assessment of variability and stability indexes used for the monitoring must be assessed, and this is the aim of the present work.

This is an essential step for bringing the method from the laboratory to real practice without loosing the performance.

Methods: Ten healthy young subjects, 7 males and 3 females (28+-3 years, 174+-11 cm, 67+-13 kg), participated to the study. They performed a straight walking at self selected speed on 250 m long dead-end road wearing 2 tri-axial accelerometers, one located at the level of the fifth lumbar vertebra and one on the right ankle.

Right heel strike instants were obtained from the angular velocity measured by the sensor on the ankle with wavelet analysis based method [4] and stride time was calculated accordingly.

The first and last three strides were removed in order to exclude gait initiation-termination phase.

Acceleration and angular velocity in vertical (V), medio-lateral (ML) and antero-posterior (AP) were acquired with sample frequency of 128 Hz. Eleven gait variability and stability measures (Standard Deviation (SD), Coefficient of Variation (CV), Nonstationary index (NI), Inconsistency of Variance (IV), Poincaré Plots (PSD1/PSD2), Maximum Floquet Multipliers (maxFM), short/long-term Lyapunov exponents (sLE/lLE), Harmonic Ratio (HR), Index of Harmonicity (IH), Multiscale Entropy (MSE) and Recurrence Quantification Analysis (RQA)) were calculated on stride time and trunk acceleration data during gait. The two latter measures produce 6 and 5 sub-measures respectively, based on the time scale in MSE or based on the feature of the recurrence plot that was analysed in RQA (recurrence rate (rr), determinism (det), average length of diagonal lines (avg), maximum length of diagonal lines (max), divergence (div)).

Each measure was calculated for the acquired signal (at 128 Hz) and for other two signals obtained from the original one by under-sampling at 64 and 32 Hz and also for anterior-posterior (AP), medio-lateral (ML) and vertical (V) acceleration

directions. The obtained measures were testing with gaussianity test (Kolmogorov-Smirnov test) in such way was possible performed the right statistical analysis: ANOVA test with a p-value of 5%.

The statistical analysis compares the obtained measures by original signal (the reference) with the measures obtained by under-sampling from the original one.

Results: CV, PSD2, HR, IH, lLE, maxFM, rr and MSE for the time shifting 5 and 6 didn't show significantly differences varying the sampling frequency.

SD, sLE, det, avg, max, div and MSE for time shifting varying between 1 and 4 shown significantly differences varying the sampling frequency.

NI, IV and PSD1 shown significantly differences only for the sampling frequency at 32 Hz.

Conclusion: The results show that the measures calculated in the frequency domain (HR and IH) and those that describe the system as a whole (maxFM and lLE) were not affected by the reduction of sampling frequency, supporting the maintenance of the performance of the method when implemented on a portable device.

MSE can be affected by reduction of sampling frequency, depending on the amplitude of selected time shift: the higher the time shift the least the measure is sensitive to frequency changes.

BIOMECHANICS ANALYSIS OF BASEBALL PITCHING: COMPARISON AMONG STANDARD, WEIGHTER AND LIGHTER BALLS

Simone Ciacci [1] Valerio Trentini [2] Andrea Giovanardi [2] Silvia Fantozzi [3,*]

[1]Biomedical and Neuromotor Sciences, [2]School of Pharmacy, Biotechnology and Sport Science, [3]Electric, Electronic and Information Engineering, University of Bologna, Bologna, Italy

Introduction and Objectives: The fundamental issues for an efficient throw are: the precision, the effect and the velocity of release of the ball (1,2). The latter can be improved, without modifying the precision, by both refining the technique of the motor task and increasing the production of power (1). Throwing balls of different weight with respect to the standard one is a typically used special training mode. Previous studies suggested that this type of training contributes to increase the throwing velocity, but no indication has been provided about the optimal ball weight to be used (3) and about the influence of this type of training on the kinematic variables of the throwing arm (2). The aim of the present study was to investigate the effect of using of weighter and lighter balls on kinematic variables of the throwing arm, ball velocity release and precision in 6 pitchers throwing 5oz, 6oz, 7oz and 4oz balls.

Methods: *Athletes and task description*. Six baseball right-handed pitchers (age 21.7 ± 3.1 years, mass 78.2 ± 7.5 kg, height 182.8 ± 7.9 cm) were analyzed. At the time of acquisition the players were in the final phase of the regular season (Italian Championship League A). After a general and sport specific warm-up, each pitcher performed at least 16 throws at maximum intensity with balls of different weights with the following sequence: 5 oz, 6 oz, 7 oz, 4 oz. A strike zone (40 cm) was placed at 18.44 m from the mound.

Kinematic analysis. The upper limb was modeled as an open kinematic chain constituted by 3 rigid segments: thorax, shoulder girdle, upper-arm, and forearm, with 7 degrees of freedom (protraction-retraction and elevation-depression of the shoulder girdle, flexion-extension, abduction-adduction, and internal-external rotation of the gleno-humeral, flexion-extension and pronation-supination of the elbow joint) (4). The 3D biomechanical analysis was performed by means of stereophotogrammetry (BTS Smart-DX 7000, 10 TVC, 250Hz, BTS Engineering Spa, Milano). 5 markers were placed on the thorax, pelvis and hand anatomical landmarks, 5 on the humerus, and 4 on the forearm to form technical clusters. Anatomical calibrations were then performed. The following phases, reflecting meaningful temporal or kinematic characteristics of the throw, were identified: cocking, arm acceleration and arm deceleration. The statistical analysis was performed using SPSS software (SPSS inc. Chicago, Illinois, USA).

Results: No differences in kinematic parameters were found between the standard and the other balls. Throwing kinematics when using the 7oz and the 4oz ball is shown in the table. The higher velocity of the ball when using the 4oz ball is associated with a lower precision of the throw (25% and 74% for the 4oz and 7oz, respectively), and with higher maximum shoulder internal rotation velocity, and maximum elbow extension velocity (table).

Conclusion: Throwing training with weighter and lighter balls in baseball may be a useful tool to improve the maximum ball velocity (1,3). The sequence of the different weighted balls used in the present study led to an improvement of the ball

velocity, but to a lower precision of the throw. These findings suggest to use balls with 1oz weight difference to get a positive effect on ball speed without altering the precision and overloading the arm throwing joints.

Table:

Pitching phases and variables	5 oz ball	6 oz ball	7 oz ball	4 oz ball
Arm Acceleration				
Max Shoulder Internal Rotation Velocity (°/s)	5102 ± 504	4749 ± 615	4786 ± 414*	5247 ± 548*
Maximum Elbow Extension Velocity (°/s)	2198 ± 395	2160 ± 421	2167 ± 453*	2260 ± 422*
Istant Ball Release				
Ball Relase velocity (m/s)	31.9 ± 1.9	30.5 ± 2.6	29.9 ± 1.7*	32.6 ± 2.3*
Arm Deceleration				
Max Ball Velocity (m/s)	35.3 ± 2.8	35.9 ± 2.8	32.9 ± 0.7*	37.0 ± 1.9*

ELITE ATHLETES EXHIBIT INCREASED VERTICAL FORCES DURING RUNNING AT DIFFERENT SPEEDS

Stephen J. Preece [1,*] Duncan Mason [1] Christopher Bramah [1]

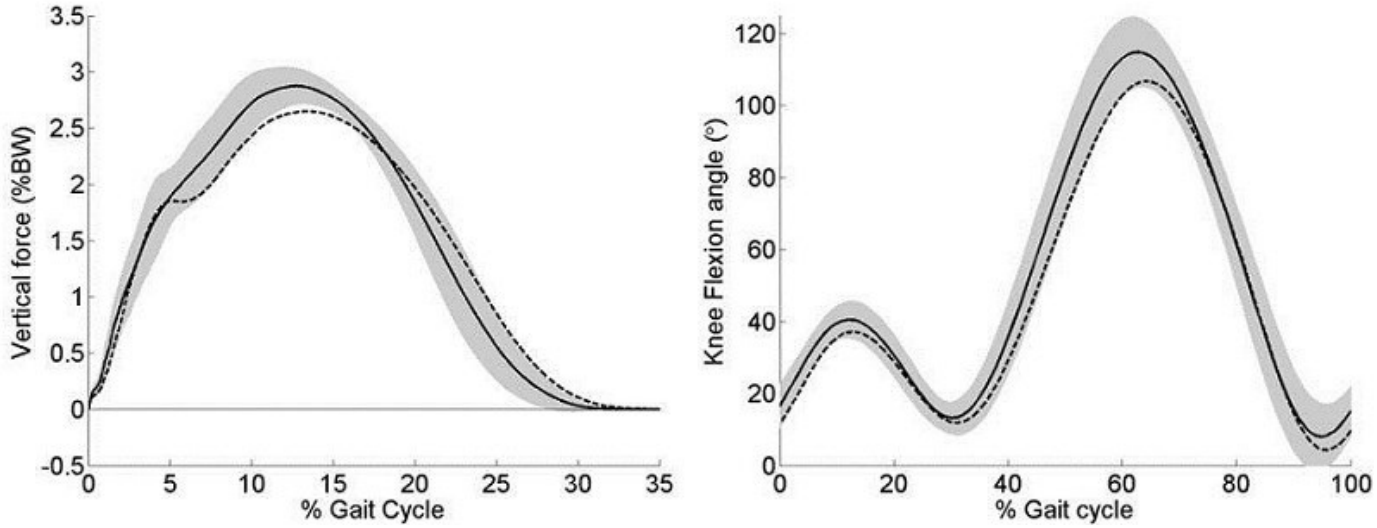
[1]Health Sciences, University of Salford, Manchester, United Kingdom

Introduction and Objectives: There has been comparatively little research carried out investigating the biomechanical characteristics of high-performing endurance elite athletes. As this group are able to maintain relatively high running speeds for long periods of time, it is likely that they have developed a running gait which is highly economical. However, there is disagreement in the literature between studies which have investigated the link between biomechanical variables and running economy. Specifically, some research has found that excessive changes in vertical momentum increase metabolic cost [1] whereas others have shown that greater vertical oscillation of the centre of mass is linked to a decrease in metabolic cost [2]. Interestingly Hiese et al [1] performed their experiments on recreational runners (10Km race times between 38-45 minutes), whereas Targuga et al [2] investigated higher level runners (10Km race times between 30-36 minutes). The different findings of these studies suggest that elite runners employ a running style which is distinctly different from that of recreational athletes. The aim of this study was therefore to compare the biomechanical characteristics between elite and recreational runners at a range of different speeds.

Methods: Fourteen elite endurance runners (8 male, mean(SD) BMI 20.6(1.9)) were matched with fourteen recreations runners (8 male, mean(SD) BMI 20.2(1.2)). To be included in the elite group, participants had to have achieved 10Km race time of less than 32 minutes (males) or less than 36 minutes (females) over the preceding 12 months. Runners in the recreational group were required to have a corresponding race time no better than 38 minutes (males) and 42 minutes (females). Both force data and kinematic data from the pelvis, lower limbs and feet were collected at four different speeds (3.2, 3.8, 4.8 and 5.5ms-1) as each participant ran along a 35m track. For each speed an ensemble average vertical force profile, normalised by body weight, was created from at least 5 separate running trials for each runner. Similarly, ensemble average kinematic profiles were calculated for the hip, knee and ankle and spatiotemporal parameters for each participant derived at each of the four speeds. Two-way ANOVA testing was then used to investigate the effect of both speed and also participant group (elite vs recreational) on a number of biomechanical parameters

Results: There were no differences in stride length between the two groups, however the elite athletes had consistently shorter stance times ($P<0.03$) across the different speeds. Visual inspection of the vertical ground reaction force (GRF) profile showed clear differences between the two groups which were evident at each of the four running speeds (Figure 1). The primary difference was the magnitude of the vertical GRF which lead to a net vertical impulse which was consistently higher in the elite group ($p<0.01$), indicating a greater range of motion of the centre of mass. The pattern of hip and ankle motion was very similar between the elite and recreational runners; however the pattern of movement at the knee showed a distinct difference at initial contact (Figure 1b). Specifically, at all speeds the athletes contacted the ground with a more flexed knee ($p<0.02$).

Figure:



Caption: Figure 1: (a) vertical ground reaction force and (b) knee flexion angle at 3.8 ms-1 (speed 2) for elite athletes (solid line with SD) and recreational runners (dashed line)

Conclusion: Our data supports the idea that elite athletes employ a running style which differs from recreational runners. This style is characterised by an increased net vertical impulse and therefore an increased vertical movement of the centre of mass. During the float phase of running, the centre of mass follows a ballistic trajectory and therefore increased vertical movement has the potential to increase stride length. However, stride length was not different between the two groups and this may have been the result of a more flexed knee configuration at contact in the elite group. Previous researchers have suggested that large changes in momentum during stance phase may lead to metabolically wasteful movement patterns [3]. However, it is possible that elite athletes are able to store energy from vertical momentum changes as elastic energy in the Achilles Tendon and to return this energy during later phases of the gait cycle. It is possible that optimal storage and return of this energy may be facilitated with a flexed knee configuration at initial contact.

AS-0064

COMPARISON OF SUBJECT-SPECIFIC TORQUE PROFILES OF ATHLETES BASED ON ISOKINETIC DYNAMOMETER DATA

Frederik Heinen [1,*] Mark King [2] Carsten Møller Mølgaard [3] John Rasmussen [4] Mark de Zee [1]

[1]Health Science and Technology, Aalborg University, Aalborg East, Denmark, [2]School of Sport , Exercise and Health Sciences, Loughborough University, Loughborough, United Kingdom, [3]Orthopaedic surgery, Aalborg University Hospital, Aalborg, [4]Department of Mechanical and Manufacturing Engineering, Aalborg University, Aalborg East, Denmark

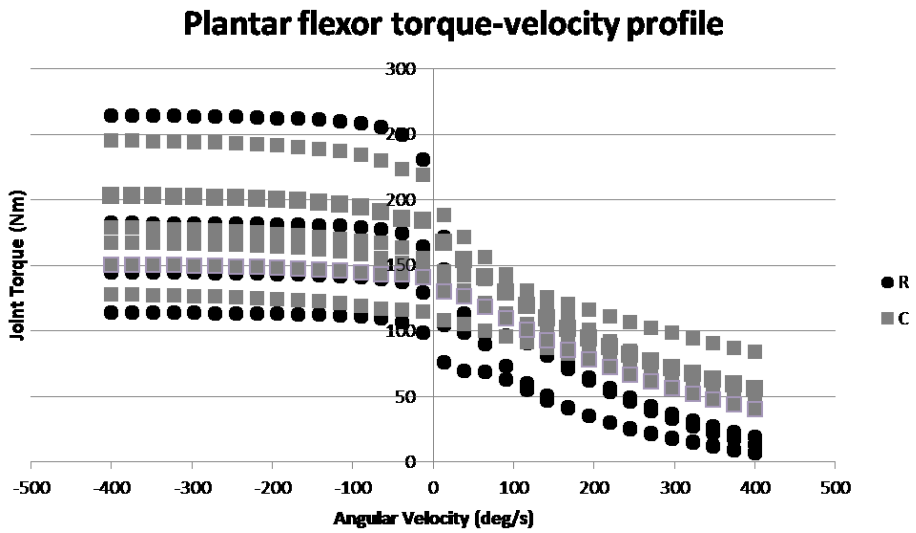
Introduction and Objectives: Isovelocity dynamometers are widely used to quantify strength properties of athletes, because the device allows collection of torque data for a joint at different angles, contraction types and velocities in a standardized manner [1]. The experimentally obtained joint torque data have been widely applied throughout literature, especially combined with torque-driven models, to generate subject-specific torque profiles and predict performance of an individual [2]. However, variation of the torque profiles amongst athletes that perform different types of lower extremity sport activities has not been well investigated. The aim of this study is to compare subject-specific torque profiles from runners and cyclists based on experimental torque data.

Methods: The experiment was conducted at two testing facilities on two different isovelocity dynamometers (Contrex multi-joint, CMV AG, Swizerland and Biodex System 4 Pro, Biodex Medical Systems, United States of America). Ten male athletes were included in this experiment. Four runners and six cyclists (body mass: 79.3kg ± 13.3, height: 1.79m ± 0.08). Isometric (five evenly spaced angles) and isokinetic (four-eight evenly spaced velocities) measurements were performed for the ankle, knee and hip flexors and extensors for the dominant leg. A similar dynamometer setup as proposed by Lewis et al. 2011 was adopted. All subjects attended a familiarization session and a testing session. Alignment of joint and dynamometer axes of rotation was performed carefully during submaximal loading. All dynamometer data was low pass filtered at 12 Hz by a fourth-order zero-lag Butterworth filter. Maximal isometric torque and corresponding joint angle were located. Isokinetic torques and angles were identified at isovelocity. Gravity correction was performed as recommended by the manufacturer's prior measuring. An optimization procedure (Simulated Annealing, [3]) was adopted to fit a nine parameter mathematical torque-angle-velocity profile to the subject-specific dynamometer data [4]. Bounds for the nine parameters were set based on literature. The objective function minimized the unbiased weighted root mean square difference between the calculated and measured isometric and isokinetic torque data as proposed by Lewis et al. 2011. The weighting encouraged the function to give a better fit with the larger torque measurements. As it was assumed more likely that the subject performed submaximal rather than supramaximal during the measurements.

Results: Only the plantar flexors optimization results are presented in the abstract. No clear difference was observed for maximal isometric torque and optimal joint angle between the two groups. However, differences in maximal contraction velocity between the cyclists and runners were observed. Large inter and intra group variability was likewise observed for the ankle plantar flexors as presented in figure 1 and table 1. Similar results were observed for the knee and hip flexors and extensors. Whether the results are influenced by usage of two different dynamometers could be argued. However, the same testing procedure was used as well as both dynamometers were calibrated as recommended by the

manufacturer prior to measurements thereby minimizing the effect. All measurements were included in optimization of the torque function approximation, including some submaximal measurements. It could be argued whether these measurements should have been excluded from the optimization. However, an objective exclusion criterion would be required to this end.

Figure:



Caption: Optimized torque-velocity profiles of all subjects at their maximal isometric joint torque angles for the ankle plantar flexor for (R) runners and (C) cyclists.

Conclusion: Differences between the optimal joint angle and maximal contraction velocity for runners and cyclists were observed. However, due to the limited number of participants in this study further investigation is needed in order to establish whether the difference is generic between athletes of different sports.

Table:

	Optimization runners (mean ± std)	Optimization cyclists (mean ± std)
Joint angle corresponding to Maximal isometric torque	32.4° ± 9.3°	33.6° ± 7.2°
Maximal isometric torque	189.9Nm ± 35.9Nm	172,0Nm ± 25,4Nm
Maximal contraction velocity	530.1°/s ± 40.6°/s	1280.4°/s ± 372.0°/s

Caption: Comparing plantar flexor data from optimized joint-torque profiles between runners and cyclists. A positive joint angle describing a more dorsi flexed ankle.

AS-0065

CAN COMPRESSION AID IN MAINTAINING JUMP PERFORMANCE OVER A FATIGUING PROTOCOL?

John W. Wannop [1,*]Marie Wolter [1]Nicole Schrier [1]Ryan Madden [1]Jay Worobets [1]Darren Stefanyshyn [1]

[1]Kinesiology, University of Calgary, Calgary, Canada

Introduction and Objectives: Recently, compression apparel has shown it can improve maximal effort, short duration performance [1,2]. While compression can improve short duration performance, it is unclear how compression influences longer duration performance. Therefore, the purpose of this study was to determine whether compression apparel could aid in maintaining jump height performance over a fatiguing protocol.

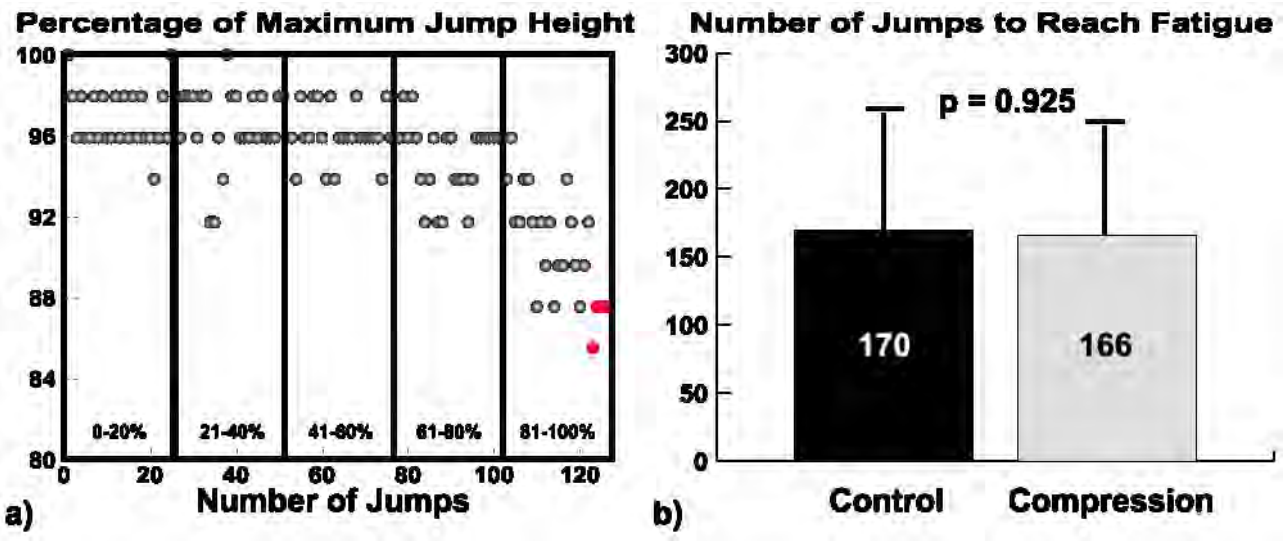
Methods: Twenty athletes participated in the study with Phase I determining each athlete's optimal compression using a previously established maximal effort jump test [2]. Phase II divided the athletes randomly into two groups, with one group performing in their optimal compression and the other in loose fitting shorts. During phase II, both groups performed maximal effort counter-movement squat jumps every twenty seconds until fatigue. An athlete was classified as fatigued if they could no longer maintain 88% of their maximum vertical-jump height. Kinematic (240Hz) and kinetic data (2400Hz) were collected during both phases with a motion capture system and a Vertec measuring jump height.

For phase I, the athletes jump height in their optimal compression was compared to the control using a paired t-test (α=0.05). For phase II, an independent t-test was used to compare the total number of jumps during the fatiguing protocol between groups (α=0.05). For kinematic and kinetic data analysis, the duration of each athlete's jumping protocol was divided into 5 sections, with each section representing 20% of the fatiguing protocol (Figure 1a). The initial 20% was used as the baseline and the difference in each variable relative to the baseline of the jumping protocol was compared for the subsequent sections between groups using a paired t-test with a Holm-Bonferroni sequential correction. If no differences were found between the two groups, additional analysis was performed by treating all athletes as a single sample. Comparisons were made using a paired t-test with a Holm-Bonferroni correction, on adjacent 20% sections of the jump decay curve.

Results: During phase I, optimal compression significantly increased the athletes maximum jump height (a mean 2cm increase, $p<0.001$). No difference in performance was seen during phase II between the 10 athletes who wore compression and the 10 athletes who wore the control (Figure 1b). No significant differences were observed for any of the variables for any joint when comparing the two groups.

Combining all athletes into a single group, a significant reduction in hip peak power and angular velocity at peak power occurred during 61-80% of the fatigue protocol ($p=0.0041$ and $p=0.0040$). A significant increase in the knee moment at peak power occurred during the 21-40% region ($p<0.001$) and a significant reduction of the ankle joint peak power ($p=0.0099$) and angular velocity at peak power ($p=0.003$) occurred during the fatigued state (last three jumps).

Figure:



Caption: a) Jump height decay curve of a representive athlete with the last points indicating fatigue b) the number of jumps of the Control and Compression groups before they reached fatigue.

Conclusion: The study indicated that compression does not increase long term jumping performance compared to a control. It should be noted that there were no negative effects of compression.

Both the hip and ankle joint limit athlete performance as fatigue progresses. When fatigued, athletes reduce their angular velocity at both joints, thereby reducing their power production and joint energy generated. The hip joint was affected earlier, and the athletes attempted to increase their knee joint moment and knee joint power to compensate. During the late stages of fatigue, the hip joint angular velocity continues to decrease, while the ankle joint angular velocity and peak power dramatically decrease, leading to the inability of the athlete to maintain performance.

In summary, compression increased initial maximum jump height and athletes maintained performance to a similar extent to loose fitting shorts during a fatiguing protocol, suggesting that compression is beneficial for athletes. With respect to fatigue, the hip joint angular velocity and power is affected first, while the ankle joint has a significant influence during the later stages of fatigue.

Table:

Joint		0-20%	21-40%	41-60%	61-80%	81-100%	Fatigue
Hip	Angular Velocity at Peak Power [°/s]	378	391	387	**362**	343	341

AS-0067

CAN PATELLOFEMORAL JOINT (PFJ) ALIGNMENT BE ASSESSED CLINICALLY USING A CUSTOM MADE CALLIPER?

Kevin D. Campbell-Karn [1,*] Thomas Korff [2] Ian McDermott [2]

[1]Faculty of Life Science and Computing, London Metropolitan University, London, [2]College of Health and Life Sciences, Brunel University, Uxbridge, United Kingdom

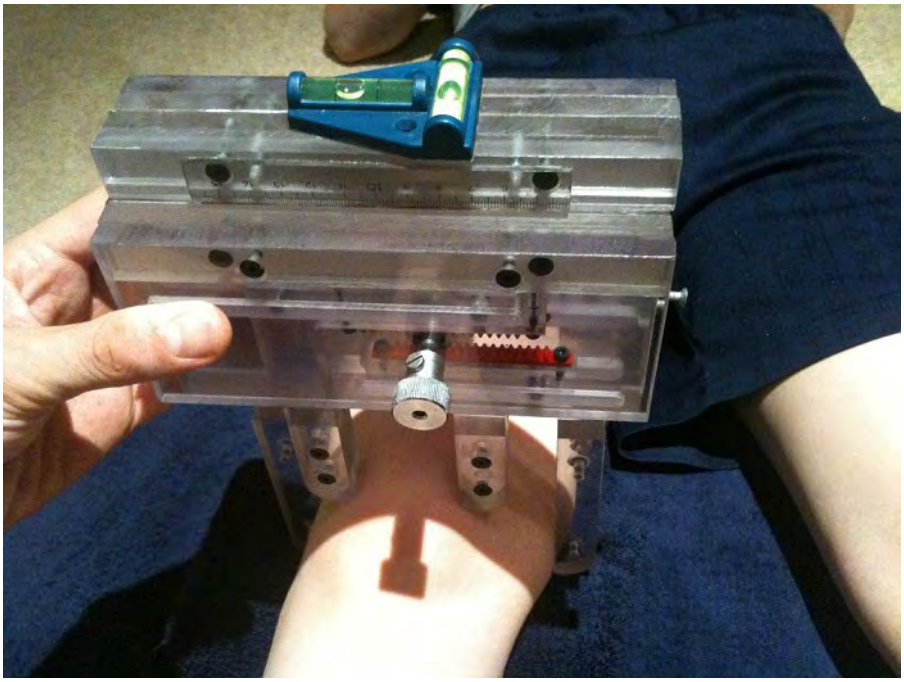
Introduction and Objectives: Knee problems are a common complaint among the general population with a high proportion of physical injuries being knee-related. Up to one in six knee related conditions have been coded as a 'patellofemoral condition' which includes anterior knee pain. However, anterior knee pain can have several causes. One common cause is mal-alignment of the patellofemoral joint (PFJ) and is considered as an abnormal static position of the patella within the trochlear groove during knee extension and flexion. This can cause undue stress to the joint and surrounding structures, with resultant damage and potential pathology. Mal-alignment of the PFJ causes patellar kinematic abnormalities predominantly in the last 20° of knee extension mainly due to the decreased congruency as the patella rises out of the trochlear groove in this range. Clinicians currently assess the alignment of the patella via measurement of the Q-angle, functional testing and the so-called McConnell technique. The latter was developed by McConnell and has been broadly adopted by the physiotherapy community when assessing and treating alignment of the patellofemoral joint. The goal of this method is to determine the centre of the patella in relation to the femoral epicondyles and is reliant on accurate localisation of the medial and lateral borders and the femoral epicondyles. Whilst the McConnell technique may be useful within a clinical context, this subjective measurement is reported to have limited reliabilityIt is clear therefore that there is a need for the position of the patella in relation to the femur to be determined more objectively and reliably. Therefore the purpose of this study was to assess the suitability and reliability of a custom-made 'patellofemoral tracking calliper' to assess the patellar position with resepct to the femur.

Methods: A calliper, which measures the medial-lateral offset of the middle of the patella with respect to the mid-point of the femoral epicondyles (Patellofemoral Tracking Calliper [PFTC]) was developed (Figure 1) and assessed for accuracy and reliability. To assess accuracy, 39 right knees were measured with the calliper and compared to the equivalent measures obtained from MRI images. For this purpose, the knee was placed in an MRI scanner with the tibiofemoral joint positioned in 30° of flexion and the rotation of the leg orientated by using a spirit level along the medial side of the foot. The knee was supported with wedges and strapped to the MRI table in this position to prevent any deviation from the desired orientation. This position was replicated for measurements with the PFTC. During MRI analysis, the midpoint of the femoral epicondyles was defined as the half distance between the widest epicondyle points and the mid-point of the patella was defined as the half distance between the widest medial and lateral borders of the patella. This followed the same measurement methods as the PFTC, however this device used these landmarks via physical contact from the calliper arms.

Thus, both the PFTC and the MRI equivalent provided information about the superficial position for the patella with respect to the femur. To assess agreement between both methods, the Pearson product moment correlation coefficient was determined, and the Bland and Altman limits of agreement test was used to assess bias and limits of agreement. Each calliper measure was taken three times, and the reliability of the PFTC was assessed using intra-class correlation coefficients (ICC).

Results: The patellofemoral tracking calliper was highly reliable (ICC=0.990-0.991). The limits of agreement with regards to the MRI equivalent method were ±8 mm. The Bland and Altman plot highlighted a systematic bias of 2 mm. The calliper measures correlated significantly with the MRI equivalent method ($r = 0.675$, $p = 0.001$).

Figure:



Caption: Figure 1. Application of the Patellofemoral Tracking Calliper

Conclusion: The patellofemoral tracking calliper is a useful tool, where the reliable assessment of patella position with respect to the femur is needed. The superficial landmarks of the patella and femur require further investigation into their accuracy in providing true alignment outcome measures of the patellofemoral joint. The McConnell method for assessing alignment may have questionable methods when the anatomical shape and interaction of the joint surfaces is considered alongside the data presented here.

FEASIBILITY AND RELIABILITY OF THREE-DIMENSIONAL ULTRASOUND FOR MEASURING HUMAN TIBIALIS ANTERIOR MUSCLE DEFORMATION DURING ISOMETRIC CONTRACTIONS

Brent Raiteri [1,*] Andrew Cresswell [1] Glen Lichtwark [1]

[1] School of Human Movement and Nutrition Sciences, The University of Queensland, Brisbane, Australia

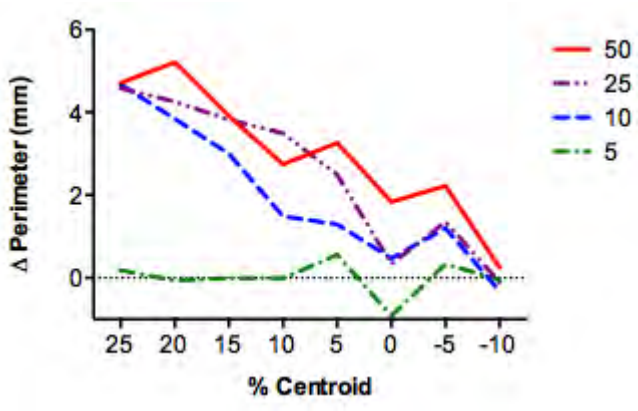
Introduction and Objectives: The deformation of muscle during contraction can potentially influence the length changes of the contractile and connective tissues. In pennate muscle, biaxial strain of the aponeurosis has been suggested to be an important parameter influencing muscle force production [1]. However, due to the difficulty in measuring deformation in muscle during contractions, these effects have not been measured in human muscles. Freehand three-dimensional ultrasound (3DUS) is a reliable and valid technique for the *in vivo* measurement of human gastrocnemius muscle belly length and volume [2] and could potentially be used to examine biaxial aponeurosis strains in humans during contractions. This study aims to determine the feasibility and reliability of 3DUS for examining *in vivo* tibialis anterior (TA) muscle deformation during voluntary isometric contractions (VIC) at varying intensities.

Methods: Subjects (n = 6) were seated in a reclined position with the plantar aspect of their left foot flush against a custom-built rigid footplate. The left ankle was at 90° (foot sole relative to the shank) and the left knee fully extended. After pre-conditioning contractions, subjects performed two ~40-s isometric dorsiflexion contractions at 5, 10, 25 and 50% maximal VIC in a randomised order. 3DUS scans of TA were performed at each contraction intensity and also at rest. The 3DUS scan involved synchronous B-mode ultrasound imaging and motion capture of the position and orientation of the transducer, while successive cross-sectional slices of the muscle were made whilst sweeping the transducer from the proximal to distal end of the muscle. Freely available software (Stradwin, Cambridge University) was used to collect and analyse all data. Muscle cross-sectional area was segmented from sequential transverse images of the scan at ~15 mm intervals along the length of TA. Muscle volume was calculated using 3D rendering algorithms and muscle and central aponeurosis lengths were calculated as the straight-line distance between the most proximal and distal locations in 3D space. The principal muscle axes (x, y and z) were determined using a weighted principal component analysis. The muscle cross-sectional area and perimeter in the transverse plane (x-axis) was calculated at 5% increments of the muscle belly length from the muscle centroid. All measures were averaged across two scans from the same contraction condition and the intra-class coefficient (ICC) and coefficient of multiple correlation (CMC) was used to assess intra-session repeatability of the measurements.

Results: The intra-session ICCs for muscle volume and muscle and central aponeurosis lengths were greater than 0.99. Muscle cross-sectional area and perimeter along the transverse plane was highly repeatable, with overall CMC values of greater than 0.99.The TA remained iso-volumetric across the contraction conditions and the muscle was found to shorten and the central aponeurosis shown to lengthen as contraction intensity increased. Muscle and central aponeurosis strain peaked at -2.9 ± 0.1% and 3.1 ± 0.4% respectively (mean ± standard error) in the 50% maximal VIC condition. The TA cross-sectional area in the transverse plane progressively increased around the muscle belly centre with increased contraction intensity, peaking at 99 ± 22 mm^2 (9.8% increase), in the 50% maximal VIC condition. The transverse muscle

perimeter also increased with contraction intensity, peaking at 5.2 ± 1.2 mm (5.6% increase), although this peaked distal to the muscle belly centre (Figure 1).

Figure:



Caption: Figure 1: Mean tibialis anterior (TA) perimeter changes from rest along the transverse plane at 5, 10, 25 and 50% of maximal voluntary isometric contraction (VIC). Negative percentages are proximal to the muscle centroid.

Conclusion: This study is the first to implement 3DUS to characterize *in vivo* muscle deformation in the human TA muscle. The TA muscle bulged centrally, orthogonal to the line of action of the muscle as contraction intensity increased. This occurred presumably because of the transverse strain present in the muscle fibres as they shortened and were constrained to maintain a constant volume. These shape changes are likely to represent variable aponeurosis strains in the transverse plane with regional differences in aponeurosis compliance.

3DUS of the TA is a feasible and reliable technique for measuring muscle volume, muscle and central aponeurosis lengths and muscle cross-sectional area and perimeter along the transverse plane during contractions. We have demonstrated that as fibres develop force, the central aponeurosis of the muscle acts like a serially arranged elastic spring and the transverse muscle perimeter increases most in the distal muscle belly. How these deformations influence storage and return of energy in the aponeurosis (which constrains the shape changes of muscles) requires further investigation.

INFLUENCE OF STRIKE PATTERN ON BIOMECHANICS ASSOCIATED WITH TIBIAL STRESS FRACTURE IN FEMALE RUNNERS

Clare E. Milner [1,*] Richard A Brindle [1]

[1]Physical Therapy and Rehabilitation Sciences, Drexel University, Philadelphia, PA, United States

Introduction and Objectives: Tibial stress fracture is a common overuse injury in female runners and requires an extended recovery time for the bone to heal [1]. Previous work has identified biomechanics associated with tibial stress fracture in female runners with a rearfoot strike pattern [2]. Large peaks in rearfoot eversion angle, hip adduction angle, and absolute free moment were predictive of previous tibial stress fracture [2]. While a rearfoot striking is the most common pattern in distance runners, recent interest has focused on non-rearfoot strike patterns. In particular, it has been suggested that non-rearfoot strike patterns may reduce the risk of overuse injury in runners [3]. The effect of strike pattern on the biomechanical variables associated with tibial stress fracture is unknown. Thus, the purpose of this study was to determine whether the magnitude of these variables differ between healthy female runners who are habitual rearfoot and non-rearfoot strikers. We hypothesized that peak rearfoot eversion angle, peak hip adduction angle, and absolute peak free moment would be smaller in non-rearfoot strikiers compared to rearfoot strikers.

Methods: As part of an ongoing study, female runners between 18 and 45 years of age running at least 10 miles per week for a year or more were recruited. All participants provided written informed consent prior to participation and all procedures were approved by the institutional review board. Fourteen participants were recruited, 7 rearfoot strikers (26 ± 5 y; 55.2 ± 7.1 kg; 1.64 ± 0.08 m; 24 ± 11 miles per week) and 7 non-rearfoot strikers (28 ± 6 y; 59.7 ± 15.4 kg; 1.67 ± 0.07 m; 23 ± 14 miles per week). Participants wore standard laboratory footwear and retroreflective markers were attached to the pelvis and right lower limb. Three-dimensional gait analysis was conducted while participants ran over ground in the laboratory at 3.7 m/s ± 5 %. Segment position and ground reaction force data were recorded synchronously for five trials. Kinematic data were filtered at 8 Hz and processed using rigid body analysis and joint coordinate systems, following standard procedures [4]. Ground reaction force data were filtered at 50Hz for the determination of free moment. Foot strike pattern was determined from strike index, with values of ≤ 0.33 indicating rearfoot strikers and larger values indicating non-rearfoot strikers. Variables of interest were extracted from each trial and averaged per participant, then within each strike pattern group. Independent t-tests were used to identify any differences between groups, with $p < 0.05$ considered significant.

Results: Both peak rearfoot eversion angle ($P < 0.001$) and peak hip adduction angle ($p = 0.003$) were significantly smaller in the non-rearfoot strikers compared to the rearfoot strikers (Table 1). However, absolute peak free moment ($p = 0.664$) was not different between groups.

Conclusion: The two kinematic variables of interest, peak rearfoot eversion angle and peak hip adduction angle, were both smaller in the non-rearfoot strikers. Our finding of smaller peak rearfoot eversion angle in non-rearfoot striking runners compared to rearfoot strikers is in agreement with previous work [5]. Peak hip adduction angle and absolute peak free moment differences between these groups have not been reported previously. These kinematic differences provide

initial evidence to support adoption of a non-rearfoot strike pattern by rearfoot striking female runners at risk of tibial stress fracture. In particular, female rearfoot strikers with large rearfoot eversion and hip adduction angles may benefit from switching to a non-rearfoot strike pattern. However, it should be noted this study was cross-sectional and identified group differences in kinematics associated with tibial stress fracture in currently healthy runners. Future work should explore gait retraining protocols to assist rearfoot striking runners with aberrant kinematics in transitioning to a non-rearfoot strike pattern, and monitor injury incidence. In summary, non-rearfoot striking female runners have smaller peak rearfoot eversion and peak hip adduction angles, but similar absolute peak free moment compared to rearfoot striking female runners.

Table: Table 1: Mean (standard deviation) for variables of interest in each foot strike pattern group

	Peak rearfoot eversion angle (degrees)	Peak hip adduction angle (degrees)	Absolute peak free moment ($x10^{-3}$)
Rearfoot strikers	7.8 (1.7)	16.9 (2.7)	5.4 (2.9)
Non-rearfoot strikers	3.0 (1.6)	11.2 (3.0)	6.1 (2.4)

DIFERENCES IN GLOBAL GAIT ASYMMETRY BETWEEN KNEE OSTEOARTHRITIS PATIENTS AND HEALTHY ADULTS

Silvia Cabral [1,*] W. Scott Selbie [2] Rita Fernandes [1 3] Flávia Yázigi [1] Vera Moniz-Pereira [1] Paulo A. Armada-da-Silva [1] Margarida Espanha [1] António P. Veloso [1]

[1] Laboratório de Biomecânica e Morfologia Funcional, U Lisboa, Faculdade de Motricidade Humana, CIPER, P-1499-002 Lisboa, Portugal, [2] HAS-Motion, Inc., Kingston, ON, Canada, [3] Departamento de Fisioterapia, Escola Superior de Saúde, Instituto Politécnico de Setúbal, Setúbal, Portugal

Introduction and Objectives: Research suggests that the gait alterations associated with knee osteoarthritis (KOA) possibly lead to between-limb asymmetries [1]. Consequently, the load is distributed unequally between the weight bearing joints, which in turn may increase the risk of developing multi-articular lower limb osteoarthritis [1-2].

Between-limb asymmetries have been reported in KOA patients. However, the asymmetry is often measured using discrete and local parameters. By using discrete parameters, the temporal information of the gait waveform is neglected, which means that potentially important asymmetries that are due to time shifts or that occur outside the chosen time frame could be missed [3-4]. Additionally, the extraction of discrete parameters is subjective and potentially difficult in atypical waveforms such as those of KOA patients [3]. Using local parameters, several values are needed to capture the global aspect of gait asymmetry and to assess the influence of specific interventions, which may lead to results that are difficult to interpret [5]. Conversely, the strength of global symmetry measures composed of continuous variables is their ability to reduce all the information from various local parameters throughout the gait waveform in one score.

The aim of this study was to determine if the global gait asymmetry score of a group of KOA patients was different from that of a healthy control group. Our hypothesis was that patients with KOA are more asymmetric than the healthy participants.

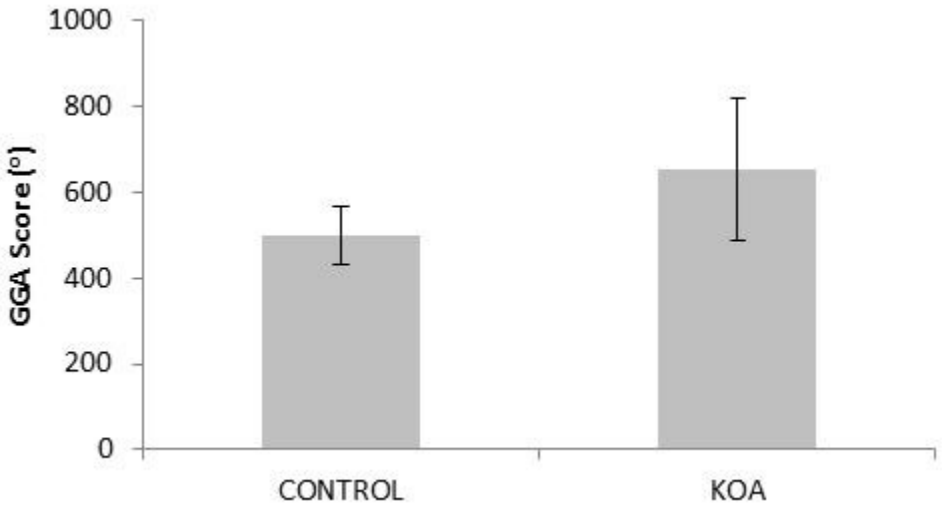
Methods: Subjects were divided in 2 groups: 14 were healthy controls (4 male, age 38.1 ± 11 years, height 1.54 ± 0.44 m, body mass 64.6 ± 10.8 Kg), who were free from any musculoskeletal pathology, and 14 were diagnosed with clinical plus radiographic KOA (3 male, age 58.2 ± 6.1 years, height 1.57 ± 0.07 m, body mass 86.6 ± 15.3 Kg).

Participants walked along an 8 m walkway at their self-selected comfortable speed. Passive markers were placed on the participants' skin, according to the calibrated anatomical system technique [6]. The 3D coordinates of these markers were collected at 200 Hz using a system with 8 high speed infrared cameras (Oqus 300, Qualisys AB, Gothenburg, Sweden), were low-pass filtered using a 4th order Butterworth filter with a cut off frequency of 10Hz and were used to create a model with 7 segments (feet, shanks, thighs and pelvis), each with 6 degrees of freedom. Joint angles were computed into the joint coordinate system [7]. The 3D joint angles of the hip, knee and ankle and the 3D absolute pelvis angle were normalized in time to the gait cycle. The global gait asymmetry (GGA) score was calculated for each cycle, by integrating the squared differences between the right and left time normalized signals, taking the square root, and adding them across all 12 variables. Thus, higher scores represent greater asymmetry levels. All data processing and model building were done in Visual3D (Version 5.01.18, C-Motion, Inc, Rockville, USA).

The GGA scores (average of 3 cycles) of the control and KOA groups were compared using an independent T-test (IBM SPSS Statistics 21, Inc. Chicago, Illinois, USA) with an alpha of 0.05. This analysis was complemented with an effect size and power analysis (G*Power 3.1.7 [8]). Data were checked for normality and presence of outliers prior to analysis.

Results: The statistical analysis shows that the KOA group had significantly higher GGA scores than the control group [mean (± SD): KOA 604 (±101º), Control 511 (±65 º)].

Figure:



Caption: Global Gait Asymmetry (GGA) score of Control and Knee OA (KOA) groups

Conclusion: As hypothesized, the overall level of asymmetry of a group of KOA patients was significantly higher than that of a group of healthy controls. Due to the different nature of the groups, further studies are needed to analyze if the asymmetry score is influenced by group characteristics other than the presence of KOA. Moreover, the variables that compose the GGA score could be selected and normalized according to their relevant contribution to the final score, so that it is better tuned to analyze gait asymmetry in KOA.

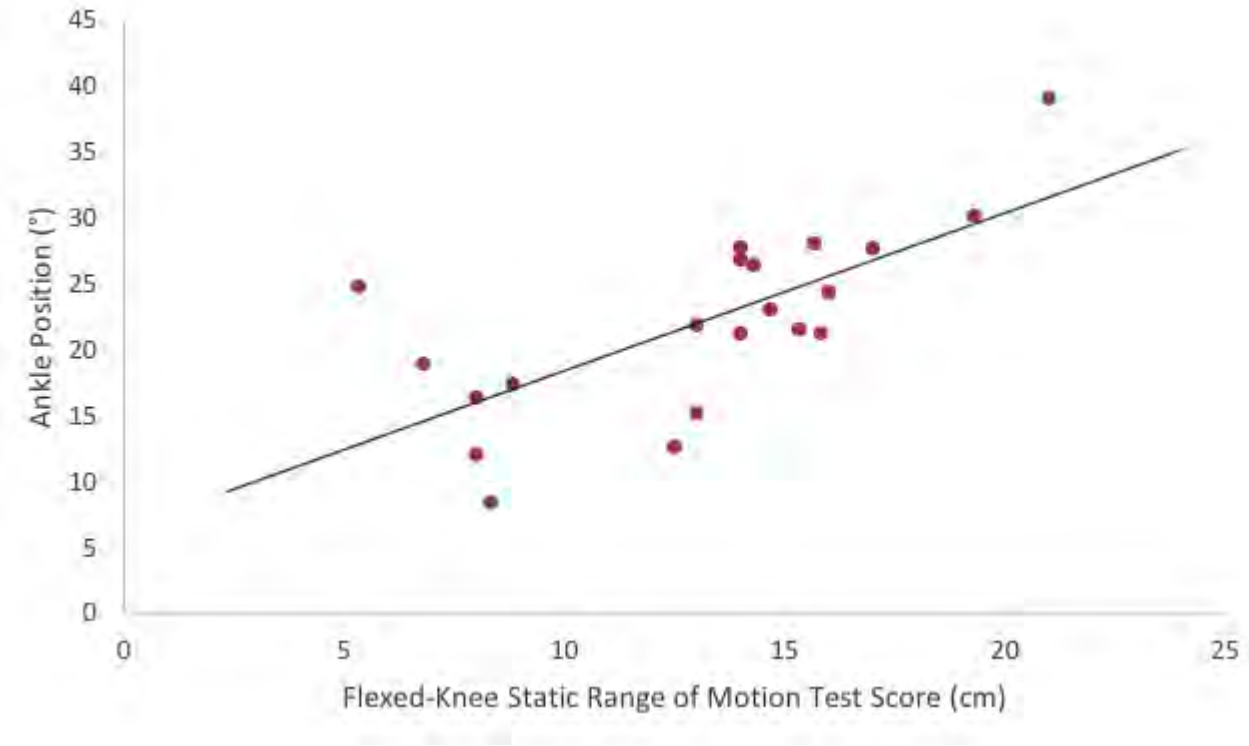
STATIC ANKLE RANGE OF MOTION IS ASSOCIATED WITH DYNAMIC ANKLE MOTION DURING A SURF-LIKE SIMULATED AERIAL TASK

James R. Forsyth [1,*]Diane L. Riddiford-Harland [1]Lina Lundgren [2]John W. Whitting [3]Jeremy M. Sheppard [2]Julie R. Steele [1]

[1]Biomechanics Research Laboratory, University of Wollongong, Wollongong, [2]School of Exercise & Health Science, Edith Cowan University, Joondalup, [3]School of Health & Human Sciences, Southern Cross University, Lismore, Australia

Introduction and Objectives: During surfing competitions, a judging panel scores surfers according to how they perform manoeuvres on a wave. Points are awarded for speed, power and flow, as well as innovation and risk-taking. Consequently, surfers who include dynamic, innovative and risky manoeuvres such as aerials, where surfers project themselves into the air before landing on the water, receive higher scores, on average, than those who only perform turns [1]. Aerial manoeuvres, however, have been associated with increased lower limb injury [2]. In land-based sports, utilising a greater ankle range of motion (ROM) over which to distribute the impact forces generated during landing is thought to reduce the risk of lower limb injury at foot-ground contact [3]. However, whether surfers use a large ankle ROM when landing aerials is unknown. Therefore, the purpose of this study was to: (i) identify the dynamic ankle motion used during landing a simulated aerial task, and (ii) evaluate the association between static ankle ROM and dynamic ankle motion.
Methods: A twin-axis electronic goniometer (Model SG110; Biometrics Ltd, UK) was used to measure dynamic sagittal and frontal plane ankle motion during repeated trials of a simulated aerial task for the trail limb of 21 consenting skilled surfers (age = 19.7 ± 4.4 years, height = 179.0 ± 7.6 cm, mass = 70.3 ± 10.2 kg, surfing experience = 12.4 ± 4.6 years). The simulated aerial task required each participant to run at a self-selected pace parallel to a thick padded landing mat (305 x 1740 x 3650 mm), jump onto a mini trampoline, and project themselves up into the air. Once airborne the participants rotated 90 degrees while positioning a soft-top surfboard (with the fins removed) under their feet, before landing on the board (and the padded landing mat), and then held a stabilised landing position for 3 seconds. Static flexed-knee ankle joint ROM was characterised using the knee-to-wall test [4]. Pearson product moment correlations were used to determine the strength of the associations between the participant's static ankle joint ROM and a dynamic ankle motion quantified during landing the simulated aerial task ($p \leq 0.05$).
Results: At initial board-mat contact, participants displayed slight plantar flexion (2.6 ± 9.7°) combined with an inverted foot position (4.0 ± 4.2°). By the Stabilisation phase of landing, the participants displayed a dorsiflexed ankle (22.1 ± 7.1°) with a neutral foot posture in the frontal plane (0.7 ± 5.8°). The greatest ankle joint range of motion was displayed during the Absorption phase (29.3 ± 7.0°; a phase during which the participants were flexing their lower limb joints to absorb the forces generated following initial board-mat contact), relative to both Pre-Landing and Stabilisation. The greatest peak dorsiflexion angle, however, was displayed during the Stabilisation phase of landing (20.6 ± 6.4°). Static flexed-knee ankle ROM was significantly correlated with peak dorsiflexion during Stabilisation ($r = 0.70$, $p < 0.001$; see Figure 1) and total sagittal ankle displacement during Absorption ($r = 0.60$, $p = 0.004$).

Figure:



Caption: Figure 1. Correlation between static flexed-knee ankle ROM test score (cm) of the trail limb and the ankle position at Stabilisation (°) during the simulated aerial task

Conclusion: Compared to previous data published on fixed-ground landing tasks [5], the participants' ankle plantar flexion was somewhat restricted by the surfboard prior to initial board-mat contact. Furthermore, those participants who had a limited static ankle ROM displayed a stiffer landing style. It is postulated that this stiffer landing technique is likely to increase ankle and knee joint loading when landing a simulated aerial task. It is therefore important that surfing athletes incorporate lower limb flexibility training, particularly soleus muscle extensibility activities to increase their static ankle ROM and, in turn, improve their dynamic ankle ROM when landing.

IMPACT OF RELIABILITY ON REPEAT KNEE EXTENSOR STRENGTH TESTING

Jamie E Hibbert [1,*] Patrick M Rider [1] Zachary J Domire [1]

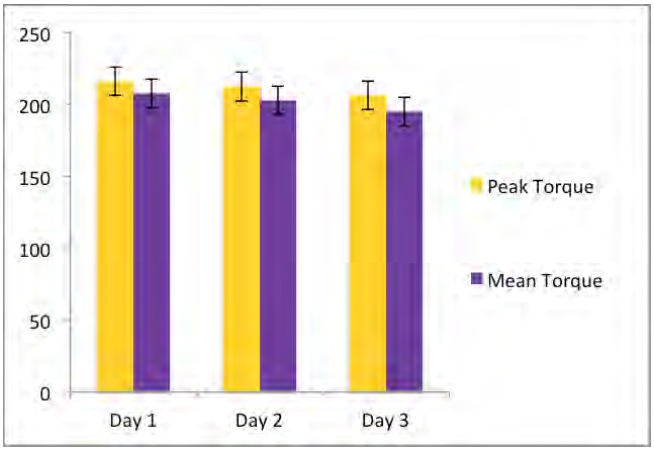
[1]Kinesiology, East Carolina University, Greenville, United States

Introduction and Objectives: Maximal strength testing is a commonly used method in both biomechanics research and clinical assessments of muscle and joint function [4]. The reliability and validity of different types of dynamometers have been shown to be acceptable in previous studies [1,2,5]. However, when testing human participants there are other factors that may cause variability in strength measurements, such as sincerity of effort and familiarization with both the equipment and environment. It is common for researchers to bring participants in for a familiarization session prior to beginning true data collection for their study [3]. The purpose of this study was to determine the effect of repeat testing on peak torque, mean torque and variability between trials. We hypothesized that peak torque and mean torque would be higher and less variable the second and third test days than on the first test day.

Methods: Twenty-five healthy, young (age 21.3±3) participants (13 males, 12 females) reported to the biomechanics lab for maximal isometric strength testing three times. Each participant completed all three visits within 7 days of beginning the protocol. Prior to each testing session, participants completed a 5-minute warm-up on a cycle ergometer. Participants then completed 3 maximal isometric voluntary contractions (MVICs) of the right knee extensors with the knee in 90° of flexion using a HUMAC isokinetic dynamometer (HUMAC NORM Testing & Rehabilitation System, CSMI Medical Solutions, Stoughton, MA). Participants were given two trial repetitions prior to the test each day for familiarization purposes. Consistent verbal encouragement by the researcher was provided during each testing session. The data collected were analyzed for peak torque produced by each subject on each day as well as the mean torque produced over the three maximal trials. The standard deviation was also calculated to determine variance between trials. Paired two tailed t-tests were used to evaluate the statistical differences in the data. A p-value of 0.05 was set as the cut off for significance. All procedures were approved by the Institutional Review Board and written informed consent was obtained from each participant prior to the start of testing.

Results: The values for the average peak torque, average mean torque, and average standard deviation were compared between the different days of testing using a 2-tailed paired t-test. It was found that there was a statistically significant decrease in the average mean torque between day 1 and day 3 ($p<0.05$) and the difference in the average peak torque ($p=0.078$) and average standard deviation ($p=0.060$) trended in the same direction. The differences in the values from day 1 to day 2 were not statistically significant. The statistical values for average mean torque, average peak torque and average standard deviation were $p=0.430$, $p=0.524$ and $p=0.501$, respectively. The differences in the values from day 2 to day 3 were also not statistically significant. The statistical values for average mean torque, average peak torque and average standard deviation were $p=0.354$, $p=0.180$ and $p=0.163$, respectively.

Figure:



Conclusion: Based on the data collected, healthy, young adults are able to produce peak knee extensor torques on the first day of MVIC testing that is not different from those produced on the second day of testing and are greater than those produced on day 3. These results are the opposite of the hypothesized results. It is possible that the decreased MVIC torque output from day 1 to day 3 could be a result of lingering fatigue from the previous sessions, however this seems unlikely due to the small number of repetitions performed. The increase in variability observed on day 3 may indicate that maximal effort was not being expended. It is possible that some participants were too comfortable with the protocol by the third day and this may have decreased their desire to perform at their true maximum effort. These results indicate that when young, healthy participants are involved in a study it may not be necessary to have a familiarization day prior to beginning testing or if the researcher does bring participants in prior to beginning the study it may be beneficial to have the participant engage in sub-maximal training trials. These results highlight the need to develop a method to control for participation motivation and sincerity of effort. One such method could involve superimposition of electrical stimulation during MVIC.

Table:

	Average Peak Torque (Nm)	Average Mean Torque (Nm)	Average Standard Deviation (Nm)
Day 1	216.32	207.59	8.79
Day 2	212.40	203.04	9.63
Day 3	206.56	194.92	11.47

THE EFFECT OF PROPHYLACTIC KNEE BRACING ON LOWER-LIMB MUSCLE FORCES DURING DOUBLE-LEG DROP LANDING

Katie Ewing [1,*] Rezaul Begg [2] Peter Lee [1]

[1]Mechanical Engineering, University of Melbourne, [2]Institute of Sport, Exercise and Active Living, Victoria University, Melbourne, Australia

Introduction and Objectives: Anterior cruciate ligament (ACL) injuries, which account for the majority of sports-related injuries, are painful, costly, and debilitating to the injured athlete. Non-contact ACL injuries often occur during landing, which is frequently performed in sporting activities. Some athletes wear prophylactic knee braces to help prevent knee injury, but the evidence support or discouraging knee bracing is conflicting [1]. Previous studies have found differences in kinematics [2] and electromyography (EMG) muscle activity [3] between braced and non-braced athletes, suggesting that bracing alters neuromuscular control. Computer-based musculoskeletal models provide a means to quantify muscle contributions to complex movements in more detail compared to EMG alone. During impact loading, muscle forces could explain the resulting tension on the ACL that can lead to rupture [4], thus providing critical information for improved injury prevention methods. To further quantify changes in muscle function due to knee bracing, the purpose of this study is to calculate and compare lower-limb muscle forces in braced and unbraced recreational athletes during a double-leg drop landing task.

Methods: Four participants who regularly participate in a landing sport have undergone testing in the Gait Analysis Laboratory at Victoria University (Melbourne, Australia). A motion analysis system consisting of ten optical infra-red cameras (500 Hz; VICON Mx, Oxford Metrics, UK) collected the three-dimensional kinematic data from 54 retro-reflective markers, while two synchronized force plates (1000 Hz, AMTI, USA) simultaneously recorded ground reaction forces. Each participant was instructed to step off a 60 cm platform with his or her dominant leg and land barefoot onto the force plate using both legs. The landing phase was defined as the duration from foot strike to maximum knee flexion angle. Subject-specific musculoskeletal models (31 degrees-of-freedom, 92 musculoskeletal tendon units) were developed in OpenSim, an open-source 3D musculoskeletal modeling software [5]. Inverse kinematics calculated the joint angles that best matched the experimental marker trajectories. A unique solution of individual muscle forces was solved via static optimization by minimizing the sum of the squares of muscle activations. It was assumed that the effect of bracing was expressed in the experimental data and thus knee brace forces and elements were not included in the simulations. The average of three trials for each condition was used for analysis. Forces were normalized to body weight (B.W.).

Results: Prophylactic knee bracing did not alter the peak vertical ground reaction force (GRF) (2.16±0.40 B.W. with brace vs. 2.15±0.32 B.W. without brace). The time of peak GRF during the landing phase was slightly increased with bracing (18.89±5.06% with brace vs. 16.16±3.51% without brace). There was also a small change in the maximum knee flexion angle (97.60±11.86 degrees with brace vs. 99.32±13.12 degrees without brace). Table 1 presents the peak force of the major muscle groups with and without bracing. Generally, slight increases in peak forces of the quadriceps, gastrocenemii, and soleus muscles were observed with bracing. The medial hamstrings were the only muscle group that

demonstrated a decrease in peak force with bracing. These results suggest that knee bracing may have a negative consequence on the knee joint during landing since the quadriceps, which produce much greater force than the hamstrings, can increase stresses in the ACL, while the hamstrings provide a protective effect. However, the large forces produced by the soleus muscle could help to protect the ACL by generating a posterior tibial force [6].

Conclusion: The usefulness of prophylactic knee braces during sporting activities remains under debate. This study provides a more quantitative assessment of the effectiveness and mechanism of knee bracing by examining changes in muscle forces during landing. To further investigate the significance of bracing on muscle function, a total of twenty participants will be tested, followed by rigid body modeling and statistical analyses.

Table:

	Medial Hamstrings	*Lateral Hamstrings*	*Rectus Femoris*	*Vastus Medialis*	*Vastus Intermedius*	*Vastus Lateralis*	*Medial Gastroc*	*Lateral Gastroc*	*Soleus*
No Brace	0.89 ±0.34	1.59±0.19	1.54±0.08	1.62±0.30	1.63±0.23	3.11±0.52	1.15±0.08	0.25±0.02	4.66±0.76
Brace	0.83±0.21	1.70±0.14	1.66±0.66	1.78±0.30	1.76±0.25	3.41±0.55	1.27±0.16	0.28±0.04	4.71±1.10

ACCURACY OF THE KNEE JOINT AXIS ORIENTATION AGAINST FREEHAND 3D ULTRASOUND

Elyse Passmore [1 2 3,*] Marcus Pandy [2] H Kerr Graham [3 4 5] Morgan Sangeux [1 2 3]

[1]The Hugh Williamson Gait Analysis Laboratory, The Royal Children's Hospital, [2]Mechanical Engineering, The University of Melbourne, [3]Gait Lab and Orthopaedics, The Murdoch Childrens Research Institute, [4]Orthopaedics, The Royal Children's Hospital, [5]Paediatrics, The University of Melbourne, Melbourne, Australia

Introduction and Objectives: Inaccurate identification of the knee joint axis leads to cross-talk and influences the hip rotation profile. The influence on hip rotation is particularly important when utilised to assess patients for de-rotation osteotomies. No gold standard exists for defining the knee axis making it difficult to evaluate previous methods. Initially the knee axis was assumed to be coincident with the trans-epicondylar axis. However, 3D imaging techniques suggest the axis is aligned with the posterior aspect of the condyles [1]. Conventional methods rely upon manual palpation or visual alignment. Another approach is functional methods which rely upon joint range of motion movements to determine the axis. Ultrasound imaging of musculoskeletal structures coupled with motion capture [2] has previously been used for identification of the hip joint centre [3]. In this study 3D ultrasound has been used to locate the most posterior aspect of the femoral condyles as the anatomical knee axis. The aim was to quantify the accuracy of conventional and functional methods to locate the knee axis.

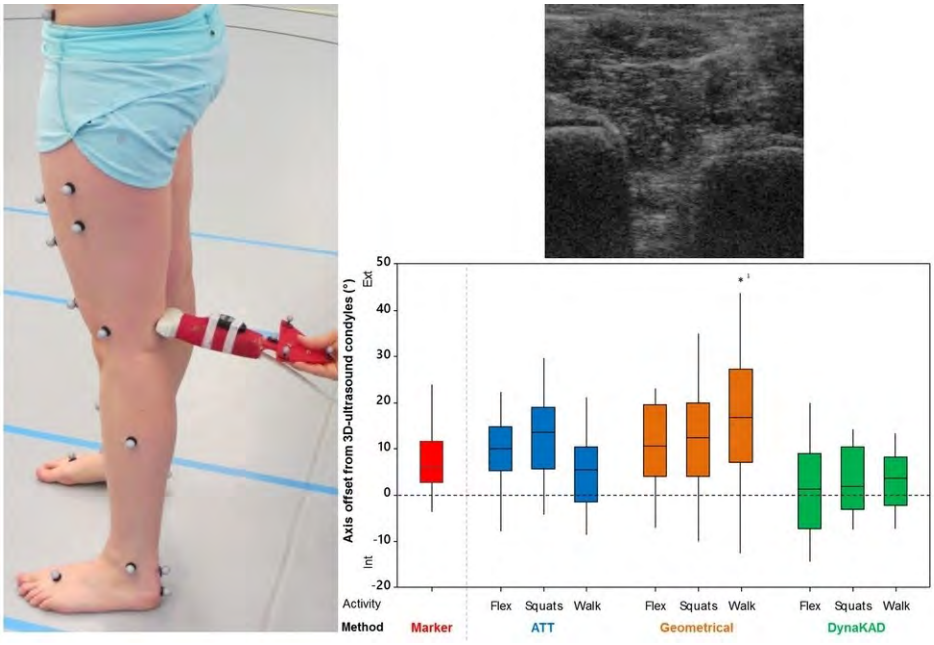
Methods: Ten healthy adults (5♂, 5♀) with no history of gait pathology gave written informed consent to participate in this study. Approval was granted by the ethics committee of the local institute. Reflective markers were attached to the subject according to the Plug-in-Gait marker set ([4], Vicon Motion Systems). Subjects walked up and down a walkway at a self-selected speed. A 10-camera motion-capture system (Vicon Motion Systems) and 5 force platforms (ATMI, Advanced Mechanical Technology, Inc) were used to measure the subjects' kinematics and kinetics.

The knee axis was determined using a conventional, marker based method through manual palpation of the epicondyles and three functional methods; the axis transformation technique (ATT or SARA) [5], the geometrical method [6] and a method closely related to the dynamic KAD (DynaKAD) [7,8]. For the ATT and geometric methods only frames where knee flexion was between 20°-90° were used to determine the axis. The functional methods were applied to various activities; three open chain active knee flexion-extensions, three bilateral squats and three walking strides.

The reference method was the condylar axis obtained from 3D ultrasound imaging. The accuracy of the other methods was expressed as the angular difference of the various knee axes in the transverse plane.

Results: The conventional axis was predominantly external compared to the ultrasound condylar axis, 7.5° on average. The ATT and Geometrical functional methods resulted in an axis mostly external with the flexion activity presenting the least amount of variability (SD: ATT 7.4°, Geometrical 8.4°). The DynaKAD method most closely aligned with the condylar axis for all activities, with the most accurate results obtained for walking (mean: 3.1°, SD: 6.1°).

Figure:



Caption: Left: subject with marker set undergoing 3D-ultrasound imaging of the posterior aspect of the femoral condyles. Right: top, ultrasound image of femoral condyles. Bottom, boxplot of angular difference of knee axes from the 3D-ultrasound condylar axis in the transverse plane (* represents outlying data points). 1 Outlying data point actual location beyond graph range.

Conclusion: We described a method to locate the knee axis in-vivo using 3D ultrasound imaging. The DynaKAD method applied to the walking activity provided the axis closest aligned to our condylar 3D ultrasound reference. This study only assessed healthy adults and our results need to be confirmed on those with pathology.

TESTING MODEL-BASED CONCLUSIONS ON THE OPTIMAL CONTROL OF HUMAN MOVEMENT USING FORMAL STATISTICAL ANALYSES

Ross H. Miller [1,*] Farzad Ehtemam [1]

[1]Department of Kinesiology, University of Maryland, College Park, United States

Introduction and Objectives: Optimal control theory (OCT) has made many elegant and reasonably accurate predictions of human motor behavior. However, the traditional implementation of OCT in biomechanics [1] is extremely computationally demanding for large-scale musculoskeletal models. Consequently, most model-based OCT studies on locomotion have used a single generic model. With data from only one "subject" that does not reflect the biological variance present in even the healthy human population, the generalizability of such results is unclear.

Recent simulation methods can rapidly generate many OCT simulations in practical amounts of time [2], opening the possibility of performing "virtual" experiments with multi-subject datasets that can undergo formal statistical analysis as is standard for laboratory-based experiments, adding an important new element of validity to simulation of human movement. Our objective was to test the hypothesis that conclusions on locomotor control from OCT are robust to healthy variation in anthropometric and muscular properties.

Methods: We used implicit direct collocation [2] to generate predictive simulations of human walking with models representing 10 subjects drawn from standard normal parameter distributions (Table 1). The basic structure of the model was the same for all 10 subjects: 12 degrees of freedom, 24 Hill-based muscles, and a model of muscle energy expenditure [3].

For each subject, walking was simulated on a temporal grid of 101 nodes/step. We first performed a data-tracking simulation that optimized the musculoskeletal states, muscle excitations, and step duration to track mean human experimental data [4] with minimum metabolic cost. The data-tracking result was used as the initial guess for predictive simulations with two different cost functions:

"Minimum Fatigue": minimize the largest muscle activation.

"Minimum Effort": minimize sum of muscle activations, each weighted by muscle mass.

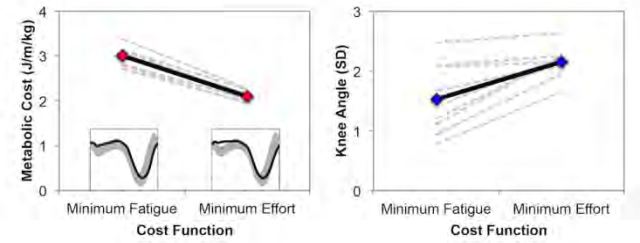
Equality constraints enforced dynamic consistency, periodicity and bilateral symmetry, and Froude number 0.14. The average deviation of the knee angle from mean human experimental data in the first half of stance [4] was expressed in multiples of the experimental standard deviation (SD). Metabolic cost and average knee angle deviation was compared between cost functions using matched-pair Student's t-tests (critical $p = 0.05$).

Results: A single simulation required ~ 20 minutes in MATLAB on an iMac. The models tracked the mean human gait data to an average deviation of 0.60±0.03 SD with a metabolic cost of 3.41±0.16 J/m/kg.

The gross metabolic cost was lower for the Minimum Effort simulation (2.10±0.11 J/m/kg vs. 3.00±0.19 J/m/kg, $p < 0.00001$). The range in differences was 0.77-1.12 J/m/kg (Fig. 1).

The average knee angle deviation was greater for the Minimum Effort simulation (2.16±0.25 SD vs. 1.53±0.55 SD, p = 0.00084). The range in differences was 0.07-1.14 SD. Minimum Effort tended to predict a straight knee in stance, while Minimum Fatigue predicted stance phase knee flexion (Fig. 1).

Figure:



Caption: Metabolic cost (left) and knee angle accuracy (right) when using the "Minimum Fatigue" and "Minimum Effort" cost functions. Dashed lines are simulations with the different models, solid lines are means over all 10 models. The inset figures in the left panel show the average knee angle waveforms predicted by each cost function, compared to the experimental data.

Conclusion:

The qualitative consistency of predicted gaits between subjects suggests it may have been safe to draw conclusions from one subject. However, the difference in the average knee angle deviation was over 1.0 SD for three subjects and under 0.2 SD for three others. These data may suggest different conclusions if considered in isolation. Simulations with multiple model parameter sets were needed to discover the average behavior and the consistency between subjects. Simulation studies have often made modeling decisions for computational speed rather than physiological fidelity, or excluded particular analyses due to computational time rather than relevance. With rapid advances in computing power and simulation methods, the validity of these limitations is diminishing. We suggest that simulation studies whenever possible should be held to the same standards of statistical rigor applied to laboratory-based studies.

NON-NEUROPATHIC DIABETIC INDIVIDUALS SHOW REDUCED ESTIMATED MUSCLE FORCES AT THE GAIT PUSH-OFF PHASE

Aline A. Gomes [1,*] Guilherme Bighetti [1] Maria Orselli [2] Marko Ackermann [3] Isabel Sacco [1]

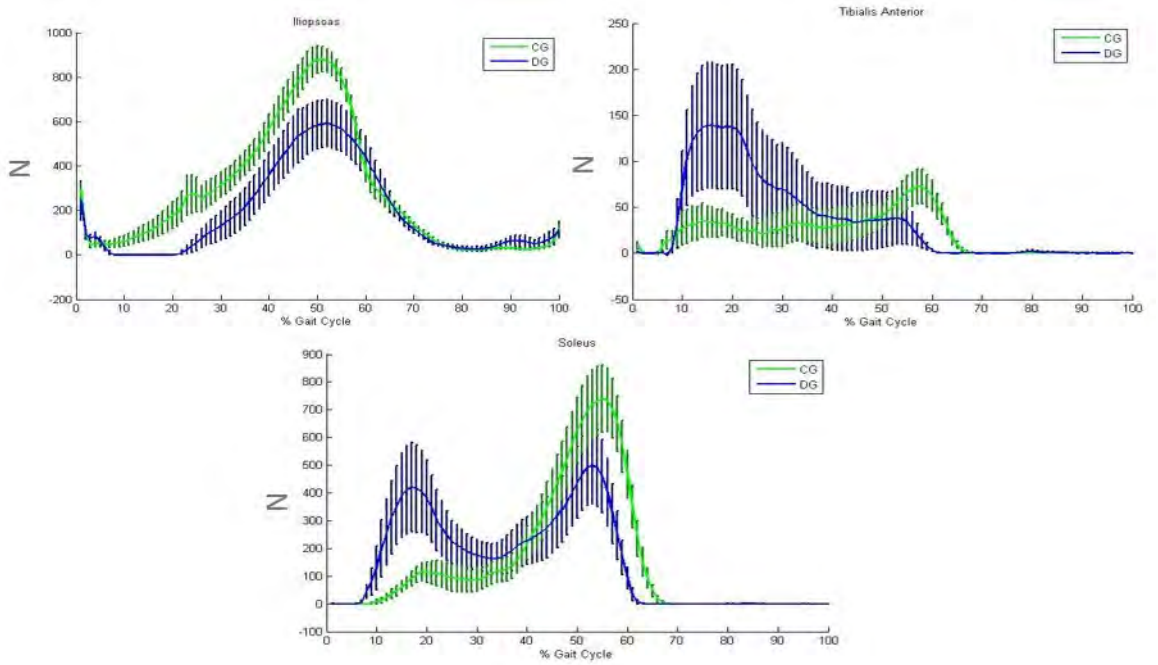
[1]Physical Therapy, Speech, Occupational Therapy Department, University of Sao Paulo, [2]Biomedical Engineering Department, Centro Universitário Franciscano, [3]Department of Mechanical Engineering, Centro Universitário da FEI, Sao Paulo, Brazil

Introduction and Objectives: Investigation of lower limb muscles force still suffers experimental limitations and computational simulations add relevant information to the knowledge already acquired by direct EMG measurements (Sawacha et al., 2012), providing, for instance, estimations of muscle forces, important to a deeper understanding of the human gait. The aim of this study is to investigate the coordination of proximal (*iliopsoas- PS* and *biceps femoris- BF*) and distal muscles (*gastrocnemius medialis – GM, lateralis – GL, soleus- SO* and *tibialis anterior- TA)* of diabetic individuals during gait using an OpenSim model and static optimization tool to estimate muscle forces.

Methods: Data from ground reaction force (GRF) and hip, knee and ankle kinematics of 7 diabetic (DG – 56.0±9.4 yrs old, 70.0± 13.6 kg, 1.7±0.1 m, 4.5 yrs of diabetes, median of 4.5 MNSI-questionnaire score) and 18 healthy individuals (CG – 53.3 ± 8.5 yrs old, 69.0±6.8 kg, 1.7±0.04 m) were used as input variables for the computational gait model gait2392 in the OpenSim software. 3D kinematic data was recorded by an 8-camera *Optitrack®* (Natural Point, EUA) at a rate of 100 Hz. An AMTI OR61000 (Watertown, EUA) platform was used to acquire GRF at 1000 Hz. The force time series of proximal and distal muscles were calculated using the static optimization tool in OpenSim. The maximum muscle force and its time occurrence were calculated during some sub phases of the gait cycle and were compared between groups by t-tests ($p<0.05$).

Results: DG individuals showed lower maximum force of IL and GM at the push-off phase, compared to CG (table 1/ fig. 1). These muscles are important for this phase, and their insufficient strength may compromise the propulsion during walking. This fact could be responsible for some alterations in spatial–temporal patterns of diabetic walking (lower velocity, step length and stride length). Mueller et al. (1994) discussed that hip flexor muscles can drive the limb forward at the offset of stance phase to compensate the impaired function of gastrocnemius (hip gait strategy) in diabetic neuropathic individuals. However, ours results revealed lower distal and proximal forces of DG during push-off, and the iliopsoas didn´t compensate the impaired function of distal muscles. At the initial stance, DG exhibited higher muscle force of GM, GL and SO, DG also presented lower TA maximum force in the push-off phase compared to CG (table 1/ fig. 1). Furthermore, DG showed a late time occurrence of GL and SO maximum force at the initial stance, and an anticipated time occurrence of TA maximum force at the initial and terminal stance, compared to CG. These important muscle force deviations already present in diabetic subjects may not be solely attributed to nerve impairment but also to skeletal muscle dysfunction and degeneration prior to neuropathic complications (Andreassen et al., 2009; Krause et al., 2011).

Figure:



Caption: Figure 1. Time series of iliopsoas, tibialis anterior and soleus muscles force of Control Group (CG – n=18) and Diabetic Group (DG – n=7) during the gait cycle.

Conclusion: DG and CG showed distinct muscle force patterns of the distal muscles. DG individuals showed a higher maximum force and late time occurrence of maximum force of GL and SO at the initial stance. The lower maximum force of IL and GM in the transition of stance to swing phase in DG could compromise the propulsion during gait.

Table:

Muscles	Maximum Force (N)		*p-value	Occurrence of Maximum Force (% gait cycle)		*p-value
	CG (n=18)	DG (n=7)		CG (n=18)	DG (n=7)	
Biceps Femoris (0 – 15%)	229.3 ± 65.7	274.1 ± 60.7	0.139	3.7 ± 0.6	3.6 ± 1.1	0.867

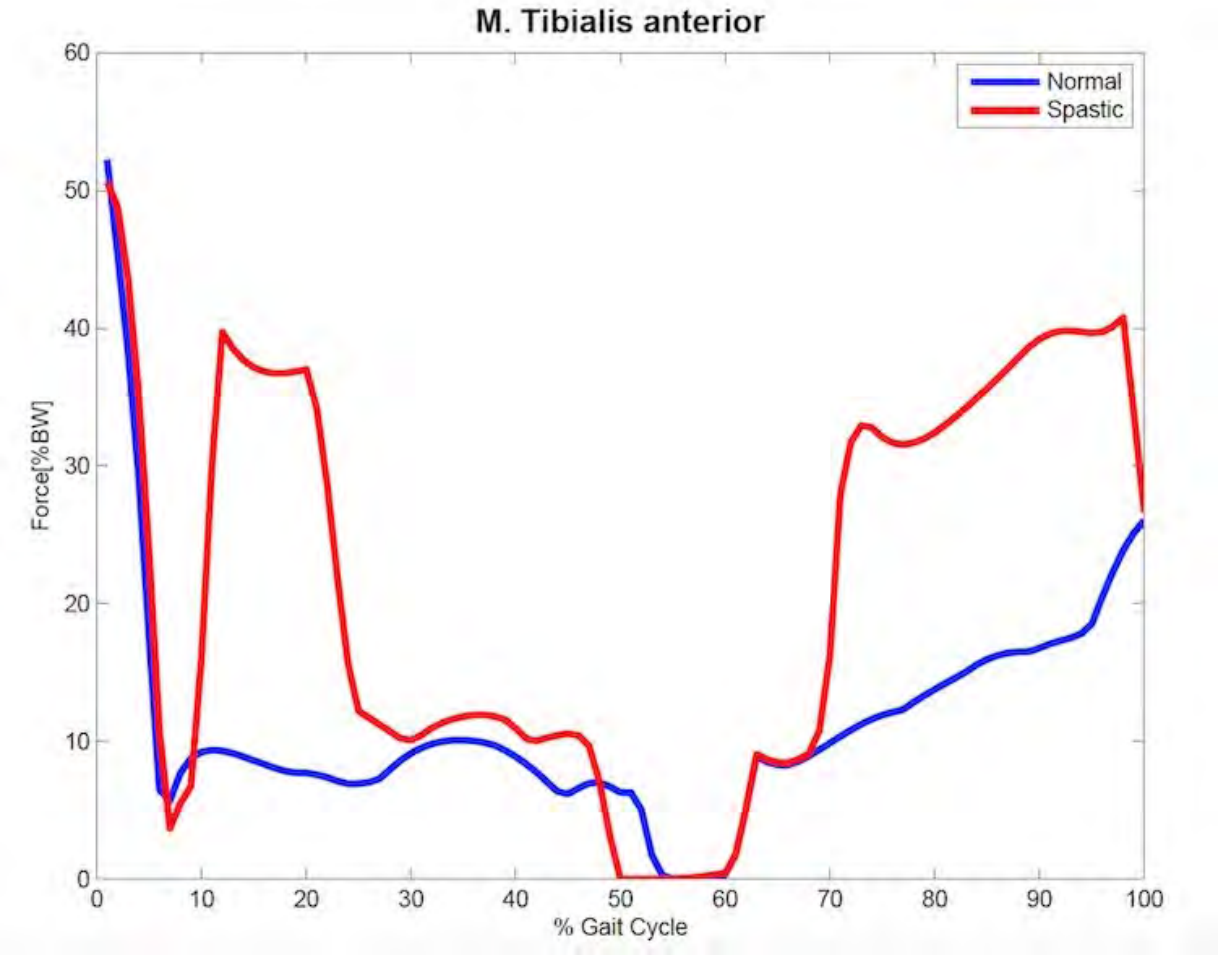
MUSCLE CO-CONTRACTIONS – A NEUROLOGICAL PROBLEM?

Christian Wyss [1] Sebastian Krapf [1,*] Marie Freslier [1] Katrin Schweizer [1]

[1] Laboratory of Movement Analysis, Childrens University Hospital Basel, University of Basel, Basel, Switzerland

Introduction and Objectives: Co-contractions are often regarded as a sign of poor coordination and muscle control. There is the concept that an agonist activation should switch off the antagonist in a physiological situation and that the reason for a co-contraction is considered a failure of reciprocal inhibition [1]. A Simultaneous agonist and antagonist activity is considered abnormal, especially in patients with spastic neurological disorders such as cerebral palsy. Another putative reason for co-contractions lies in gaining stability by locking the joints spanned by the antagonistic muscles [2].
The hypotheses of this paper are first, that a co-contraction of an antagonist can be produced in an inverse dynamic model solely by changing the mechanical behavior of the agonist. This can be achieved in the absence of any neurological disorders. Second, we hypothesize that co-contractions not necessarily improve joint stability.
Methods: An instrumented gait analysis was performed in a healthy, normally developed 29 year old woman (53.6 kg, 1.62 m). The representative trial from 12 trials was determined using the SMaRT method [3]. Muscle modeling was done with the AnyBody Lower Extremity Model (AnyBody Version 6.0.3). The PlugInGait marker setup was supplemented by one marker below the lateral malleolus and one marker on the 1st and 5th metatarsal head to improve modeling of the subtalar joint. Kinematics were optimized using an algorithm introduced by Andersen [4]. For scaling a length mass fat scaling method [5] was applied. In a first step (norm model) an inverse dynamic analysis using force dependent kinematics [6] was performed. The model calculates the translation between talus and tibia in anterior-posterior and distal-proximal direction in the local coordinate system of the ankle joint. In the second step (stiff model) co-contractions were evoked by changing muscle stiffness only. This was achieved using the AnyMuscleActivityBound class of the AnyScript language by setting the upper bound of the muscle activity proportional to the muscle's shortening velocity, which we derived as a result from the first step (normal model). Thereby, the gastrocnemii muscles depend more on their stretch velocity which increases stiffness with faster muscle contraction.
Results: During the whole stance phase there is a slight co-contraction of the tibialis anterior muscle even though the examined subject was healthy and showed no spasticity (Fig 1, blue).
Increasing stiffness enlarged the force of the gastrocnemii muscles in early stance and in late swing phase. This change resulted in a contemporary increase of the tibialis anterior muscle force (Fig 1, red).
The second parameter of interest was the shift at the ankle joint. In the normal situation there is a translation in posterior direction with a peak of 1.6 mm at 20% of the gait cycle. Increased muscle stiffness leads to an unstable situation at 10% gait cycle shown by oscillation of the translational movement. In contrast to the "norm model", the "stiff model" showed a massive translation of the talus in posterior direction at the moment of co-contraction of the tibialis anterior muscle (between
40 - 60% and between 70 - 90% of the gait cycle).

Figure:



Caption: Figure 1

Conclusion: We conclude that increased activity of a biarticular muscle due to a stiffer material behavior may lead to a co-contraction of its antagonists without the presence of any neurological disease. Consequently, it is not conclusive that co-contractions are a sign of a neurological disease as many clinicians still assume. Moreover these co-contractions result in an increased translational shift which indicates a potential joint instability.

IS KINETIC ASYMMETRY IN BELOW-KNEE AMPUTEE GAIT INEVITABLE? -- A PREDICTIVE SIMULATION STUDY

Anne Koelewijn [1,*] Antonie van den Bogert [1]

[1]Department of Mechanical Engineering, Cleveland State University, Cleveland, OH, United States

Introduction and Objectives: An important goal for amputee walking is to regain a symmetric walking pattern. Below-knee amputees are often able to regain close to normal joint kinematics in the hip and knee when using a prosthetic foot [1], but the joint moments are asymmetric and different from joint moments in able bodied gait [1], which may contribute to a higher occurrence rate of osteoarthritis in amputees [2].

We hypothesize that amputees choose to have asymmetry in joint moments to minimize the effort of walking. To test this hypothesis, we used a musculoskeletal model to predict amputee gait with and without a symmetry constraint on the hip and knee moment. The results were compared in terms of effort of walking.

Methods: Predictive simulations of gait were performed with a sagittal plane model having nine degrees of freedom and 16 muscles. An open loop optimal control problem was formulated to find a gait cycle that minimizes deviation from normal gait kinematics and a weighted sum of muscular effort, which was defined as the mean of the cubed muscle activations. The model and solution method were identical to [3], but a full gait cycle was simulated.

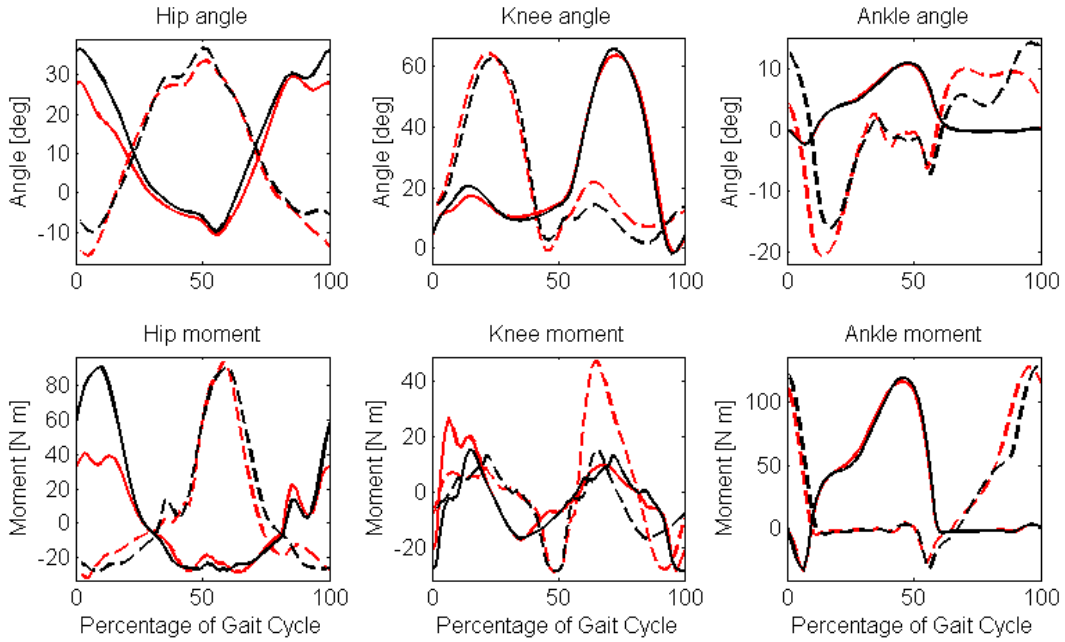
The optimal control problem was solved for an able-bodied system and a below-knee amputee system. For the latter case, three muscles in the lower leg were removed and replaced by a passive rotational spring in the ankle that applies a moment to the ankle given the angle and angular velocity. The stiffness and damping of the spring were chosen to be equal to 600 [Nm/rad] and 15 [Nms/rad].

The optimal control problem for the below-knee amputee system was first solved without symmetry constraint (baseline), then with a symmetry constraint on the hip moment, with a symmetry constraint on the knee moment and with a symmetry constraint on the hip and knee moment. The symmetry constraint was defined such that the joint moment in the left and right leg should be the same with a phase shift of 50% of the gait cycle.

Results: Table 1 gives an overview of the results that were found for the predictive simulations. The mean muscle activation decreased by 1.4% with a symmetry constraint applied to the hip moment. An increase of 0.76% and 4.3% was seen when a symmetry constraint was placed on the knee moment and the knee and hip moment, respectively. The symmetry constraint on the knee moment also improved the symmetry in the hip moment. However, the opposite was true when a constraint is placed on the hip moment.

Figure 1 shows joint angles and joint moments when a symmetry constraint was applied to the knee and hip moment (black line), compared to the baseline (red line). One can see that the symmetry constraint yields a decrease in peak extension knee moment of the intact leg (dashed line), but an increase in peak extension hip moment in the residual leg (solid line).

Figure:



Conclusion: The amputee model was able to walk with perfectly symmetric joint moments, but the hypothesized increase in effort did not occur. The effort even decreased when a symmetric hip moment was imposed on the model. The kinematic tracking error increased slightly in all cases where joint moment symmetry was required. This indicates that there is a trade-off in below-knee amputee gait between walking with symmetric joint moments and walking with normal kinematics. When the amputee model walked with symmetric joint moments, the knee and hip moments, while symmetrical, were very different from a normal able-bodied joint moments. Especially, the peak hip extension moment in the both legs became excessively high, suggesting that it is not advantageous for below-knee amputees to walk with symmetric joint moments, since this might yield an increased chance of developing osteoarthritis in both legs. Therefore, our results show that it is desirable to have a kinetic asymmetry in below-knee amputee gait.

Table:

System	Mean Muscle Activation	RMS tracking error [deg]			Peak Knee Extension Moment		Peak Hip Extension Moment	
	x1e-2	Hip	Knee	Ankle	Residual	Intact	Residual	Intact
Able-Bodied	7.88	3.7	1.5	1.7	41.6	41.6	43.5	43.5

DOES ACHILLES TENDON CONTRIBUTE TO THE FORCE POTENTIATION INDUCED BY STRETCH-SHORTENING CYCLE?

Atsuki Fukutani [1 2 3,*] Andrew Sawatsky [1] Timothy Leonard [1] Walter Herzog [1]

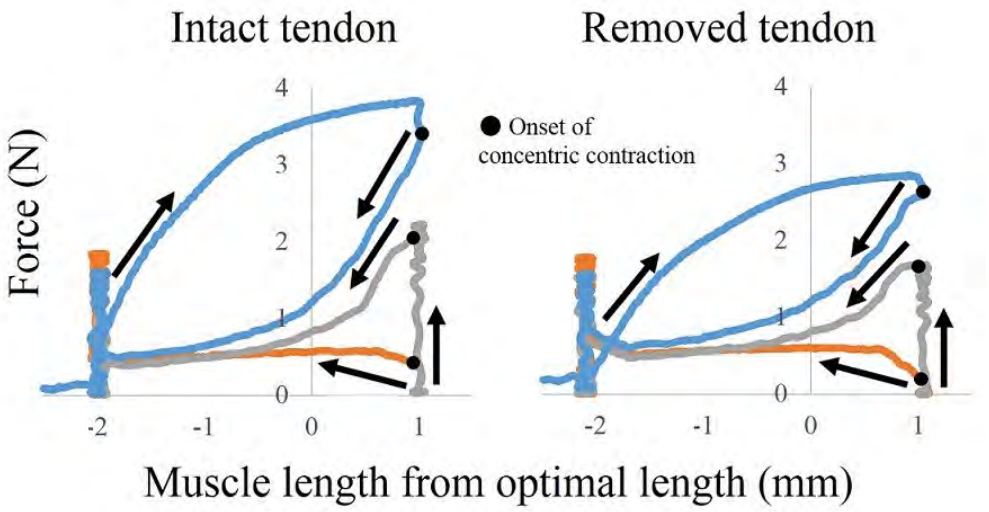
[1]Kinesiology, University of Calgary, Alberta, Canada, [2]Research Organization of Science and Technology, Ritsumeikan University, Shiga, [3]Research Fellowship for Young Scientists, Japan Society for the Promotion of Science, Tokyo, Japan

Introduction and Objectives: Tendon elongation is considered to be the primary reason for the force potentiation by stretch-shortening cycle (SSC effect) because tendons can store elastic energy during the eccentric phase and release it during the subsequent concentric phase [1]. In addition, tendon elongation can optimize muscle length changes [2]. However, direct examination of the influence of tendon elongation on the SSC effect has not been conducted. Therefore, the purpose of this study was to examine directly whether tendon elongation contributes to the SSC effect by comparing the amount of SSC effect obtained for the following two conditions; (1) SSC with the tendon fully intact, and (2) SSC with the free tendon removed.

Methods: The soleus muscle of rats was dissected free of surrounding connective tissue with the blood supply left intact. In the “intact tendon” condition, the calcaneus was held rigidly by attaching it to a load cell. For the “removed tendon” condition, the muscle-tendon junction was identified and held rigidly using a specifically designed tendon clamp, thereby eliminating the free tendon from contributing to the mechanics of the soleus under these conditions. In both conditions, three types of contraction were evoked to calculate the amount of the SSC effect. First, a concentric contraction without prior activation (Pure CON) was performed. Second, a concentric contraction following an isometric contraction was performed (Pre ISO).Finally, a concentric contraction immediately following an eccentric contraction was performed (Pre ECC). Muscle lengthening and shortening was 3 mm, and the lengthening and shortening velocities were 6 mm/s and 20 mm/s, respectively. Work done during the concentric phase was quantified as the determinant for the SSC effect. The SSC effect was expressed as the relative value of work obtained in Pre ISO and Pre ECC with respect to Pure CON.

Results: For the intact and removed tendon conditions, work done during the concentric phase was largest for the Pre ECC (intact: 3.34 ± 0.20 $J \cdot 10^{-3}$; removed: 3.22 ± 0.03 $J \cdot 10^{-3}$), followed by the Pre ISO (intact: 2.46 ± 0.11 $J \cdot 10^{-3}$; removed: 2.38 ± 0.26 $J \cdot 10^{-3}$), and finally the Pure CON (intact: 1.45 ± 0.06 $J \cdot 10^{-3}$; removed: 1.44 ± 0.16 $J \cdot 10^{-3}$). The SSC effect was significantly greater for the Pre ECC (intact: 230.8 ± 22.7%, removed: 226.0 ± 27.6%) than the Pre ISO (intact: 169.3 ± 0.7%, removed: 165.5 ± 0.5%) independent of the tendon condition. For all corresponding concentric contractions, the work done was similar for the intact and removed tendon conditions. However, peak forces at the onset of the concentric phase were higher in intact than in removed tendon condition.

Figure:



Caption: Force-length loop obtained during SSC with the tendon intact (left) and the tendon removed (right). Orange, gray, and blue lines show force-length data obtained for the Pure CON, Pre ISO, and the Pre ECC conditions, respectively. Work done during the concentric phase was calculated as the area under the force-length curve obtained during concentric contraction.

Conclusion: Although many studies have suggested that tendon elongation is the primary factor for the SSC effect, no difference in the SSC effect was found between the intact and removed tendon conditions. This result may be attributable to a negligible tendon elongation. The fact that we observed a substantial SSC effect even with the tendon removed indicates that tendon elongation is not the primary factor for SSC effect. Other factors contributing to the SSC effect could be the stretch reflex response, pre-activation, and residual force enhancement. Because a fully-tetanic electrical stimulation was used in this study, the influence of any stretch reflex response can be discarded. We confirmed that the SSC effect was found in Pre ISO, where no active lengthening was present, thus pre-activation likely contributes substantially to the SSC effect. Considering that the SSC effect was larger in the Pre ECC than the Pre ISO, active lengthening-induced force potentiation (residual force enhancement) likely also contribute to the SSC effect. Peak force at the onset of the concentric contraction was different, although work done was similar between the intact and removed tendon conditions. Since work performed was similar, we exclude the possibility of muscle fatigue or damage as the cause for the reduced peak forces in the tendon removed conditions. This surprising result will need to be considered in detail in the future. In conclusion, tendon elongation does not contribute to the SSC effect in the rat Achilles tendon, and large SSC effects are possible without a free tendon. This result may be applied to the human Achilles tendon which is thought to be relatively stiff as well. More compliant and/or longer tendons, such as in kangaroo hind limbs, which are known to store and release elastic energy, may behave differently than observed here in the rat soleus.

A BETTER UNDERSTANDING OF CEREBRAL PALSY PATHOLOGY USING 3D SUBJECT-SPECIFIC MUSCULOSKELETAL MODELING

Ayman Assi [1,*]Abir Massaad [1 2]Ziad Bakouny [1]Nour Khalil [1]Christophe Sauret [3]Wafa Skalli [3]Ismat Ghanem [1]

[1]Laboratory of Biomechanics and Medical Imaging, School of Medicine, University of Saint-Joseph, [2]Gait lab, SESOBEL, Beirut, Lebanon, [3]Laboratoire de Biomécanique, Arts et Métiers ParisTech, Paris, France

Introduction and Objectives: Spasticity in children with cerebral palsy (CP) affects muscle function and geometry and is related to the development of skeletal malalignments during growth, which can both cause gait alterations [1,2]. Assessment of the pathology is usually based on the evaluation of muscle function, the medical imaging of skeletal lower limbs and gait analysis. Generic models are widely used in the literature in order to understand CP pathology. The aim of this study is to use 3D subject-specific data obtained from musculoskeletal modeling along with gait analysis in order to better understand motor dysfunctions in CP and to compare these to normal locomotion in typically developing (TD) children.

Methods: Twenty-two spastic CP children (mean age: 11±3; diplegia N=16, hemiplegia N=6; GMFCS I N= 14, GMFCS II N=6, GMFCS III N=2), with neither medical nor surgical histories, had undergone 3D gait analysis. Joint kinematics of the lower limbs were calculated in the frontal, sagittal and horizontal planes. An EOS® biplanar X-ray exam was performed in order to calculate the 3D skeletal parameters of the pelvises and the lower limbs: femoral anteversion, tibial torsion, neck shaft angle, acetabular parameters and pelvic parameters [3]. This was performed on 44 lower limbs of CP children. Axial MRI acquisitions were performed on 28 lower limbs of the CP group, in order to obtain 3D subject-specific reconstructions of 18 muscles in each limb [4] (Figure 1). Based on these reconstructions, each muscle's length and volume were calculated and then normalized to lower limb length and body mass respectively. All kinematic and musculoskeletal parameters were age-matched to 22 lower limbs of TD children. Statistical differences were investigated between the CP and TD populations for all parameters (T-test and Wilcoxon). Correlations between the parameters were evaluated using the Pearson and Spearman tests.

Results: Femoral anteversion, pelvic incidence and sacral slope were significantly increased in CP when compared to TD children ($p<0.001$). Anova test showed a significant difference for the femoral anteversion between TD children and CP children with GMFCS level II. The normalized lengths of the gracilis, vastus intermedius, soleus, adductor brevis and longus were significantly smaller in CP children with GMFCS level II compared to TD children ($p<0.001$). The normalized muscle volumes of the CP children were smaller for the femoral biceps longus, rectus femoris, gastrocnemius medius, vastus intermedius, adductor brevis and longus in CP children with GMFCS II when compared to TD children ($p<0.001$). Fifteen lower limbs of children with CP presented excessive internal hip rotation during gait when compared to normative values. For these 15 lower limbs, femoral anteversion was significantly increased in children with CP ($p<0.001$), when compared to TD children, and was correlated to mean hip rotation during stance phase ($R=0.54$). 3D acetabular anteversion and abduction were correlated to hip rotation at initial contact ($R=0.64$) and peak hip rotation during stance phase ($R=-0.5$) respectively.

Figure:

Caption: Figure 1- Example of subject-specific 3D reconstruction of musculoskeletal lower limbs in children with cerebral palsy

Conclusion: For the first time, musculoskeletal 3D subject-specific parameters in CP could be compared to those of TD children. In these preliminary results, femoral anteversion, pelvic parameters and hip adductors, among other muscles, were only shown to be significantly altered when GMFCS was higher than I. These results showed that 3D femoral anteversion might contribute to internal hip rotation during gait, which is not in concordance with previous studies based on generic models [5,6]. Moreover, 3D acetabular parameters, studied for the first time in CP, were shown to be related to internal hip rotation during gait. Larger groups of subjects will allow us to better understand the evolution of the musculoskeletal deformities that occur during the growth of spastic CP children, when compared to the growth of TD children.

WALKING VS. NORDIC WALKING EXERCISE: DIFFERENCES IN TRUNK MUSCLE ACTIVITY AND IMPACT ACCELERATION

Luca Zoffoli [1] Francesco Lucertini [1] Ario Federici [1] Massimiliano Ditroilo [2,*]

[1]Department of Biomolecular Sciences - Division of Exercise and Health Sciences, University of Urbino 'Carlo Bo', Urbino, Italy, [2]Department of Sport Health and Exercise Science, University of Hull, Hull, United Kingdom

Introduction and Objectives: According to the International Nordic Walking Association, Nordic Walking (NW) is "… *a form of physical activity, where regular, natural walking is enhanced by the addition of the active use of a pair of specially-designed Nordic Walking poles*". When compared to walking (W), previous research has shown that NW can enhance several physiological parameters, including the energy expenditure [1]. Notably, NW has been successfully used with the elderly, in obesity management, in chronic low-back pain, etc [2].

Despite the increasing popularity of the NW as an exercise intervention there is a paucity of biomechanical research to explain the effectiveness of this type of exercise and its benefits over W.

The role of the trunk muscles during walking, for example, is of great interest because altering their function can lead to pathologies such as chronic low-back pain [3]. Likewise, information on the strain experienced by the lumbar spine, as measured by accelerometry, may be relevant [4]. Accordingly, this study aimed to concurrently measure the activity of 5 trunk muscles and the impact accelerations at the sacrum whilst performing W and NW at different velocities and slopes.

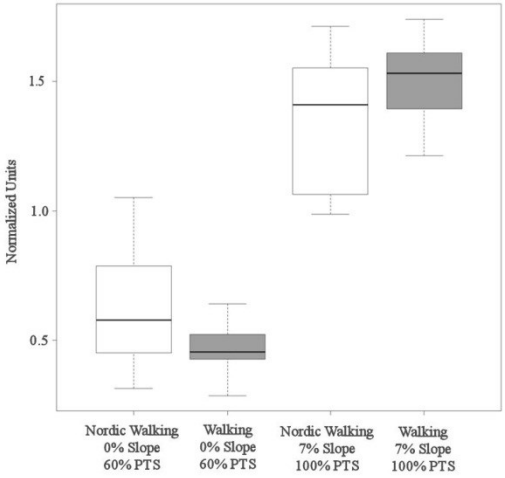
Methods: Twenty-one healthy participants (10 males and 11 females) aged 31.2 ± 8.3 years old have been recruited for this study, which required two visits to the lab on separate days. The first visit was used to familiarise the participants with the procedures and to determine the Preferred Transition Speed (PTS, the greatest speed at which the participant can comfortably walk before starting running). During the second visit EMG electrodes were placed on the following muscles: upper (RAp) and lower (RAd) portion of the Rectus Abdominis, medial portion of the External Oblique (EO), Erector Spinae (ES) and Multifidus (MF) on the arm-dominant side. Further, two 3D accelerometers were placed over the tibia and sacrum. Following 5 minutes of warm-up, walking (either W or NW) was performed at different slopes (0% or 7%) and different speeds (60%, 80% and 100% of the PTS). Each trial was performed for 1 minute, separated by at least 1 minute rest, in random order.

All signals were sampled at 1500Hz at 16bit-resolution. Appropriate filtering and processing were carried out to obtain a linear envelope for EMG and a smoothed acceleration signal. They were then time-normalised to 101 points and the 30 central valid steps for each tested condition were averaged point by point. For each muscle the mean EMG amplitude was calculated and then normalized to the W-0% slope-100% PTS condition. Vertical and resultant sacrum acceleration peaks were determined whereas vertical peaks of the tibia were only used as a reference to calculate steps length and frequency.

Generalized Estimating Equations were used to determine whether statistical differences in the dependent variables occurred across type of walking, slope and speed conditions.

Results: The key results presented here focus on the effects of type of walking and slope on the nine dependent variables and on the interaction of type of walking, slope and speed on the MF muscle. Step length, step frequency and EO mean amplitude show a significant difference between W and NW. Specifically NW induced an increase in step length (1.63±0.21 vs. 1.54±0.21 m, $p<0.001$) and a reduction in step frequency (0.93±0.12 vs. 0.98±0.11 Hz, $p<0.001$) whilst the activity of the EO muscle is increased in NW when compared to W (1.15±0.83 vs. 0.72±0.34, $p<0.05$). Slope reduced step frequency (0.93±0.12 vs. 0.98±0.11 Hz, $p<0.001$) and increased the activity of the EO muscle (0.98±0.66 vs. 0.89±0.68, $p<0.01$). The activity of the MF muscle is significantly augmented when walking uphill (figure 1). Interestingly, at lower speed the MF exhibited greater amplitude during NW whereas at higher speed the trend is reversed (figure 1).

Figure:



Caption: The effect of type of walking, slope and speed on the Multifidus muscle. The thick line represents the mean values. Min, Max, first and third quartile are also reported.

Conclusion: The results suggest that the poles used during NW altered the lower limb walking kinematics producing effects similar to those related to uphill walking and this makes it generally suitable for healthy individuals. NW yielded a greater activity of the EO muscle arguably because of the higher trunk torsion due to longer steps. Further, whilst it did not influence the impacts at the sacrum level, it did alter the recruitment pattern of the lower back muscles (MF) suggesting the effectiveness of NW at specific conditions. Based on the latter result, this particular muscle would be stressed to a lesser extent in patients suffering from low-back pain if they undertook NW uphill and W on a flat surface.

LOWER AGONIST ACTIVATION MAY EXPLAIN WHY LENGTHENING THE RECTUS FEMORIS MUSCLE DOES NOT INCREASE KNEE EXTENSION TORQUE

Theodoros Bampouras [1 2,*] Neil Reeves [2] Bill Baltzopoulos [3] Constantinos Maganaris [4]

[1]Medical and Sport Sciences, University of Cumbria, Lancaster, [2]School of Healthcare Science, Manchester Metropolitan University, Manchester, [3]Centre for Sports Medicine and Human Performance, Brunel University, Uxbridge, [4]Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom

Introduction and Objectives: Knee extensor muscle torque has been shown to change with different hip joint angles. The change in position can affect the biarticular rectus femoris muscle, which contributes approximately 17% to quadriceps torque output. Consequently, the position change will affect the overall torque generated by the knee extensors. Indeed, musculoskeletal modelling studies predict higher quadriceps torque with the rectus femoris muscle in a lengthened position (e.g. supine) compared to a shortened one (e.g. seated). However, this has not been confirmed by results from experimental studies. As experimental studies typically utilise voluntary contractions of the quadriceps, the reasons for this contradiction could be due to differences in agonistic muscle activation capacity or differences in antagonistic muscle co-activation, in one position compared to the other. The aim of the present study was to establish whether this discrepancy is attributed to differences in muscle activation capacity and / or differences in antagonistic muscle co-activation.

Methods: Following Institutional Ethics approval, nine healthy, active males (age 30.2 ± 7.7 years, stature 1.78 ± 0.09 m, body mass 81.7 ± 11.2 kg), free from any musculoskeletal injuries, were tested in seated (hip joint angle = 90˚), and supine (hip joint angle 160˚) (full hip joint extension = 180˚) positions, with the knee and ankle joint angles at 90˚ for both conditions. Subjects were fixed in a custom-made dynamometer, specifically developed for assessing isometric contractions and had very limited compliance of the lever arm and the bed. In addition, firm fixation was ensured with straps over the pelvis and tested thigh. The lower leg was securely strapped to the force transducer. For the supine position, additional constraints were placed on the shoulders preventing extraneous movement. Subjects performed seated and supine maximum voluntary isometric contractions (MVC) and torque from the quadriceps was recorded. Antagonistic torque was estimated from bicep femoris EMG during isometric maximal and submaximal knee flexion contractions. Corrected MVC torque for both positions was also calculated, as the sum of the recorded torque during the respective MVC and the antagonistic torque elicited by co-contraction. Finally, supramaximal electrical stimulation intensity was examined in both positions to confirm that the same level of stimulation intensity can activate the muscles to similar levels with the rectus femoris lengthened and shortened. Subsequently, quadriceps submaximal tetanic stimulation (with the same stimulation intensity) was also performed in both positions and torque was recorded (STIM). Differences between the two positions for all variables were examined using a dependent Student's t-test and effect size (ES) was calculated for significantly different comparisons.

Results: MVC was not significantly different between supine (245 ± 71.8 Nm) and seated (241 ± 69.8 Nm) positions. Similarly, corrected MVC was not significantly different in supine (257 ± 77.7 Nm) compared to seated (267 ± 87.0 Nm)

positions. Supramaximal stimulation intensity did not differ between positions, however STIM was significantly higher (p=0.001, ES = 1.0) in supine (111 ± 31.9 Nm) than seated (99 ± 27.5 Nm) positions.

Conclusion: The higher STIM torque in the supine compared to the seated position agrees with predictions from musculoskeletal model studies. However, when the contractions were voluntary (and, thus, neural input involved), neither MVC nor corrected MVC were different. The combination of these results suggest that the discrepancy in quadriceps torque between musculoskeletal modelling and experimental studies is not because of antagonistic co-activation but due to reduced rectus femoris activation capacity in the lengthened (supine) position. This reduced activation is likely attributed to a) inadequate fixation of the pelvis during the supine assessment position, and b) reduced vestibular feedback in the supine position, resulting in reduced muscle activity. These findings should allow closer monitoring of the true torque and standardisation of muscle function assessment procedures. Additionally, they should assist the development of more realistic muscle models which will account for the change in activation capacity in different muscle lengths.

LONG-TERM BIOMECHANICAL ADAPTATION IN A BIOLOGICALLY-RECONSTRUCTED FEMUR AFTER EWING SARCOMA

Giordano Valente [1,*] Lorenzo Pitto [1] Sabina Piroddi [1] Enrico Schileo [2] Andrea Roncari [1] Alberto Leardini [3] Marco Manfrini [4] Fulvia Taddei [1]

[1]Medical Technology Laboratory, [2]Computational Bioengineering Laboratory, [3]Movement Analysis Laboratory, [4]Musculoskeletal Oncology, Rizzoli Orthopaedic Institute, Bologna, Italy

Introduction and Objectives: Biological reconstruction of the femur using massive bone allograft (MBA) is a worldwide solution for limb-salvage surgery after bone sarcoma. Because of the risk of MBA mechanical failure and size limitations of vascularised fibula autografts (VFA), a combination of VFA placed inside a MBA represents an original solution [1]. However, the remodelling and long-term survival of the reconstruction are not consistent [2], and there is limited knowledge about functional outcomes after surgery based on quantitative data.

Our aim is to study the long-term biomechanical adaptation in a paediatric oncology case of biologically reconstructed femur, by analyzing: (i) musculoskeletal forces and muscle compensation strategies in different motor tasks through image-based musculoskeletal modeling; (ii) mechanical stress in the reconstruction during the motor tasks through finite element analysis, also including potential revision surgery scenarios.

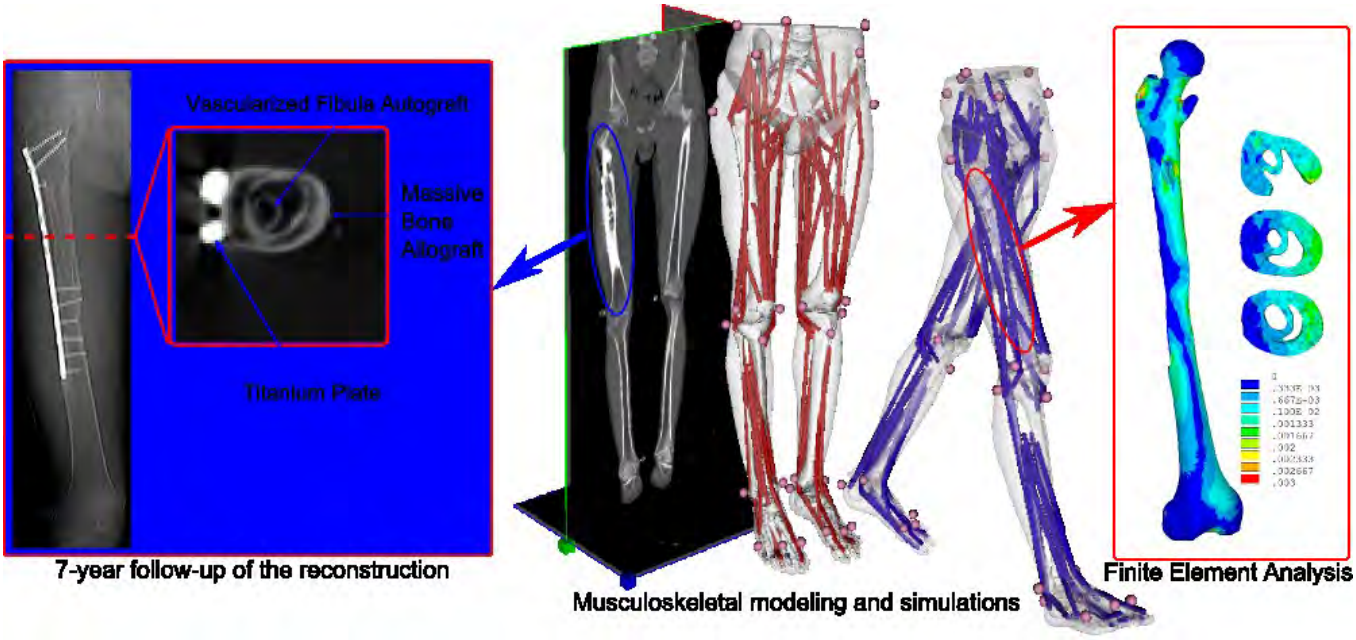
Methods: The patient (male, 8 years old) underwent a biological reconstruction of the proximal right femur, and was then continuously disease free. CT scans of the lower limbs were acquired post-operatively and during follow-ups at every 6 months for routine controls. The evolution of bone morphology and density was quantitatively evaluated. After 7 years, the patient underwent gait analysis (walking, chair rise/sit, stair ascent/descent, squat) and CT scanning after being instrumented with the same reflective marker setup [3]. A 9-body segment, 12 degree-of-freedom articulated 3D linkage actuated by 85 musculotendon actuators was created from these images (Figure) using a previously developed framework [4], and a typical inverse dynamics and static optimization approach was then applied to calculate muscle and joint contact forces during each motor task. Subject-specific finite element models of both femurs were built using a validated procedure [5]. The subject-specific muscle and joint contact forces were applied as loading conditions onto the corresponding nodes, and physiologically-oriented constraints were used [6]. Plate and screws safety was tested in terms of von Mises stresses against fatigue limit. Bone principal strains and strain energy density were computed to assess risk of fracture [5] and remodeling stimulus [7], respectively. In the operated femur, the finite element analyses were repeated simulating different screw-removal configurations to reduce the expected stress-shielding.

Results: Overall, joint contact forces were larger in the contralateral limb during all motor tasks, except for walking. Knee and ankle loads were markedly higher (up to 3 body-weight difference), particularly in double-support tasks (chair rise/sit and squat). Muscle compensation strategies showed large forces of the vasti and gastrocnemius muscles of the contralateral limb, while gluteii and biarticular hip muscle forces of the operated leg were marked.

Plate and screws stresses were below critical values for titanium alloy fatigue in all motor tasks. While maximum strains were not critical in both femurs (safety factor of 3 or above) in the non-demanding motor tasks, the average strains in the

operated femur were lower than in the intact contralateral. A marked regional variation in strains and strain energy density was observed within the allograft: normal levels in medial compartment, extremely low values in anterior and posterior compartments. Despite the allograft thinning already observed during follow-up, the mechanical condition in the anterior and posterior compartments appears compatible with a further bone resorption. When simulating different patterns of proximal screws removal, we found that their complete removal would be needed to restore a more physiological bone strain configuration.

Figure:



Caption: Workflow of subject-specific musculoskeletal modeling and simulations of the motor tasks and finite element analysis of the femurs

Conclusion: This study presents a successful integration of subject-specific musculoskeletal modeling and finite element organ level analysis of a long-term biomechanical reconstruction after Ewing sarcoma. The predicted musculoskeletal forces and muscle compensation strategies can provide advice for rehabilitation therapy in specific clinical scenarios. The results from finite element analysis allow interpretation of the complex bone remodeling mechanism, and seems not to imply a high risk for the remaining screws and plate, nor for bone in the medial compartment, but suggests caution in the post-operative phase due to reduced bone thickness and density in the lateral compartment.

AS-0084

A SIMPLE, MRI-BASED METHOD FOR MEASURING 3D MOMENT ARMS OF HUMAN MUSCLES UNDER DYNAMIC CONDITIONS

Elizabeth Clarke [1,*] Joshua Martin [1] Agnes d'Entremont [2] Marcus Pandy [3] David Wilson [2] Robert Herbert [4]

[1]Kolling Institute, Sydney Medical School, University of Sydney, Sydney, Australia, [2]Mechanical Engineering and Department of Orthopaedics, University of British Columbia, Vancouver, Canada, [3]Mechanical Engineering, University of Melbourne, Melbourne, [4]Neuroscience Research Australia, University of New South Wales, Sydney, Australia

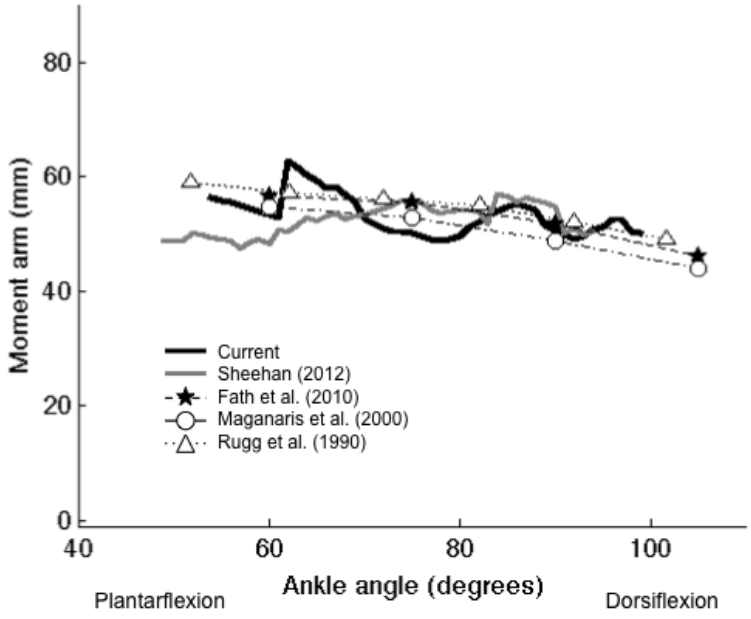
Introduction and Objectives: Muscle moment arms are widely used in biomechanics. Applications include measuring muscle length changes with joint angle and determining muscle force from joint torque and subject-specific musculoskeletal models. Some applications require subject-specific muscle moment arms to be measured non-invasively in living human subjects. Many researchers capture joint and tendon images in a single anatomical plane (2D) but this may overestimate the 3D muscle moment arm [1]. Other methods capture tendon and joint images at one or a few static joint positions, but it may be interesting to know how the moment arm changes throughout the joint's range, and moment arms may differ under static and dynamic conditions [2]. A 3D dynamic MRI method has been developed [3] but it uses cyclic rotation of the joint and MRI-gating. We aimed to develop and validate a simple method for non-invasively and dynamically measuring 3D muscle moment arms in vivo from a single joint rotation cycle in humans.

Methods: The Achilles tendon moment arm was measured in 5 men and 5 women aged 22-48 years. Participants lay supine in a 3T scanner (Philips Achieva) and the relaxed ankle was slowly rotated through range. Two sets of scans were obtained: a high resolution 3D MRI scan of the stationary joint (3D T1-weighted FSE, 4.7 minutes, flip angle 90º, matrix 320×320, FOV 160×160mm, TR/TE = 355.76/16.68ms, slice thickness 1mm; approx. 4 minutes) and a series of ultra-fast MRI scans of the slowly moving joint (ultrafast (turbo) gradient echo, flip angle 10º, matrix 320×320, FOV 320×320mm, TR/TE = 2.731/1.34ms, slice thickness 4mm, slice gap 0.4-3.0mm depending on joint size, 40 dynamics (phases), 8 slices, 104 seconds,). Bone and tendon geometries were manually segmented [4] from the high-resolution images to create 3D models. The high-resolution bone models were registered with the dynamic scans to reconstruct the bone motion, using custom Matlab code [4]. Tibio-talar helical axes were calculated for consecutive joint angles and the mid-line of the tendon was calculated for each joint angle. The muscle moment arm was determined at each joint angle as the length of the mutual perpendicular between the joint axis and the tendon line-of-action. A validation was conducted by rotating a dissected sheep tibia about a fixed gelatin-filled axis of rotation, using a gelatine-filled latex tube as a tendon surrogate. These components had known trajectories and physical measurements. The moment arm (from the tendon surrogate to the gelatine-filled axis of rotation) was measured using the MRI method (at 14 angles) and directly from the apparatus at the same rotation angles. The image processing was repeated 3 times. The mean RMS error between the MRI measurements and the corresponding physical measurements was calculated to assess the accuracy of the MRI method.

Results: The mean Achilles tendon moment arms across the ankle range of motion for the 10 subjects in this study were similar in scale to other studies (see Figure 1), despite differences in the methods, subjects, loading (relaxed versus active

muscle contraction) and definitions (centre of rotation, ankle angle and tendon line-of-action). Three trials of MRI validation data from 14 apparatus positions yielded a mean RMS error of 3.2 mm. The 95% confidence interval for the mean absolute error between MRI and physical measurement was 2.3-3.5 mm. The mean Achilles tendon moment arms for individual subjects in the current study ranged from 39.6 mm to 64.1 mm, therefore the upper 95% confidence limit of the error equates to an error of 5-9%.

Figure:



Caption: Figure 1. Comparison with data from literature

Conclusion: We have developed a simple method for measuring moment arms of human muscles under dynamic conditions. The method was validated against physical measurements from a surrogate apparatus. Potentially the method could be applied under active muscle conditions and to different joints. The method is capable of measurements from a single cycle of joint rotation, which could be particularly advantageous for clinical populations or under conditions of high muscular effort.

CONTROL OF MUSCULOSKELETAL ARM MODEL USING MUSCLE SYNERGY

Reza Sharif Razavian [1,*] Borna Ghannadi [1] John McPhee [1]

[1]Systems Design Engineering, University of Waterloo, Waterloo, Canada

Introduction and Objectives: Muscle synergy has been considered as a possible mechanism employed by the human nervous system to control movements [1]. This theory suggests that the nervous system may contain sets of muscle activity patterns, i.e. certain muscles are activated together via fixed patterns. Many researchers have studied the synergies by looking at the measured muscle activity signals, but few have used synergies to generate a desired action using the muscle synergy framework. In this project, we have used muscle synergies to control the motion of a musculoskeletal arm model.

Methods: A planar 2 degree of freedom musculoskeletal arm model is studied in this project. The arm muscles (Hill-type muscle model) are lumped into six muscle groups, including mono- and bi-articular flexors and extensors (see Fig. A). We have used muscle synergies to produce arbitrary hand acceleration, efficiently and in real-time. This two-stage process is described below.

1. Identifying the synergies

The measurable muscle activities during an action is the summation of multiple synergies. Non-negative matrix factorization (NNMF) is widely used to extract the underlying synergies from the measurable muscle activities [2], and has been used here to obtain the synergies.

First, we used a standard optimization routine to find the muscle activation levels that would result in a certain hand acceleration. This optimization problem was solved for a variety of joint angle configurations, and different directions of hand acceleration. Next, this large data set is used to obtain the muscle synergies. In each joint angle configuration, matrix $\mathbf{A}_{6\times 24}$ containing the six muscle activities for 24 acceleration directions is formed. With NNMF, matrix $\mathbf{A}$ can be approximated as $\mathbf{A}_{6\times 24} \approx \mathbf{S}_{6\times m}\,\mathbf{C}_{m\times 24}$, where m is the number of synergies, and $\mathbf{S}$ and $\mathbf{C}$ are the synergy and coefficient matrices, respectively.

For this project, it is assumed that the synergies are posture-dependent [3]; i.e. the synergy matrix $\mathbf{S}$ is a function of the two joint angles. Although the synergies are calculated at a limited number of joint angle configurations, it is possible to obtain the synergies at an intermediate posture by interpolating the synergy matrix data.

2. Using the synergies to produce arbitrary hand accelerations

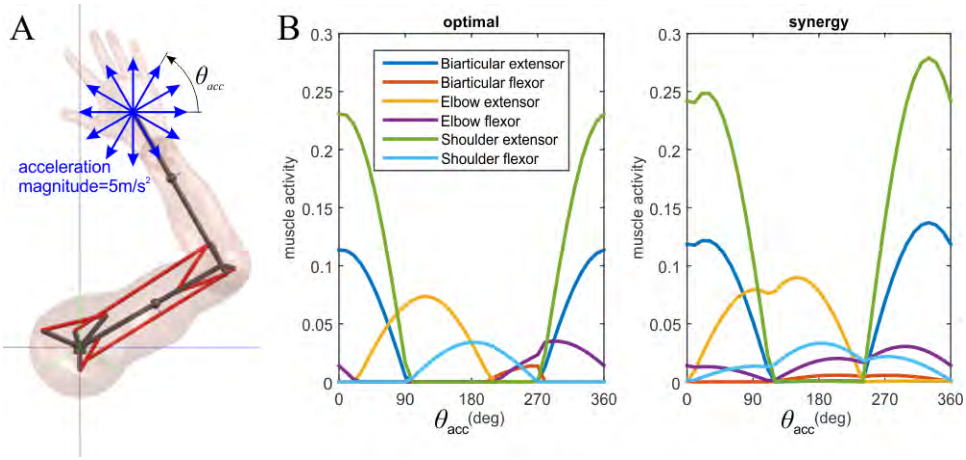
The activation of each synergy results in hand acceleration in a certain direction. The acceleration vectors resulting from all m synergies can be considered as a basis set for the two-dimensional vector space. In other words, any arbitrary hand acceleration vector can be written as a linear combination of the synergy-produced acceleration vectors. Since the synergies can only be activated in one direction (muscles can only pull), the linear combination is meaningful only if the coefficients are positive, which leads to a positive decomposition problem.

Mathematically, in an n-dimensional space, $n+1$ basis vectors are necessary for positive decomposition of any arbitrary vector. With three synergies, our 2D decomposition problem will have a unique solution. The uniqueness of the answer is

one fundamental aspect that is missing in many muscle synergy studies. In general, if the muscle synergies are obtained so that the generalized forces generated by the synergies span the operational space, there will be a unique solution to the synergy-sharing problem, and consequently a unique solution for the muscle force-sharing problem.
Additionally, since the relation between the muscle activations and the resulting acceleration is linear in this approach, the same coefficients of the vector decomposition can be used to make linear combinations of the synergies, which will result in the desired hand acceleration.

Results: Fig. B shows the activity of the six muscles versus the direction of the hand acceleration. The synergy-based control is compared against the optimal solutions. As can be seen, the activity patterns are similar, but not identical. The small difference is unavoidable with the dimension reduction of muscle synergies. The time to calculate the solution, however, is substantially lower in the proposed synergy method (20 times faster than the optimization).

Figure:



Caption: A. The 2D arm model. B. Comparison of the muscle activities: muscle synergy versus optimization.

Conclusion: We showed that muscle synergies can be used to control a musculoskeletal arm in real-time. Using this muscle synergy approach, the indeterminate force-sharing problem reduces such that the solution is unique. Our results showed that the dimension reduction allows for the fast solution of the force-sharing problem in musculoskeletal systems, while resulting in close to optimal muscle activities. Our method can be enhanced by introducing closed-loop control logic that may include predictive and learning properties of the human motor control system.

DEDUCING MUSCLE SYNERGIES FROM EXPERIMENTAL JOINT MOMENTS

Anantharaman Gopalakrishnan [1 2,*] Luca Modenese [3] Andrew Phillips [1 2]

[1]The Royal British Legion Centre for Blast Injury Studies at Imperial College London, [2]Structural Biomechanics, Civil and Environmental Engineering, Imperial College London, London, United Kingdom, [3]Griffith Health Institute, Centre for Musculoskeletal Research, Griffith University, Gold Coast, Australia

Introduction and Objectives: Prior experimental research has supported the existence of muscle groupings or 'synergies' which can be co-activated by a common control signal to actuate a family of limb movements in vertebrates. Muscle synergies could simplify the control of redundant musculature (more muscles in comparison to degrees of freedom (DOFs)), by reducing the dimensionality of the control problem. Each synergy's 'structure' can be quantified by a set of scalar muscle weightings (representing the extent of membership of each muscle to a synergy) and a synergy control signal which excites each muscle in proportion its weighting value. Excitations reaching each muscle would be an algebraic sum of the contributions from each synergy. This study adopted the hypothesis [1] that an invariant set of muscle weightings along with movement-specific synergy controls is capable of actuating a family of movements. Traditionally, the statistical factorization of experimental EMG during a family of functionally similar movement tasks has been used to deduce muscle synergy structure. This approach is limited by the inability to record EMG from all muscles and the expertise needed to avoid issues such as cross-talk. In this study, we present an alternative computational technique – synergy constrained torque decomposition (SCTD) [2] – for deducing muscle synergy structure from experimental joint moments. We applied this technique to deduce muscle synergies for a family of healthy walking movements and compared the results to EMG-derived synergies (termed 'experimental synergies') from a study by Clark et al. [3]

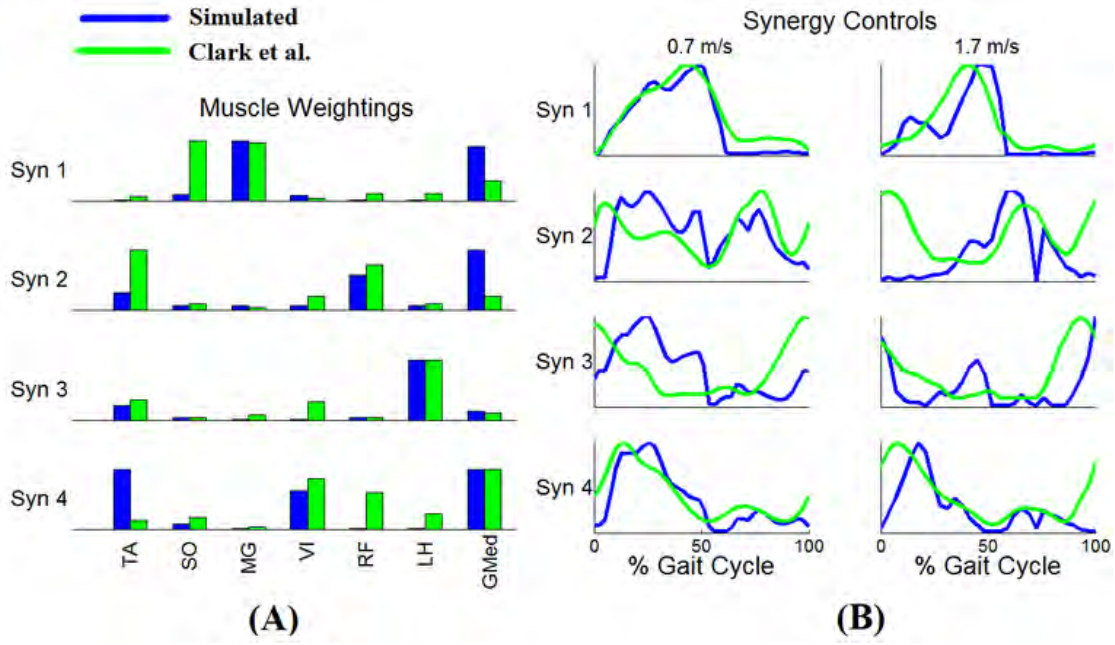
Methods: A single healthy subject walked on an instrumented treadmill at speeds of 0.7 and 1.7 m/s while marker-based motion capture and force plates respectively recorded the kinematics and kinetics (ground reaction forces) of gait. Three consecutive gait cycles at each speed were taken to collectively represent a family of walking. An OpenSim [4] musculoskeletal model of the right leg (5 DOFs, 24 muscles) was then scaled to match the subject's anthropometry followed by inverse kinematics which computed the joint angle trajectories from marker data. OpenSim's inverse dynamics tool was used to compute joint moments for the family of walking movements using joint angle trajectories and kinetics.

SCTD was formulated as an optimal control problem (OCP) whose unknowns were the muscle weightings and speed-specific synergy control signals. When excitations formed by the synergies were input to models of muscle dynamics, they resulted in 'simulated', muscle-generated moments at the 5 DOFs of the musculoskeletal model. The OCP's cost function sought to minimize the differences between simulated and experimental joint moments. The OCP was solved using the method of direct collocation, to solve for muscle weightings and synergy controls at each speed. The experimental synergies from Clark et al. (2010) were compared to their simulated counterparts by computing similarity indices – dot product of the normalized muscle weighting vectors from two synergies; an index of 1 would indicate exactly similar

muscle groupings – and correlation coefficients – between control signals from two synergies – between correspondent synergies from each dataset.

Results: Four muscle synergies were deemed sufficient for simulating the joint moments for the walking tasks, which was equal to the number of synergies determined by Clark et al. (2010). The mean similarity index computed between correspondent synergies from the experimental and simulated datasets (see Figure A) was 0.76 +- 0.14 (averaged over four synergies), which was taken to indicate similar muscle groupings in the two datasets. The mean correlation coefficients between synergy controls from the two datasets (Figure B) was 0.53 ($p < 0.01$) which was taken to indicate moderate similarities between experimental and simulated synergy controls.

Figure:



Conclusion: SCTD succeeded in identifying muscle synergies from a family of walking joint moments which bore several resemblances to their EMG-derived counterparts. This suggests that the examination of variations in EMG as well as joint moments across a family of movements, points toward the presence of similar, underlying synergy based control structures for walking. SCTD could assign muscle groupings to all the muscles in the model, which overcomes a limitation of EMG-derived synergies. However, SCTD results were still susceptible to errors arising from factors such as noisy motion capture data and generalized musculoskeletal model parameters. The ability of SCTD to account for dynamic muscle behaviour permits models of muscle spindles and Golgi tendon organs to be included in future studies, to see how afferent feedback would affect synergy structure.

DECLINE OF CONDUCTION TIME MAY LEAD TO CENTRAL NERVOUS SYSTEM ADAPTIONS THAT ARE IMPORTANT FOR POSTURAL CONTROL AND GAIT

Shuqi Zhang [1,*] Li Li [1]

[1]Health & Kinesiology, Georgia Southern University, Statesboro, United States

Introduction and Objectives: Slowed time course of the efferent / afferent pathway and slow processing time at the central level have been considered as the main causation of decreased postural control in aging population. However, there is no report of the correlation between the time course of pathway and measures of postural control. Therefore, this study is aimed at examining the correlation between different time courses of neuro-pathway (lower extremity sensory / motor nerve conduction velocity, and conduction time of H-reflex) and signal processing (characterizes of H-reflex) as well as the measures of postural control in aging population.

Methods: Six participants (one male, five female) were recruited. The proximal sural nerve conduction nerve conduction velocity (SCV) test, tibia nerve conduction velocity (MCV) test, plantar pressure sensitivity (PPS) tests, and H-reflex test at soleus muscles, were conducted. Based on the results of the H-reflex tests, we have also calculated the peak magnitude of H-wave (H), the peak magnitude of M-wave (M), H / M ration (H/M) and H-index. H-index was calculated using the equation of $H_{\text{-index}}$ = the square of (the height of the participants in cm / H-M latency in ms) X 2. For physical performance, the participants performed quite standing trials with their eyes open and closed, as well as a 6-minute walking (6MW) test and a timed-up and go test (TUG). Pearson correlations were used to examine the correlations among the measures of nerve function test as well as the correlations between the measures of nerve function tests and the outcomes of the physical tests.

Results: Age (70.5 ± 7.4 years old), body mass (82.4 ± 25.3kg), and height (162.7 ± 7.5 cm) of participants were recorded. The nerve function tests were conducted while the skin temperature was above 31°C. PPS (4.5 ± 0.84) among the participants were close to 5 points and indicates minimal loss of foot sole sensation. Therefore the following results were not under the influence of foot sole numbness as often the case for many elderly. The observed MCV (29.3 ± 2.2, range from 26.2 to 31.5 m/s) and SCV (22.7 ± 3.5, range from 17.2 to 25.7 m/s) are lower than the 40 m/s, the recognized healthy lower threshold for healthy elderly reported in the literature. The observed average conduction velocities were lower for sensory than that of the motor nerves. The observed range for sensory (~37%) was wider than that of the motor (~18%) conduction velocities. The observed $H_{\text{-index}}$ (75.6 ± 16.8, ranging from 53.0 to 97.3) has the largest variation (58.6%) among the three conduction time related measures. The other H-reflex related values were: H (1.00 ± 0.74 mv), M (4.57 ± 1.99mv), and H/M (0.25 ± 0.23). For the physical performance tests, participants exhibited greater 95% sway areas ($A_{95\%}$) during eyes closed conditions (205 ± 246 mm*mm) comparing to the eyes opened conditions (177± 115 mm*mm). But average sway velocities (V_{AVG}) were comparable for eyes closed (317 ± 72 mm/s) and eyes opened (O: 321 ± 76 mm/s) conditions. On average, participants walked (523 ± 116 m) in 6 minutes, and spend (7.07 ± 1.44ms) during TUG tests. Those values indicate normal locomotion capacities among participants. The correlation results are very revealing. SCV was positively correlated with $H_{\text{-index}}$ ($r = 0.811$, $P < .05$), where correlation between MVC and H-index

were not significant ($P > .05$), suggesting H-index value were mainly influence by sensory nerve among this population. Further, SCV was negatively correlated with H/M (r = -0.972, $P < .001$) and H (r = -0.951, $P < .001$), but positively correlated with M (r =0.805, $P < .05$). These observations, slower sensory conduction velocity accompanied by greater H-wave, could mean that sensory nerve impairments lead to increase spinal facilitation of H-reflex, as a compensatory mechanism. Along the same line, $H_{\text{-index}}$ was negatively correlated with H/M (r = -0.749, $P < .05$), but positively correlated with M (r = 0.823, $P < .05$). Although we have failed to observe significant correlation between $H_{\text{-index}}$ and any physical performance, but H/M was positively correlated with V_{AVG} (eyes open: r = 0.808, $P < .05$; eyes closed: r = 0.786, $P < .05$). The observations indirectly links the greater sway velocity with slower $H_{\text{-index}}$ since them both (V_{AVG} and $H_{\text{-index}}$) correlated with greater H/M value.

Conclusion: Slowed sensory nerve conduction velocity with increased conduction time of H-reflex were accompanied by increase the magnitudes of H and H/M, may indicates central nervous system adaptation to peripheral impairments during aging. These changes in the tested nervous system were not directly related to postural control and locomotion tests without observable foot sole numbness. The lack of correlation here may suggest H-reflex related pathway is not the primary reflexive mechanism for postural control and locomotion when cutaneous sensation is intact.

THE EFFECT OF SLOPE ON THE ACTIVITY AND VARIABILITY OF SEVEN PROXIMAL LOWER LIMB MUSCLES DURING WALKING

Annette Pantall [1,*] Jade Sharrer [2]

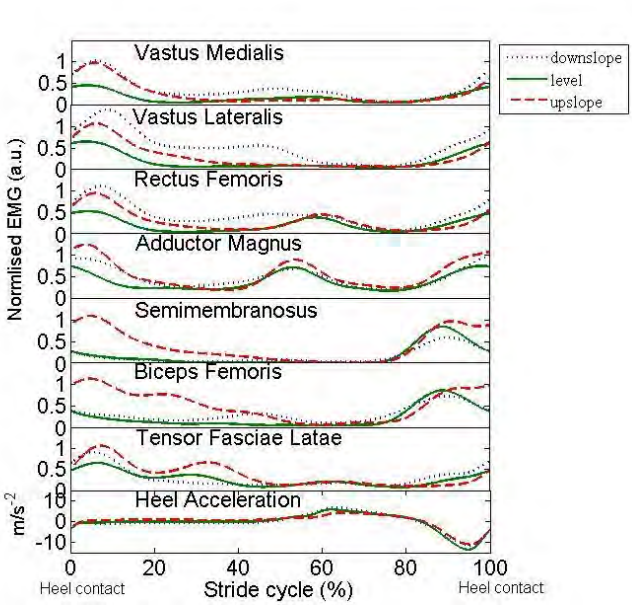
[1]College of Osteopathic Medicine, [2]Department of Kinesiology, Michigan State University, East Lansing, United States

Introduction and Objectives: Slope walking is associated with increased instability and greater risk of falling [1].The purpose of this study was to investigate lower limb muscle activity patterns during walking on level and sloped surfaces with an incline of 4.8°, the angle the American with Disabilities Act specifies for handicapped access ramps.Most previous studies have investigated walking on slopes with inclines of 8.5° and greater [2,3].We anticipated altered motor activity patterns for slope walking compared to level walking due to different mechanical demands.Specifically, we hypothesized that the adductor magnus (AM) and tensor fasciae latae (TFL) would exhibit increased activity during slope walking to improve mediolateral stability. Additionally, we expected the inter-stride variability for all muscles to be greater for slope walking compared to level walking.

Methods: Four healthy females participated in the study. Electromyographic (EMG) signals were recorded from vastus medialis (VM), vastus lateralis (VL), rectus femoris (RF), AM, semimembranosus (SM), biceps femoris (BF) and TFL of the right lower limb at a sampling rate of 1000 Hz.Bipolar surface electrodes were attached over the muscle bellies and an accelerometer was attached to the posterior calcaneus (Biometrics Ltd; Gwent, United Kingdom).The participants walked on a straight level surface at their comfortable self-selected speed for 200 m and then 10 times up and down a 4.2 m ramp with an incline of 4.8°.All data processing was performed in the MATLAB environment (v R2013a, The Mathworks, Natick, MA, USA). The EMG data were band pass filtered, rectified and smoothed at 10 Hz and divided into stride cycles, using heel contact times determined from filtered accelerometer data. EMG stride data were then time normalized and amplitude normalized to the maximum recorded during upslope walking.Repeatability was assessed through calculation of the coefficient of multiple correlation (CMC), a value of 1 indicating maximum repeatability and 0 minimum repeatability [4].The effect of slope on EMG amplitude was determined for each muscle with the significance set at $p<0.05$.

Results: In total, 81 steps were analyzed for downslope (mean stride duration 1041ms ±23), 513 steps for level (mean stride duration 1030ms ±22) and 69 steps for upslope (mean stride duration 1127ms ±39).All muscles changed significantly from level to slope walking. VM, VL and RF increased during early stance for upslope and throughout stance for downslope walking.AM increased during late swing and early stance for downslope and upslope. SM and BF increased during late swing and throughout stance.BF for downslope walking displayed an additional burst of activity during late stance.TFL increased during early stance for slope walking and there was a further increased bout of activity for upslope during midstance. Averaged across participants, the CMC for AM was below 0.90 for all 3 conditions and the average CMC across all muscles was lowest at 0.89 for downslope.

Figure:



Caption: Mean stride cycle EMG amplitude for 7 proximal lower limb muscles and mean heel acceleration averaged across 4 participants for downslope, level and upslope walking.

Conclusion: Results for VM, RF, SM and BF were similar to previously reported findings recorded from steeper slopes.VL showed a similar increase to VM during slope walking with a greater increase for downslope walking due possibly to the increased step width during downslope walking with altered patellofemoral mechanics [1]. The adductor AM and abductor TFL displayed increased activity during early stance, increasing mediolateral stability. The lower repeatability of AM suggests that neural control of this muscle may be a major factor in mediolateral instability for all walking conditions. The lower repeatability for downslope walking across all muscles suggests that motor control is less stable for this walking condition. In conclusion, even at gentle inclines, different motor control strategies are employed by all muscles. Clinically, an understanding of neural control strategies in healthy subjects will help understand problems in clinical populations during slope walking, for example, in individuals with transfemoral amputation [5].

Table:

	DOWNSLOPE	LEVEL	UPSLOPE
Heel Acceleration	0.993	0.994	0.991

GAIT CHARACTERISTICS OF OBSTACLE CROSSING IN OLDER ADULT FALLERS WITH AND WITHOUT PARKINSON'S DISEASE: INFLUENCE OF OBSTACLE TYPE AND DUAL TASK

Lisa Alcock [1,*] Brook Galna [1] Jeffrey Hausdorff [2] Sue Lord [1] Lynn Rochester [1]

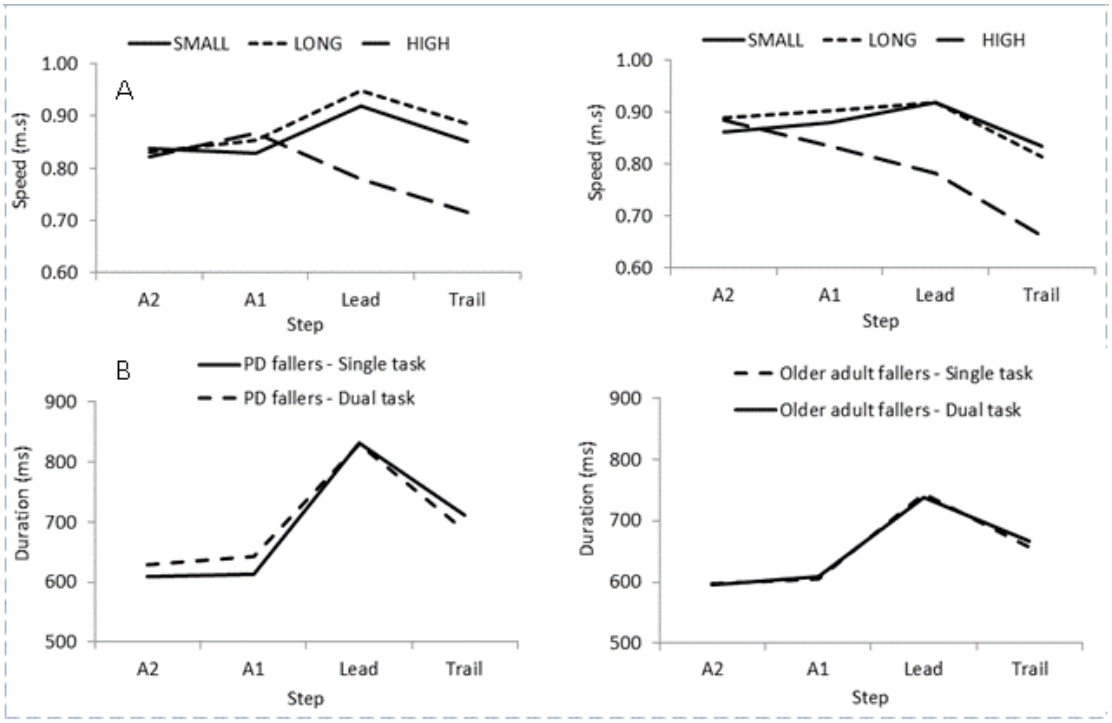
[1]Institute of Neuroscience, Newcastle University Institute of Ageing, Newcastle University, Newcastle upon Tyne, United Kingdom, [2]Department of Neurology, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel

Introduction and Objectives: The prevalence of falls is high in older adults and people with Parkinson's disease (PD) [1,2] with up to 50% falls resulting from a trip on an obstacle [3]. Safe obstacle negotiation requires accurate modulation of gait during the approach and crossing phases. Gait must also be adaptive to overcome environmental hazards of varying dimensions, including those that are small (i.e. clearing a carpet edge), long (i.e. avoiding a broken tile) or high (i.e. negotiating a pavement increment). In addition, successful obstacle negotiation can be compromised when performing a concurrent cognitive task [4]. Although previous studies have identified obstacle crossing impairments in people with PD and older adults [5], little is known about how the interaction of increased cognitive and motor demands may compromise safety during obstacle negotiation. The aim of this study was to understand the temporal-spatial characteristics of obstacle negotiation as a function of obstacle type and explore this relationship with respect to dual task in older adult fallers with and without PD.

Methods: Gait was measured in 9 people with PD (Mean age[SD]68.9[7.1]y, Hoehn & Yahr II-III) and 10 older adults (76.6[7.9]y) with a history of recurrent falls whilst negotiating three different sized obstacles (H/W/D): small (2/60/2cm), long (2/60/15cm) and high (15/60/2cm). Spatiotemporal gait characteristics (walking speed, step length, duration and width) were measured using an instrumented walkway (GAITRite). All obstacle conditions were completed under single and dual task (maximal digit span recall). A general linear model was used to evaluate the effects of obstacle type (small, long, high) and obstacle step (penultimate (A2) and final (A1) approach steps, and the lead (Ld) and trail (Tr) crossing steps) on gait characteristics under both single and dual task in PD and older adult fallers.

Results: There was a main effect of step for all gait outcomes ($p<.029$) and of obstacle type for speed, width and duration ($p<.001$) such that the crossing steps were completed more slowly with a wider step for the high obstacle. As expected, there was a main effect of cognition whereby all conditions were completed at a slower speed during dual task ($p=.039$). Interaction effects were observed for speed (ObstacleType*step $p<.001$ and ObstacleType*step*group $p=.037$), length (ObstacleType*step $p=.029$ and Cognition*step $p=.003$), width (ObstacleType*step $p=.008$) and duration (ObstacleType*step $p<.001$ and Cognition*step*group $p=.041$). Interaction effects revealed that lead and trail crossing steps were slower than approach steps for both groups; PD fallers slowed down earlier in the approach phase compared with older adult fallers (A1; Figure 1a). In addition, dual task had a significant effect on step duration such that the approach steps were of longer duration and the trail limb step was shorter in length for PD fallers compared to that observed during single task (Figure 1b). Although not significant, it is of interest to note that there was a tendency for people with PD to widen their step considerably when crossing the small (26% increase) and high (28% increase) obstacles but not the long obstacle (1% increase) when performing the dual task.

Figure:



Caption: Figure 1 – Interaction effects of dual task on speed (A) and step duration (B) for PD and elderly fallers

Conclusion: Our findings suggest a complex interaction between the mechanical and cognitive demands of obstacle negotiation in PD and older adult fallers. Both groups modulated their gait in response to obstacles of varying sizes, with the greatest changes observed when crossing the high obstacle which presented greatest mechanical challenge. Performing a dual task resulted in slower obstacle negotiation, with the greatest effect seen during the trail crossing step. PD fallers were slower during their approach and this prolonged the motor planning phase, suggesting greater cognitive interference during the approach. PD fallers also took longer to complete both crossing steps irrespective of obstacle type or cognitive load resulting in a longer time spent in single limb support, when maintaining postural control is most difficult. Increasing step width when crossing small and high obstacles may be a compensation to help widen their base of support and maintain postural control. A lack of step width adaptation when negotiating long obstacles may be a result of needing to lengthen their step and thus hinder the ability to widen steps, putting people at a greater risk of falling sideways. These results highlight the need for further work to understand the physical and cognitive demands of obstacle negotiation.

EFFECT OF WRIST POSTURE AND RATE OF FORCE DEVELOPMENT ON FINGER INDEPENDENCE

Steve May [1] Peter Keir [1,*]

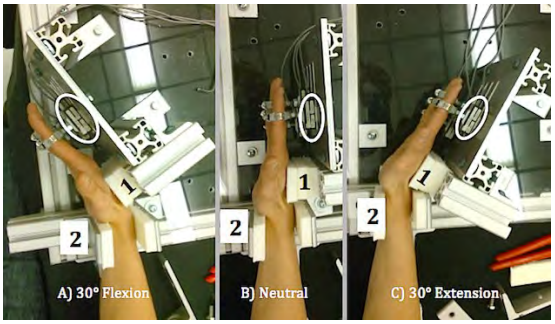
[1] Kinesiology, McMaster University, Hamilton, Canada

Introduction and Objectives: When asked to move or apply a force with an individual finger, movements and/or forces tend to occur in the other fingers to varying degrees [1]. This involuntary "enslaving effect" (EE) is attributed to both mechanical and neural factors. While posture affects muscle length and thus muscle force, the effect of wrist posture on EE has yet to be examined. Wrist posture alters muscle length, which modulates both active and passive muscle force and likely alters the stress in interconnections between tendons. Rate of motion has been shown to affect enslaving [2], as has changing force levels in isometric contractions [3]. The purpose of this investigation was to evaluate the effect of wrist posture on enslaving effect during isometric finger exertions with constant force, as well as increasing, and decreasing forces at different rates.

Methods: Twelve male participants performed submaximal isometric finger flexion and extension exertions of the index and ring fingers with all fingers secured to force transducers via adjustable rings (MLP50, Transducer Techniques, Temecula, CA, USA). Trials were performed at 3 wrist angles: (i) 30° flexion, (ii) 0° (straight), and (iii) 30° extension (Figure 1). Each trial consisted of the task finger (index or ring) performing a 5 second isotonic contraction at 25% maximum voluntary contraction (MVC) and two ramp contractions. Ramp contractions increased to 50% MVC and returned to zero with a 0.5 s hold at 50%. They were performed at 25% MVC/s and 10% MVC/s. Each condition was repeated 3 times for a total of 108 trials. Surface EMG (Biometrics Ltd., Gwent, UK) was recorded from each compartment of extensor digitorum (ED 2-5) and flexor digitorum superficialis (FDS 2-5). Force in the non-task (slave) fingers were normalized to MVC to yield enslaved force (EE). Enslaved forces and EMG were analyzed at 25% MVC for the isotonic, ascending and descending contractions. Multiple rANOVAs were followed up with Tukey's HSD where necessary (IBM Statistics 20.0, SPSS Inc. Chicago, IL, USA).

Results: There was a significant posture x direction x slave finger interaction seen by greater EE of the fingers adjacent to the task finger in extension exertions with the wrist extended (all $F_{4, 44} > 2.6$, $p < 0.05$). Thus, for extension exertions, enslaving was higher at shorter muscle lengths (Table 1). There was a significant posture x compartment interaction in muscle activity for extension exertions (both $F_{14, 154} > 15.512$, $p < 0.0001$), and ring finger flexion exertions ($F_{14, 154} = 3.918$, $p < 0.0001$) where muscle activity of non-task fingers was significantly greater at shorter muscle lengths (extended or flexed wrist, respectively). In ramp exertions, rate and phase significantly affected EE for both index and ring finger exertions (all $p < 0.001$). In fingers adjacent to the task finger, EE was higher with the slower force rate in the descending phase. Despite the EE being higher with a slower force rate and in the descending phase, muscle activity was not significantly increased in these exertions ($p < 0.05$).

Figure:



Caption: Figure 1. Top view of the apparatus securing the hand into: (A) 30° wrist flexion, (B) 0°, and (C) 30° wrist extension. Force transducers (circled) were attached to padded rings . "1" = adjustable dorsal hand support, and "2" = adjustable wrist support.

Conclusion: We found that wrist posture significantly affected enslaving, most notably in fingers adjacent to the task finger in extension exertions at a shorter muscle length. When the extensors were active and shortened there was an increase in muscle activity across all compartments, suggesting the extensors may be controlled to some extent by a common drive. Additionally, the rate of force production and type of contraction (isotonic, increasing or decreasing force) both had a significant effect on enslaving, without increasing muscle activity.

EFFECT OF FATIGUE ON HIGH SCHOOL UNDERHAND FEMALE PITCHERS

Andrew Kraszewski [1,*] Mandi Gibbons [1] Howard Hillstrom [1] Andreas F. S. Kontaxis [1]

[1] Leon Root Motion Analysis Laboratory, Hospital for Special Surgery, New York, United States

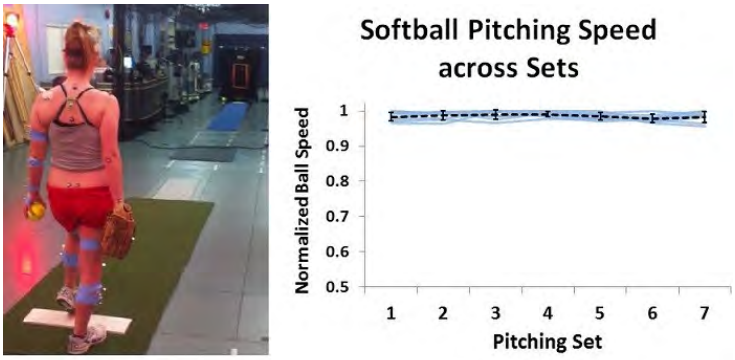
Introduction and Objectives: The repetitive stress that occurs with pitching alters both structural as well as functional mechanics of the shoulder complex. [1] In addition to structural adaptations, functional factors, such as abnormal scapular motion, has been noted in previous pitching studies [2] and may contribute to the development of shoulder pain. Most of our current knowledge related to the mechanics of pitching is derived from simplified kinematic measurements of the humerus relative to the trunk. No data exists outlining the three-dimensional motions of the humerus relative to the scapula during an underhand softball pitch, although these motions have been identified in clinical studies as key contributors to the development of shoulder pain

The purpose of this investigational team is to develop a protocol to objectively determine normative pitching kinematics (scapula and humeral thoracic) for the high school female underhand pitcher and identify potential kinematics adaption due to fatigue

Methods: Eight female high school athletes between the ages of 15 and 18 years were recruited for this study. Only softball pitchers in their sophmore or junior years were included that had no history of previous shoulder injury. The kinematic recordings were performed in a motion analysis laboratory using a 12 camera 3D motion capture system recording at 200Hz. A set of reflective markers were used to define technical and anatomical frames for the hand, forearm, humerus, scapula and trunk (Figure). The marker placement and the anatomical calibration of bony landmarks followed the recommendations of ISB [3]. For the dynamic tracking of the scapula, a special device was designed based on the recommendations of Karduna et al [4]. In order to mimic a game-like situation, a pitching mound was set up at regulation distance (43') from home plate where a pitching target with a designated strike zone was located. All athletes completed 105 pitches in sets of 15 with a rest of 5 minutes between intervals. Speed and accuracy were measured for all throws; accuracy was defined as a ball or strike from a single observer and speed throw was recorded with a radar gun placed close to the home plate. Voluntary maximal isometric strength of the internal and external rotators was evaluated before and after pitching using a Biodex dynamometer (Biodex Medical Systems, Shirley, New York) in three positions (45° IR, 0° neutral, and 45° ER) with the arm abducted in 45 deg. A paired t-test (2-tail) was used to compare pre- and post-pitching strength.

Results: Results showed a large glenohumeral (GH) motion during pitching, but with a very consistent pattern for all 3 DoF (Table). Statistically significant differences were noticed on glenohumeral flexion and rotation ROM as well as scapula protraction ROM, but all differences were small. Measures of ball speed also showed consistency within subjects with the ball velocity values being constant between first and last pitch. Pre and post-pitching strength measurements also showed no significant changes, indicating no fatigue among the players. Accuracy data (ball or strikes) were variable with no specific pattern across the 105 pitches.

Figure:



Caption: (a) Indoor pitching set-up. Athletes pitched from a mount to a a designated strike zone at regulation distance. (b) Ball speed data showed that athletes were able to maintain pitch velocity during all 7 sets (105 pitches)

Conclusion: The study has demonstrated a protocol for the study of underhand softball pitching. To our knowledge, this is one of the first studies to analyze humeral thoracic as well as scapula thoracic kinematics during softball pitching. The results do not indicate any GH kinematics changes during the throwing protocol which may suggest that the subjects are not fatiguing during the 105 throws. This is also supported by the constant strength and speed ball values that did not drop during the 105 pitches.

Table:

Shoulder Joint Parameters		
	Set 1	**Set 7**

INTEGRATED ANATOMICAL DATABASE FOR THE CREATION OF A COMPLETE MUSCULOSKELETAL MODEL OF THE HUMAN HAND

Faes Kerkhof [1,*] Evie Vereecke [1]

[1]Development and Regeneration @ Kulak, Leuven University, Kortrijk, Belgium

Introduction and Objectives: By combining arthrokinematics with soft-tissue anatomy and known external forces, a musculoskeletal model (MSM) can be created. These models make calculations of muscle and joint forces possible and are a valuable tool to explore the functioning of healthy and pathological joints.

Gathering the data needed to create a MSM can be challenging. 3D osteological data can easily be acquired through CT and MR imaging. Physiological data (muscle length, cross-sectional area, pennation angle, etc.) from arm and hand muscles exist as well. However, precise information of muscle pathways and moment arms are hard to obtain. Previous studies often used specimens with altered tissue properties due to embalming, or described muscle pathways without using a bone reference frame making it impossible to determine precise pathways and moment arms. To date, there is no integrated data set in which osteological and soft-tissue data have been collected together, which might also explain why a complete MSM of the hand has not yet been developed. Therefore, the goal of the present study is to create an integrated and open anatomical database of the human hand that can be used for musculoskeletal modelling.

Methods: A fresh-frozen cadaveric arm was mounted in a frame with a polycarbonate rod for stabilization. Four polycarbonate bone pins where used to create a fixed anatomical reference frame of the forearm. The Philips screw indent of the bone pins were used to assure repeatable, precise tip placement of the 3D digitizer stylus (Polhemus Fastrak). To obtain the bone geometry and the precise localisation of the bone pins in relation to the bone, a CT scan of the entire rig-mounted specimen was made. The cartilage and soft tissue geometry was visualised with a 3T MRI scanner using contrast fluid. For each muscle-tendon unit (MTU), origin, insertion and via points were digitized using a 3D digitization system with sub-millimeter accuracy (+/- 0.5 mm). Muscle attachment points >5 mm were digitized as a single point. All other attachment points where digitized along the edges of the muscle ‘footprint’. In total, 19 intrinsic and 20 extrinsic muscles were digitized. In addition, origin and insertion of the major ligaments were also digitized using the same protocol. After digitization, the MTU was prelevated from the specimen and muscle mass, MTU length, muscle belly length, fascicle length, pennation angle, muscle volume, external and internal tendon length were measured. Subsequently, the physiological cross-sectional area was calculated for each muscle. Distances were measured with a digital caliper and muscle mass was determined using a digital scale (+/-0.01 g). The pennation angle was measured at three places within the muscle belly. Muscle volume was determined by the volume of water displaced in a measuring glass by submersion of the muscle belly. For the smallest intrinsic muscles (< 1 ml), volume was calculated by multiplying the mass with the average muscle density of the larger hand muscles.

Results: The results of this study provide important information which can be used to build more complete and more accurate musculoskeletal models of the human hand. Importantly, this study combines osteological and soft-tissue data from the same specimen, data which is fully digitized and quantified.

The decision to collect data from only one specimen was a conscious decision. Previous investigations have shown that there is a high variation in anatomical properties between individuals as well as a wide variety of motor control strategies to perform a single task. Hence, creation of an "average" forearm would contribute little to our understanding of joint functioning. Ideally, a subject-specific model of the hand should be created based on morphological parameters from the patient (using MRI, EMG and ultrasound), but this will be a topic for future investigation. First, we want to create an accurate and validated MSM of the hand.

Conclusion: By creating an open access and digitized anatomical database of the human forearm and hand, information is available to create a more accurate and more complex MSM. Furthermore, by the open nature of this study, everyone who wants to make a model of the hand, can create one and/or the data can be complemented with additional functional data (e.g. force data, other kinematics, EMG). In addition, the fact that it considers an integrated dataset makes that combining different datasets is no longer necessary.

USE OF SCAPULOHUMERAL RHYTHM, SYMMETRY AND KINEMATICS TO IDENTIFY ABNORMAL MOVEMENTS OF THE SHOULDER

Aliah F. Shaheen [1,*]Alexander van Heesewijk [1]Alexander van Heesewijk [1]

[1]Mechanical Engineering Sciences, University of Surrey, Guildford, United Kingdom

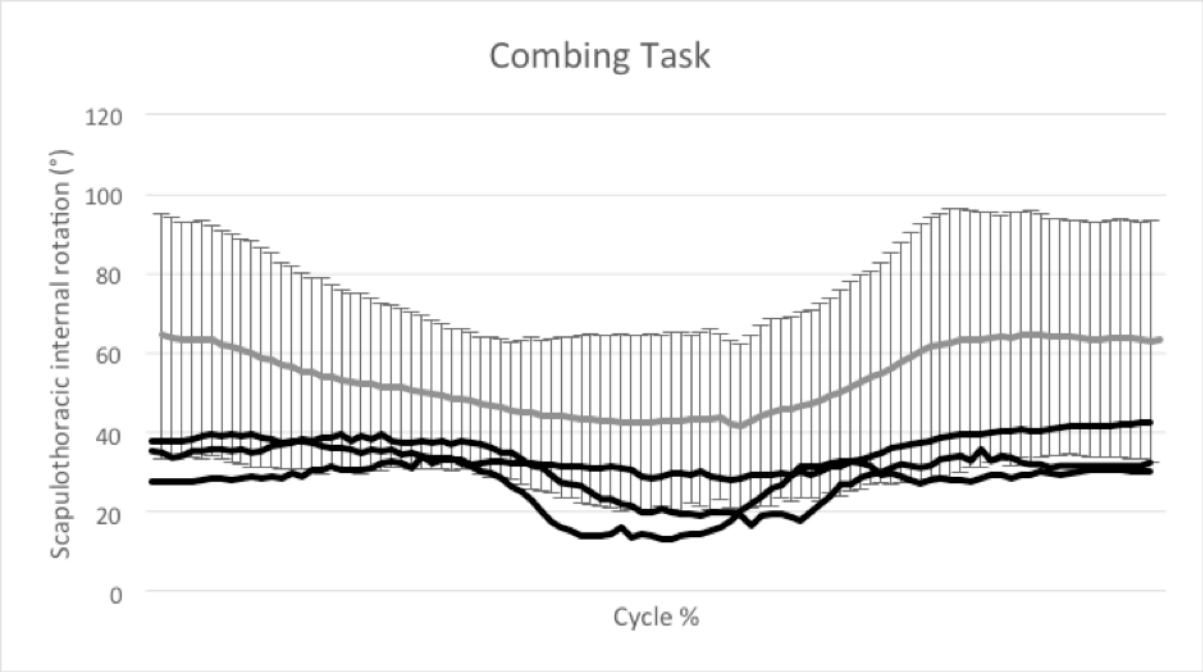
Introduction and Objectives: Abnormal shoulder movement and biomechanics have been associated with a number of shoulder pathologies [1]. However, previous studies investigating the nature of abnormal movement present in different pathological populations have reached different conclusions regarding both the direction and degree of movement deviation. Instrumented movement analysis techniques have been used for decades to analyse gait; these methods are commonly used to quantify deviations from normal movement in pathological populations. However, the use of these techniques has not been extended to benefit clinical applications in upper-limb pathology. This is because of a number of technical issues in measuring and quantifying upper-limb movement, such as the presence of sot-tissue artefact and its large range of movement. In addition, the large variability in upper-limb movement has been reported to hinder the use of traditional techniques in detecting the presence of abnormal movement. Although some studies have reported statistical differences between pathological and healthy populations [1], the parameters describing a normal shoulder movement are not fully defined meaning that it is difficult to identify the type of abnormal movement present in a single symptomatic subject. Understanding the abnormal movement present in the symptomatic shoulder could provide important insight into the mechanisms responsible for developing pathology or injury and it could be used to direct rehabilitation.
Scapulohumeral rhythm refers to the ratio of scapulothoracic and glenohumeral movement during elevation in the scapular plane, it is one of the most basic measures of coordination and it has been suggested as an indicator for the presence of abnormal deviation. Shoulder symmetry and scapular resting position and movement have similarly been suggested as possible indicators for pathological deviation.
The aim of this study was to investigate the use of scapulohumeral rhythm, symmetry and shoulder kinematics to identify the presence of abnormal shoulder movement in symptomatic shoulders compared to normative values obtained from healthy individuals.
Methods: Measurements from 8 healthy shoulders and 3 symptomatic shoulders were collected, participants were asked to fill-out DASH forms [2] to assess their physical function. Asymptomatic participants did not have history of upper-limb pathology or pain, symptomatic participants had a mean DASH score of 86 ±10, but they were not classified according to their underlying pathological condition. A motion analysis system with 11-cameras (Qualysis) running at 200 Hz was used to capture the data of reflective markers attached to the participants' upper-limb and pelvis. Measurements were obtained of both dominant and non-dominant side to assess symmetry. Participants performed flexion and scaption as well as three tasks simulating activities of daily living (ADLs); combing the hear, washing the back and putting on a seatbelt.
Data obtained from the healthy shoulders were used to compute mean rotations and normative bands (± 1 standard deviation). Rotations obtained from the pathological subjects were then overlaid and examined for obvious deviations.

Coordinate frames were defined for the thorax, scapula, humerus and pelvis and Euler angle rotations were used to compute the scapulothoracic, glenohumeral and thoracic rotations according to the ISB recommendations.

Results: The variability of the joint angular rotations were high in healthy shoulders, this meant that none of the pathological subjects consistently fell out of the normal range. In addition, the joint ranges of motion of the pathological subjects were comparable to those of the healthy subjects. However, the scapular internal rotation seemed to show the greatest difference between the pathological subjects and the healthy population in some of the performed tasks; for example hair combing is illustrated in the figure.

Interestingly, shoulder symmetry was not a good indicator of the presence of abnormal movement with healthy and pathological shoulders showing similar degrees of asymmetry between their dominant and non-dominant side. Only one of the pathological subjects had a scapulohumeral rhythm which was significantly higher than the normative range.

Figure:



Caption: Mean and standard deviations of scapular internal rotation in healthy shoulders (grey) and the rotations of the three pathological subjects (black)

Conclusion: The high variability present in the normal shoulder means that it is difficult to identify the presence of abnormal movement in pathological populations. Joint kinematics remain to be better at identifying pathological deviations than other measures such as scapulohumeral rhythm and symmetry. However, a combination of these measures may be a superior alternative in detecting abnormal movements in symptomatic shoulders.

INTRAMUSCULAR EMG AND KINEMATIC ANALYSIS OF HAND POSTURES THAT CORRESPOND WITH GRASPING AND POINTING TASKS

Marije De Bruin [1 2,*] Sarah Wohlman [1 3] Wendy Murray [1 2 3 4]

[1]Sensory Motor Performance Program, Rehabilitation Institute of Chicago, [2]Physical Medicine and Rehabilitation, Northwestern University, Chicago, [3]Department of Biomedical Engineering, Northwestern University, Evanston, [4]Edward Hines Jr. VA Hospital, Hines IL, United States

Introduction and Objectives: In our daily life, we constantly and almost unconsciously use our hands during what seem to be uncomplicated tasks: making a sandwich, tying our shoelaces, or shaking someone's hand. However, the hand is astoundingly complex, both from a mechanics and control point of view: over 20 degrees of freedom are controlled through nearly 40 muscles.

The muscles that control the hand can be divided into intrinsic and extrinsic muscles. The intrinsic muscles originate and insert within the hand, whereas extrinsic muscles originate in the forearm and cross the wrist before inserting on the fingers and thumb. Persons that lose their hand through amputation also lose the intrinsic muscles. As a result, any prosthetic hand controller that relies on EMG activity of muscles as input signals (e.g. i-Limb, Bionic arm) only has access to the extrinsic muscles of the hand.

Creating a controller for a multi degree-of-freedom prosthetic hand that allows the artificial hand to behave like the intact hand requires a broader understanding of how hand muscles produce complex hand motions. Previously, studies involving complex movements have focused on EMG only (e.g. [1]) or used surface EMG sleeves that are not able to attribute activity to a specific muscle (e.g. [2]). Our objective was to characterize how people perform movements that resemble pointing and grasping. To reach this objective, we simultaneously collected both hand kinematics and muscle activations of thumb and index finger during American Sign Language (ASL) gestures. The gestures were selected so that they resemble pointing or grasping.

Methods: Fourteen subjects were included after having given informed consent, the human subjects protocol was approved by the IRB of Northwestern University. Intramuscular EMG data were recorded using bipolar, fine-wire electrodes. The electrodes were inserted into each muscle, using a 27-gauge hypodermic needle. EMG signals were collected at 2000 Hz using a Delsys Bagnoli-16 system (Delsys Inc., Boston MA) and filtered 4th order Butterworth band-pass 10-500 Hz, notch 59.5-60.5 Hz, and low-pass 8 Hz). The highest peak activity per muscle was selected after applying a Gaussian smoothing algorithm with a 100ms window.

Subjects were instrumented with a Cyberglove II (Cyberglove Systems LLC, San Jose CA) to measure kinematics of the thumb. A custom calibration protocol was used to convert voltages of the Cyberglove sensors to joint angles [3]. Joint angles were collected at 100 Hz and interpolated to 2000 Hz to enable comparison with EMG.

Subjects were instructed to closely follow a video of a hand gesturing an "L", "D" or "O" in ASL (Fig. 1A). The video included the same initial position for each trial (Fig. 1A, screen 1&5). Subjects then moved to the posture intended to signal starting and ending of the ASL movement (extended fingers, Fig. 1A, screen 2&4). Joint angles of the middle finger

were then used in a customized algorithm [4] to automatically and objectively determine start- and endpoints of the trials and normalize them to time.

Results: We have developed an experimental protocol that enables subjects to perform complex hand gestures in a standardized and repeatable manner. This approach, combined with a data processing algorithm implemented to objectively define the start and endpoints of the complex gesture, result in a well-defined, time-normalized gesture (Fig. 1A-C). This methodology enables us to directly compare the motion and EMG data across trials and subjects, similar to comparison of several gait cycles in gait analysis. In an example subject, the standard deviation of MCP flexion-extension of the thumb is less than 10 degrees across three trials when the hand is in the target posture (cf., 40-65% of trial, Fig. 1D). However, the muscle activation strategies this subject used to achieve the posture sometimes varied considerably across trials (cf., standard deviations of muscle activation during L, Fig. 1D).

Figure:

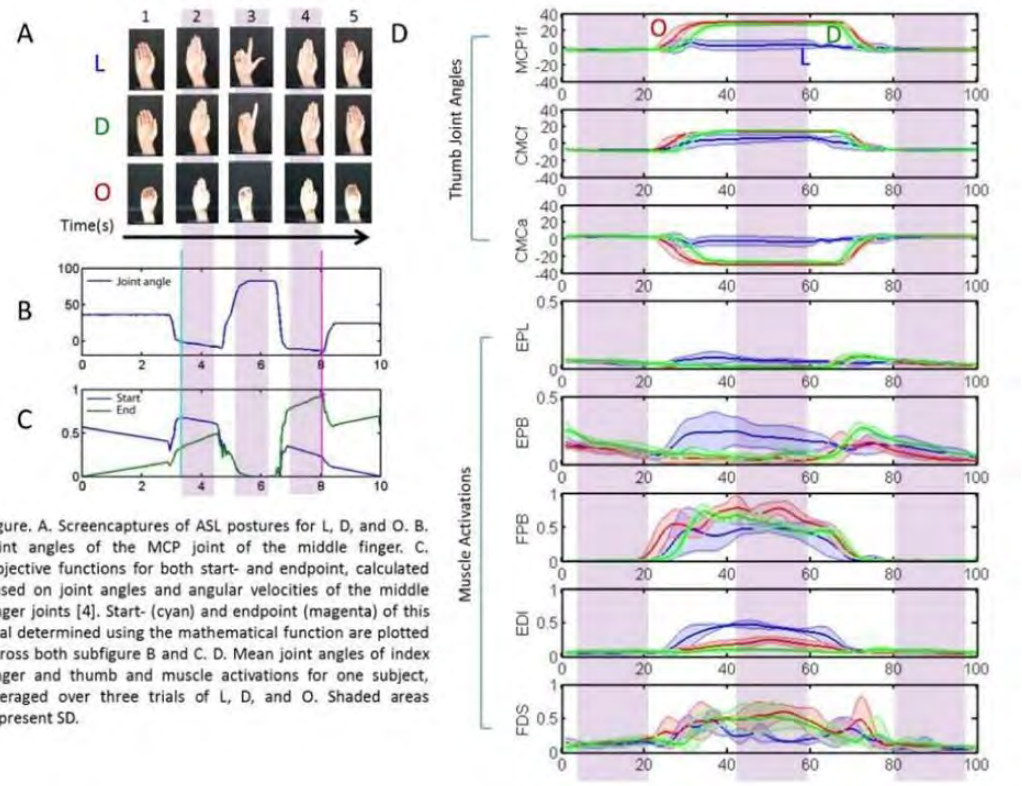

Figure. A. Screencaptures of ASL postures for L, D, and O. B. Joint angles of the MCP joint of the middle finger. C. Objective functions for both start- and endpoint, calculated based on joint angles and angular velocities of the middle finger joints [4]. Start- (cyan) and endpoint (magenta) of this trial determined using the mathematical function are plotted across both subfigure B and C. D. Mean joint angles of index finger and thumb and muscle activations for one subject, averaged over three trials of L, D, and O. Shaded areas represent SD.

Conclusion: We have collected a substantial dataset, describing how subjects both move their hand and activate the muscles of thumb and index finger during the performance of different ASL letters. Our long-term goal is to use the EMG-data from this study to drive feed-forward simulation of a musculoskeletal system of the upper extremity and compare the kinematic outcomes of the simulations to the experimentally measured joint angles. The chosen letters approximate functional movements, like pointing, grasping, or pinching, without actually exerting external forces on the system, which simplifies modeling these movements. Using this model will not only advance our knowledge about the control of the intact hand, but will also enable us to study situations in which sets of muscles are lost to injury or disease.

ANALYSIS OF MUSCLE ACTIVITIES OF THE BOWLING ARM IN CRICKET DURING DELIVERY PHASE

Rucha Kashalkar [1]Vikram Mhaskar [1]Graham Arnold [1]Rami Abboud [1]Weijie Wang [1,*]

[1]University of Dundee, Dundee, United Kingdom

Introduction and Objectives: Cricket is a popular sport world-widely, especially in commonwealth countries. Upper limb injuries remain to be of concern in cricket fast bowlers. Shoulder injuries are more common in these bowlers. Efficient muscle action combined with a co-ordinated movement of the bowling arm will help sportsmen to generate higher ball speed and reduce injuries. So far, the muscle activities of the bowling arm during delivery phase have not been fully investigated. The aim of this study was to study the electromyography (EMG) in the upper limbs during delivery phase in cricket.

Methods: Twenty right handed male fast to medium bowlers were recruited for this study. The data collection was carried out in an indoor pitch with artificial grass simulating field bowling action. The EMGs and joint movements of the bowling arm were collected using Delsys® and Vicon® systems, respectively. A nine reflective marker of model was used to calculate the joint ranges of motion (RoM) in the shoulder and elbow. EMG was collected by surface electrodes connected through a wireless recording system for the Biceps, Anterior deltoid, Lateral deltoid, Pectoralis major, Trapezius, Latissimus dorsi and Triceps. The EMG from 80 individual bowling deliveries was processed in terms of maximum voluntary contraction (MVC). Root mean square (RMS) of muscle activity, onset and termination positions, maximum muscle activity, and position of maximum activity in the delivery phase were calculated. The bowlers were compared in 2 groups, professional (N=36 deliveries) and amateur (N=44 deliveries) for selected variables.

Results: The Pectoralis major was found to be the most active and important muscle (RMS= 63% of MVC). Maximum muscle activity surpassed its MVC value for Pectoralis major were 195% of MVC, for the Anterior deltoid 151% of MVC and for Latissimus dorsi 102% of MVC. The peak muscle activities for all muscles were found to occur within 40-60% of the delivery phase. Muscle activation sequence was also analysed. The comparison between the two groups for RMS and maximum muscle activity revealed significantly different results for Anterior deltoid ($p<0.01$) and Latissimus dorsi ($p<0.01$). Joint ROMs were also found to be statistically different between the two groups. The elbow angles were found to be varying above the legal limit in amateur bowlers.

Conclusion: The Pectoralis major and Latissimus dorsi are important contributors to speed in cricket bowling. Professional bowlers use these two muscles along with co-ordinated movement of the trunk and the bowling arm to produce higher ball speeds. Amateur bowlers tend to use Anterior deltoid instead of Latissimus dorsi which may predispose them to overuse injuries. This study provides a helpful guide for coaching and rehabilitation purpose for cricket bowling.

THE TIME-COURSE CHANGE OF PITCHING BIOMECHANICS IN A SIMULATED BASEBALL NINE INNINGS

Ryosuke Akaguma [1,*] Shoma Kudo [1] Akinori Nagano [2]

[1]Department of Sport and Health Science, [2]Faculty of Sport and Health Science, Ritsumeikan University, Shiga, Japan

Introduction and Objectives: In Japanese amateur baseball scenes, we often see one player pitch in two or three successive games over 100 pitches per game under the hot summer sun. Decreasing ball speed and / or control in the latter stage is a major determinant of victory or defeat. The purpose of this study was to reveal the mechanism and effect of pitching fatigue in the latter stage.

Calabrese (2013)[1] divided pitching motion into six stages: Wind-up, Stride (Early Cocking), Late Cocking, Acceleration, Deceleration, and Follow Through. They studied the behavior of kinetic chain to seek the factor of fatigue. Their study analyzed one pitching motion when the pitcher had already been fatigued. We examined the time-course change of kinetic chain when pitchers do pitching over 100 pitches in this current study.

Escamilla et al. (2007)[2] studied pitching motion through approximately 100 pitches with an optical motion capture system. The study focused on joint angle and torque. We performed detailed analysis using the kinetic data from force plate. Using force plate, we can obtain information about the change of postural perturbation at the time of standing, and postural shifting at the time of landing.

Methods: College baseball players were recruited as subjects (age 21±0.5). (1) The subjects threw 15 pitches per inning for 9 innings. Pitching interval was 5 seconds. This protocol simulated a baseball game in the laboratory. Inning intervals were 5 minutes. (2) We measured back muscle strength, grip strength, CMJ (counter movement jump height), and heartbeat in inning intervals. (3) The subjects threw only fastball at full speed. The measure of control was divided into 3 categories: (a) strike zone (b) a ball zone away from the strike zone by two balls (c) others. We obtained kinematic and kinetic data of pitching motions with an optical motion capture system (MAC3D) and force plate (TF-4060-B). The data were further analyzed using a musculoskeletal model (nMotion musculous, nac).

Results: (1) Maximum height of the elbow at the time of a throw decreased in the 9th inning compared to in the 1st inning. The value decreased approximately 3cm~5cm. For subject A the change was from 128.3cm to 125.0cm. For subject B the change was from 141.6cm to 137.8cm. For subject C the change was from 112.7cm to 107.0cm (height above the ground).

(2) In subject C, the maximum height of left heel at the time of standing gradually decreased (max=67.4cm in 9th inning, min=30.3cm in 3rd inning). Subject A and B did not exhibit this decrease (subject A, 69.3cm±3cm. subject B, 69.0cm±2cm).

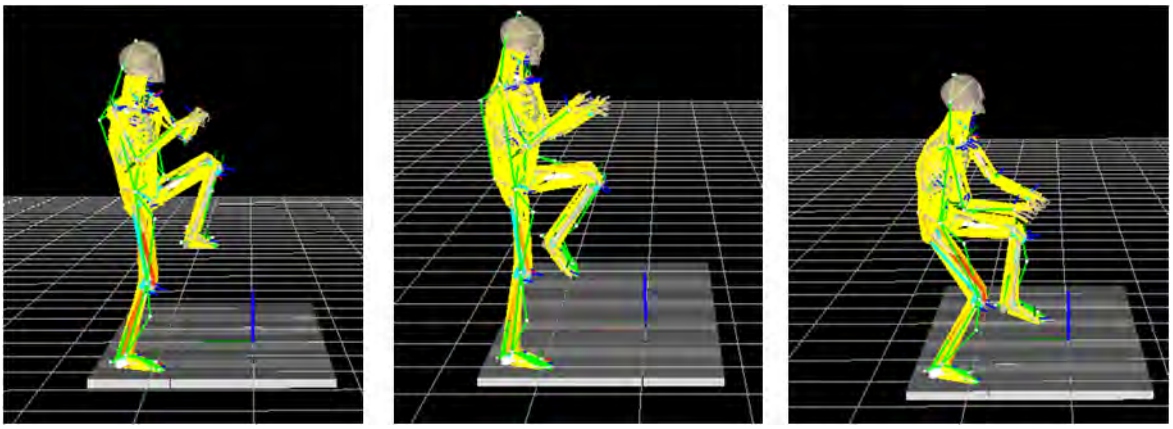
(3) Ball speed did not change significantly. The ball speed of subject A changed from 108 km/h to 109 km/h. The ball speed of subject B changed from 98 km/h to 105. The ball speed of Subject C changed from 117km/h to 112 km/h (average of 1st inning and 9th inning).

(4) There were no change in the values of: back muscle strength, grip strength, CMJ and heartbeat.

(5) Wrist speed did not decrease. The wrist speed of subject B and C hardly changed from 1st to 9th inning. The wrist speed of subject A decreased until 6th inning, but the value improved after 7th inning.

(6) The time from the instant when the front leg contacts the ground to the instant when the elbow height gets maximum decreased in subject A and B. Subject C did not exhibit this tendency. Whether the subject bent the knee or not is thought to be a reason.

Figure:



Caption: Snapshot of pitching kinematics for subject A, B and C

Conclusion: All subjects decreased the height of the elbow at the time of throwing.

There were no significant change of values in back muscle strength, grip strength, CMJ, and heartbeat.

The change pattern of pitching form was subject specific.

THE MECHANICAL POWER OUTPUT – VELOCITY CURVES FOR VELOTRON ERGOMETER CYCLING AND TRACK CYCLING, AND THE RELEVANCE FOR CYCLING PERFORMANCE AND PACING RESEARCH.

Florentina J. Hettinga [1,*] Patrick Schoenmakers [1] Albert Smit [2]

[1]School of Biological Sciences, Centre of Sport and Exercise Science, University of Essex, Colchester, United Kingdom, [2]Netherlands Olympic Committee*Netherlands Sports Confederation, Papendal, Netherlands

Introduction and Objectives: Interaction with a realistic environment is an important aspect determining pacing behaviour in athletes[1]. To understand cycling performance, it is important to evaluate this performance in a well-controlled laboratory setting, while simulating competition. Besides reliability of the testing equipment, ecological validity is an important aspect. The computer-controlled, electronically-braked Velotron Racermate cycle ergometer has been introduced to closely resemble competitive situations. On screen opponents can be offered, it allows gearing and wind and hilly conditions can be imposed. Another important aspect is that in contrast to most other ergometers, the Velotron claims to incorporate the non-linear relation between mechanical power output and velocity. Due to the effects of air-frictional forces, which are non-linearly related to velocity, it will cost an athlete more energy to accelerate above his/her mean power output than it will save him/her effort to equally decelerate below mean power output in a competitive race. Any variations in velocity over the race thus lead to larger energy costs throughout the race. This biomechanical aspect is essential in determining successful pacing behaviour in competition[2,3] and is of influence on the decisions that athletes make during the race regarding their energy expenditure. Therefore, the modelling of this non-linear relation between mechanical power output and velocity in a well-controlled valid laboratory setting is essential in studying pacing behaviour. The aim of the present study is therefore to determine the relation between mechanical power output and velocity in Velotron cycling compared to track cycling.

Methods: The relation between mechanical power output and velocity in incremental cycling for a cyclist of 75kg on the Velotron Racermate Dynafit (6Hz sampling rate) was determined with a recommended Velotron drag factor setting of 100%, which should be comparable to neutral (no wind) conditions. The Velotron was propelled using a dynamic calibration rig to simulate a continuous pedalling cadence of 90 RPM. The rig was attached to the crank of the Velotron via a counterbalanced double universal joint. The axle was centred at the bottom bracket of the Velotron cycle and attached to the crank at the position of the left pedal. By upshifting gears (18 different gears with 18-33 for the lowest velocity and 56-12 for the highest) while keeping the cadence on 90 rpm, a range of velocities and accompanying power outputs could be evaluated. The calibration rig was powered by a 3 Ph – AC electro motor with a maximum power output of 2.2 kW. Power output and speed were collected over 30s of steady state cycling per stage, resulting in the power-velocity curve. The relation between mechanical power output and velocity was also determined on a cycling track. Data of an elite track cyclist (bodymass + bike: 89.9 kg) were obtained while riding in a standard position with hands on the handlebars on a 250m indoor velodrome in Apeldoorn, The Netherlands. The track bike was equipped with a SRM 7 track system (Schoberer Rad Meßtechnik, Jülich, Germany). Sample rate was set at 2 Hz and actual measured values for wheel circumference were set. 2 Laps at six different speeds were cycled, starting at 30 km/h, with an increase of 5 km/h

to 55 km/h. For Velotron cycling as well as track cycling, trendlines were added based on least-squares fits, and coefficients of determination were obtained.

Results: Best fits were obtained using power fit trendlines, evidencing the non-linear character of the power-velocity curves (Velotron: $r^2 = 0,9971$; Track: $r^2 = 0,9962$). In Velotron cycling as well as in track cycling, a linear model resulted in a lower coefficient of determination (Velotron: $r^2 = 0,9252$; Track: $r^2=0,9835$). The required power output to obtain a certain velocity was ~18 % higher in Velotron cycling compared to equal velocities in track cycling. See figure 1.

Figure:

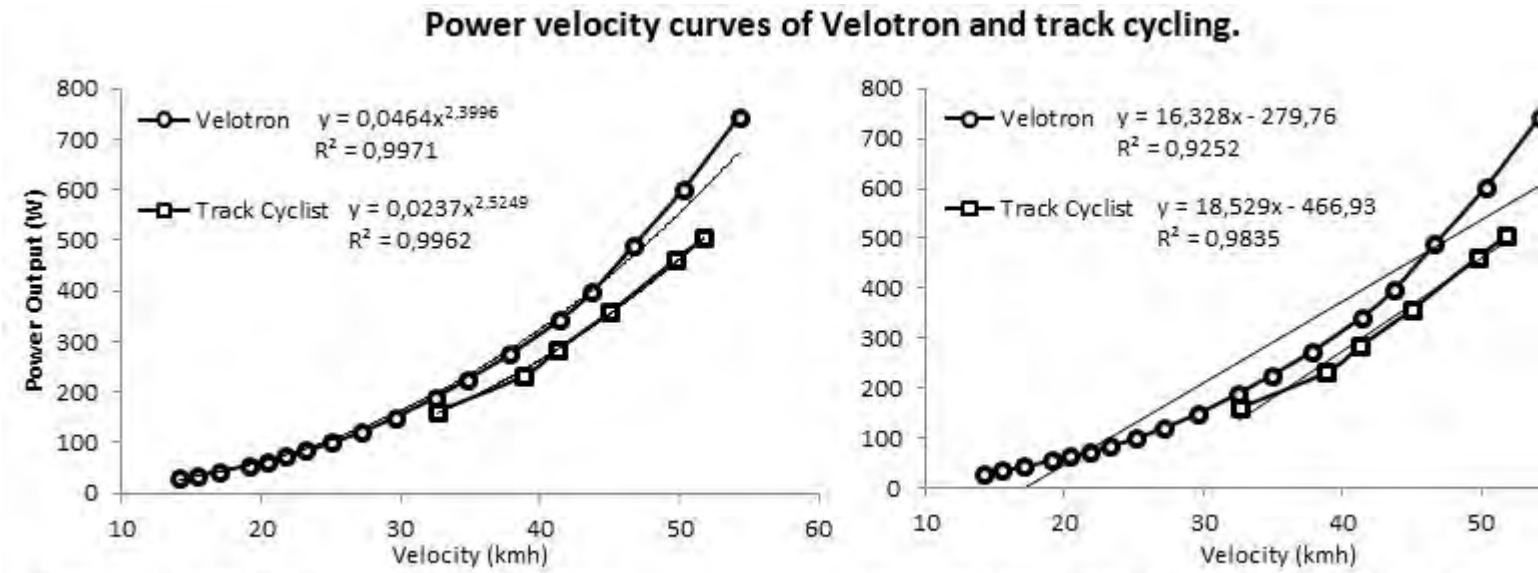

Figure 1a. Best fit Velotron and Track cycling data

Figure 1b. Linear fit Velotron and Track cycling data

Caption: Mechanical power output-velocity curves of Velotron ergometer cycling and track cycling, with best fit power (1a) and linear (1b) trendlines added.

Conclusion: It seems that the Velotron provides a realistic and valid setting to study pacing behaviour with respect to the non-linear power-velocity relation that has been shown to be relevant for choosing effective pacing strategies[2,3]. The large range of velocities tested on the Velotron clearly showed a non-linear curvature, comparable to track cycling evaluated over a smaller range of velocities (within the domain of human capabilities). However, Velotron cycling seemed to underestimate track cycling performance: Lower velocities were reached at similar power outputs in Velotron cycling compared to track cycling. Future research should aim to study if a draft setting of <100% could more closely mimic track cycling performance.

AS-0100

MOVEMENT SCREENS: MEASURING MOVEMENT DYSFUNCTION OR MOVEMENT SKILL?

James Becker [1] Anthony Vidal [1,*] Mimi Nakajima [1] Will Wu [1]

[1]Kinesiology, California State University, Long Beach, Long Beach, United States

Introduction and Objectives: Movement screens are becoming an increasingly popular form of assessing athletic readiness. Currently popular screens are designed to place individuals in extreme positions where weakness and imbalances become noticeable if appropriate stability and mobility is not utilized by the athlete. It has been suggested that tests assessing multiple domains of function (e.g., balance, strength, and range of motion) can possibly help with early identification of athletes at risk for injury[1]. Using fundamental movement patterns, coaches and practitioners are able to evaluate athletes' dynamic and functional capabilities to quickly identify deficits in mobility and stability.

To date, designers of movement screens fail to understand the difference between skill and mobility. Therefore, one might ask whether "movement dysfunctions", commonly observed on these screens, are more reflective of a lack of skill that can be easily fixed with properly designed test instructions. An abundance of studies within the motor control and learning literature demonstrate the importance of providing proper verbal instructions and demonstration/ observational learning to performers [2]. The purpose of this study was to evaluate performance on the overhead squat (OHS), a common test used in movement screens, when performed with three different sets of instructions.

Methods: Twenty participants performed the OHS under three instructional conditions. For the baseline condition (B) each participant was first instructed to perform three consecutive repetitions of the OHS with no further instructions. Participants then performed the OHS under one of two sets of instructions: instruction demonstration and practice (IDP), or the instructions used by the Functional Movement Screen (FMS)[3]. For the IDP condition each participant was given verbal instructions on how to perform the OHS consistent with motor control and learning principles of instruction. After the verbal instructions where given each participant viewed a demonstrator performed the correct OHS. Next, they performed three non-consecutive practice OHS to allow for any corrections needed in the squat form. Upon completion of the demonstration and practice, the participant performed three consecutive OHS which were recorded for analysis. For the FMS condition each participant performed three OHS squats after receiving the exact instructions from the FMS testing protocol[3]. To account for the three practice squats in the IDP condition, participants were instructed to perform three 'washout' squats prior to the FMS instructions keeping the total number of squats consistent between compared conditions. The order in which participants performed the IDP or FMS conditions was randomized.

A 12-camera motion capture system (Qualisys, Gothenburg, Sweden) was used to record three-dimensional marker trajectories. A thirty one reflective marker set was used to create a thirteen segment model to calculate the center or mass (COM). Custom LabVIEW (National Instruments, Austin TX) programing was used to calculate the following dependent variables. Peak ankle dorsiflexion of each repetition, body COM vertical displacement; horizontal distance from body's COM to the dowel's COM and, forward trunk lean were calculated at the point of the body's COM lowest vertical point (representing the bottom of the squat position) for each OHS. Averages of the three repetitions were

calculated and used in analysis. One-way ANOVAs were used to examine differences in variables between B, FMS, and IDP conditions.

Results: COM displacement was greater in IDP (0.45±0.10 m.) than FMS condition (0.32±0.20m.; $p = 0.003$), but not different than baseline (0.39±0.12m.; $p = 0.047$). Forward trunk lean was also greater in IDP (0.33±0.65m.) than FMS condition (0.29±.096m.; $p = 0.013$) but not different than baseline (0.30±0.07m., $p = 0.048$). Ankle dorsiflexion was greater in IDP (21.33°±5.22) than FMS condition (17.62°±6.26; $p = 0.01$) but not different than baseline (20.94°±4.7; $p = 0.035$). Bar to body distance was not different between any conditions.

Conclusion: The results of this study show that OHS performance can be immediately altered by the use of properly designed instructions, demonstrations, and practice. Considerations of these results are critical when conducting movement screen assessments and evaluating mobility, as practioners must be able to dissociate skill and function. If conducted properly, movement screens can provide valuable information that provides detail on restrictions of mobility and range of motion. However, if conducted poorly, any conclusions regarding functional limitations may simply reflect a lack of movement skill.

RELATIONSHIP BETWEEN PELVIS-TORSO COORDINATION AND STRIDE CHARACTERISTIC VARIABILITY

James Becker [1] Renae Jackson [1,*] Will Wu [1] Mimi Nakajima [1]

[1] Kinesiology, California State University, Long Beach, Long Beach, United States

Introduction and Objectives: In a given year, approximately half of all runners will sustain an overuse related musculoskeletal injury [1]. Previous studies have shown higher levels of bilateral asymmetry in runners who have sustained stress fracture injuries [2], however, kinematic factors responsible for the observed kinetic asymmetry have not been clarified. For example, asymmetry in the distance the foot contacts the body in front of the center of mass (foot contact distance, FCD) would result in asymmetric braking forces and loading rates. A separate series of studies have reported low levels of coordination variability are associated with chronic overuse injuries in runners [3]. In regards to FCD in particular, the coordinated movement between the transverse plane rotation of the pelvis and torso may be important since altered coupling of pelvis-torso movement affects pelvis rotation, which in turn affects FCD. However, to date, links between torso motion and stride characteristics such as FCD have been minimally examined. Therefore, the purpose of this study is to examine the relationship between variability in transverse plane pelvis-torso coordination and variability in FCD and secondly, to determine if asymmetric pelvis-torso coordination is associated with asymmetric FCD's.
Methods: Whole body kinematics were recorded on 20 runners (sex: 10 male, 10 female; age: 25.7 ± 7.8 years; weekly mileage: 48.5 ± 16.9 miles) using a 12 camera motion capture system (Qualisys, Gothenburg, Sweden) while participants ran on a treadmill, at self selected speeds approximating their easy training pace. Marker trajectories were exported to Visual 3D (C-Motion, Inc., Rockville MD) where pelvis and torso segment angles were determined relative to the laboratory system. A vector coding technique was used to quantify coordination of movement between the pelvis and torso segments in the transverse plane. Coordination variability was determined by calculating the standard deviation of coupling angles across the gait cycle. FCD was defined as the distance between the foot center of mass and the whole body center of mass at the moment of foot contact. Timing of foot contact and toe off were determined using the methods suggested Fellin et al [4]. The coefficient of variation was used to quantify variability in FCD. A symmetry index was calculated from mean coupling angles during the left and right strides, and FCD on left and right strides, respectively. The symmetry index was then used to evaluate asymmetries in pelvis-torso coordination and FCD, with a higher value indicating a higher level of asymmetry. The relationships between coordination variability and FCD variability and coordination asymmetry and FCD asymmetry were evaluated using simple linear regression.
Results: There was a significant relationship between variability in pelvis-torso coordination and variability in foot contact distance for both the left strides (R^2 = 0.214, p = 0.039) and right strides (R^2 = 0.214, p = 0.039). There was no significant relationship between asymmetries in pelvis-torso coordination and FCD asymmetries (R^2 = 0.009, p = 0.679).
Conclusion: The results of this study suggest there is a relationship between the coordinated movements of the torso and pelvis, which may affect stride parameters such as FCD. Previous studies have suggested there is a link between reduced variability and repetitive joint loading. Although the functional consequences of these relationships need to be examined further, increased FCD variability may be a mechanism whereby runners avoid loading the lower extremity in

exactly the same location and manner on each stride. Both coordination variability and movement asymmetry have been suggested as possible factors in overuse injuries. However, the lack of any relationship between asymmetry in pelvis-torso coordination and asymmetry in FCD suggests that movement variability and movement asymmetry may be involved injury etiology through different mechanisms, however this requires further clarification. Additional research examining how the movement and coordination of the upper body affects lower extremity movements, especially as it relates to running injuries is required.

THE RELATIONSHIP OF SEPARATION FACTORS ON THROW DISTANCE OF FEMALE HAMMER THROWERS

Suzanne Konz [1,*]

[1]Kinesiology, Marshall University, Huntington, WV, United States

Introduction and Objectives: Athletes utilizing their entire kinetic chain to throw need to separate the hips and shoulders, typically, to provide a rigid block over which they accelerate the implement being thrown. The hammer is unique in that it provides 3 different separation factors that allow the athlete the opportunity to accelerate the hammer. The separation factors occur between the feet and hips, the hips and shoulders, and the shoulders and the ball. No literature statistically has investigated the relationship of these separation factors and throwing technique of female hammer throwers. The aim of this study was to determine relationship of the separation factors on the final throw distance for female hammer throwers.

Methods: The best performances of the top 10 female throwers at the 2014 USA Track and Field Nationals and 2014 USATF CV OTC meet were examined. Video was captured using two 60 Hz cameras. The best throw of each athlete was digitized and analyzed using the Contemplas Motus 10.0.1 motion analysis system.

Results: : Correlation analysis of separation factors within a throw revealed the separation between the feet and hips at take-off of Turn 1 ($p=.000$ $r= .824$), the separation between the feet and hips at take-off of Turn 4 ($p=.03$ $r=. 866$), the separation between the shoulders and hammer at take-off of Turn 4 ($p=.01$ $r= -.919$), the separation between the shoulders and hammer at touch-down of Turn 4 ($p=.01$ $r= -.934$) correlate with throw distance. A stepwise linear regression of separation factors indicated that the separation of feet and hip at release ($\beta= .050$), the separation of hips and shoulders at touch-down at Turn 1($\beta= -.058$), and the separation of hips and shoulders at touch-down at Turn 2 impact throw distance ($\beta= .007$). A stepwise linear regression of all hammer throw factors ($p<.000$ $r=1.00$) indicates that the separation of the feet and hips at release and the vertical position of the hammer at the take-off during Turn 4 are predictors of throw distance.

Conclusion: The interesting item with the analysis is that there still is no clear path to understanding which components impact throw distance. The fact there is no agreement between the correlation and stepwise linear regression is interesting. A second interesting component is the negative impact that too great of a separation can negatively impact at throw as in the correlation results of Turn 4 take-off and Turn 4 touch-down. It is at this point the ball should be moving at its highest velocities prior to release. By opening the separation factors at these points, the athlete may actually lose control of the system. Athletes use different separation factors during their throw to maintain cable tension, momentum, and speed. No clear cut method to predict hammer throw distance can be developed due to athlete variability within this group.

A COMPARISON OF OVERGROUND AND TREADMILL GROUND REACTION FORCES DURING LOAD CARRIAGE

Angela Boynton [1,*]

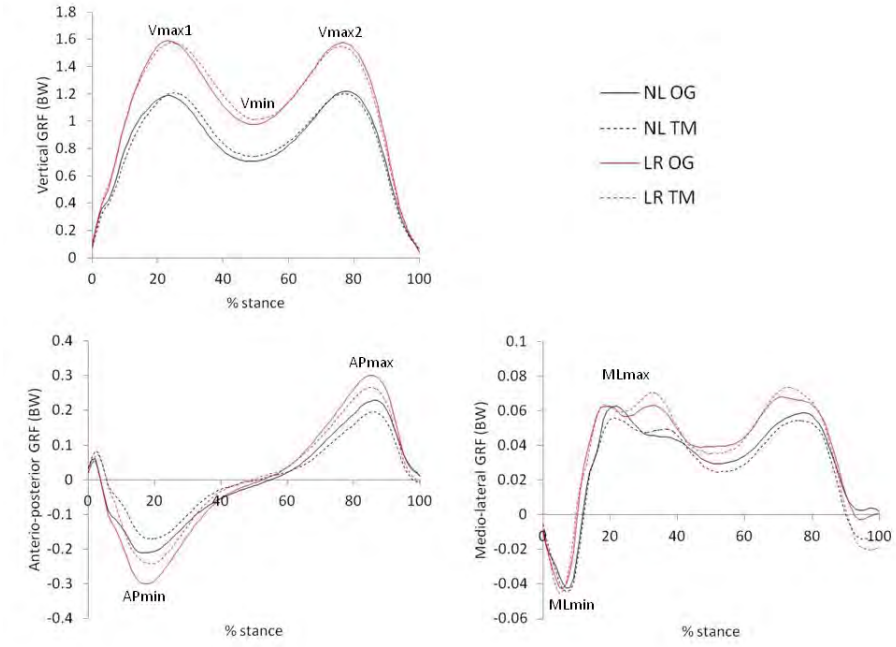
[1]Human Research and Engineering Directorate, US Army Research Laboratory, Aberdeen Proving Ground, MD, United States

Introduction and Objectives: Force-sensing treadmills (TMs) provide a convenient means to study the effects of military load carriage on gait dynamics, particularly over long durations. During overground (OG) walking, stance time and peak ground reaction forces (GRFs) increase with carried load [1, 2]. While generally considered equivalent, minor biomechanical differences have been reported between OG and TM walking. In particular, reductions in stance time and peak GRFs are associated with unloaded walking on a TM compared to OG [3, 4]. Differences between OG and TM gait dynamics can limit our ability to generalize the results of TM-based studies to outcomes in a real-world environment, but the impact of load carriage on the magnitude of those differences is currently unknown. Therefore, the objective of this study was to quantify differences in GRFs between walking OG and on a TM with a militarily relevant load.

Methods: An instrumented TM (AMTI Corp.) embedded in the laboratory floor was used to collect GRF data (1200 Hz) for 12 subjects (8M/2F, 1.80±0.07 m, 86.6±12.6 kg) with recent military load carriage experience. Subjects walked at a self-selected pace OG across the surface of the TM and then at a matched pace on the TM, unloaded (NL) and while carrying a 33kg rucksack (LR). A minimum of 5 strides per combination of walking mode and load condition were analyzed for each subject. For each load condition, mean differences in stance time and peak GRFs (Vmax1, Vmin, Vmax2, APmin, APmax, MLmin, MLmax in Figure 1) were calculated between walking modes, and their statistical significance was determined using paired t-tests (α=0.05). Differences between walking modes were additionally compared to the mean inter-stride variability during OG walking (OGvar) for each variable and any difference found to be greater than the calculated OGvar was considered meaningful.

Results: Mean differences in stance time were negligible (<0.01 s) during both unloaded and loaded walking. Mean stance phase GRF curves for each walking mode and load condition combination are shown in Figure 1, and calculated differences between peak values are summarized in Table 1. A statistically significant but non-meaningful increase in the loading peak GRF (Vmax1) occured with TM walking during the NL condition. Statistically significant differences in peak GRFs were also found in the anterio-posterior direction. Peak braking (APmin) and propulsive (APmax) forces were significantly less during TM than OG walking for both load conditions, however, only the LR condition differences exceeded the OGvar values. These reductions in peak braking and propulsive forces may be related to fluctuations in the TM belt speed following heel contact and just prior to toe-off. The subsequent deceleration and acceleration of the TM belt at those time points could serve to dampen the reaction force, and this effect might be magnified as the applied forces increase with carried load.

Figure:



Caption: Figure 1. Stance phase GRFs during OG and TM walking with and without a loaded rucksack.

Conclusion: While peak vertical and medio-lateral GRFs appear to be comparable between OG and TM walking, peak anterio-posterior forces are significantly reduced during TM walking, and these differences exceed OG inter-stride variability when a heavy military load is carried. Changes in joint moments and muscle activity related to this difference between OG and TM walking kinetics could limit the utility of instrumented treadmills for assessing the effects of load carriage in studies where fatigue is of interest or one desires to generalize the results to OG walking. Further study is needed to determine the impact of the observed GRF differences on those variables.

Table:

GRF peak (%BW)	NL			LR		
	difference	t-test	OG var	difference	t-test	OG var
Vmax1	2.5	**0.02**	3.5	0.2	0.73	7.6
Vmin	1.5	0.11	4.7	2.2	0.32	4.6
Vmax2	0.5	0.58	3.8	-2.2	0.35	4.1
APmin	-2.8	**0.00**	4.0	-5.6	**0.00**	**2.9**
APmax	-2.3	**0.00**	2.9	-3.1	**0.00**	**1.8**
MLmin	0.7	0.05	1.7	0.4	0.22	1.7
MLmax	-0.1	0.12	4.2	-0.5	0.38	3.0

Caption: Table 1. Peak GRF differences between OG and TM walking with and without a loaded rucksack. Negative differences indicate TM value less than OG value.

EFFECT OF SUBJECT-SPECIFIC MUSCULOSKELETAL GEOMETRY ON MODEL PREDICTIONS

Vincenzo Carbone [1] Marjolein van der Krogt [1,2] Sjoerd Kolk [3] Jan Schepers [4] Bart Koopman [1,*] Nico Verdonschot [1,5]

[1]Laboratory of Biomechanical Engineering, University of Twente, Enschede, [2]Department of Rehabilitation Medicine, VU University Medical Center, Amsterdam, [3]Department of Rehabilitation , Radboud University Medical Centre, Nijmegen, Netherlands, [4]Materialise, Leuven, Belgium, [5]Orthopaedic Research Laboratory, Radboud University Medical Centre, Nijmegen, Netherlands

Introduction and Objectives: When exploring complex biomechanical problems, such as in orthopedic surgery to simulate the effects of joint replacements and tendon transfers, or in sport to optimize athletes' performances and prevent injuries, subject-specific musculoskeletal models are essential to achieve reliable predictions. Therefore, it is crucial to develop efficient methods that allow collecting personalized information in a fast and accurate way, without intensive manual intervention.

In this study, we reconstructed the subject-specific musculoskeletal geometry of the lower extremity of ten healthy subjects from MRI scans, using the TLEM*safe* modeling workflow [1], and we assessed the effect of personalization on the model predictions.

Methods: Ten healthy subjects (5 males, age 40.1±15.7 years, height 174.9±11.1 cm, weight 74.8±11.9 kg) were analyzed. For each subject, MRI scan of the lower extremity was obtained (3T, T1-weighted, voxel size of 1.0*1.0*3.0 mm for pelvis, knee and ankle region, and 1.0*1.0*8.0 mm for the remaining upper and lower leg). Then, several gait trials at comfortable, slow and fast speed were measured using 3D motion capture and force-plate data.

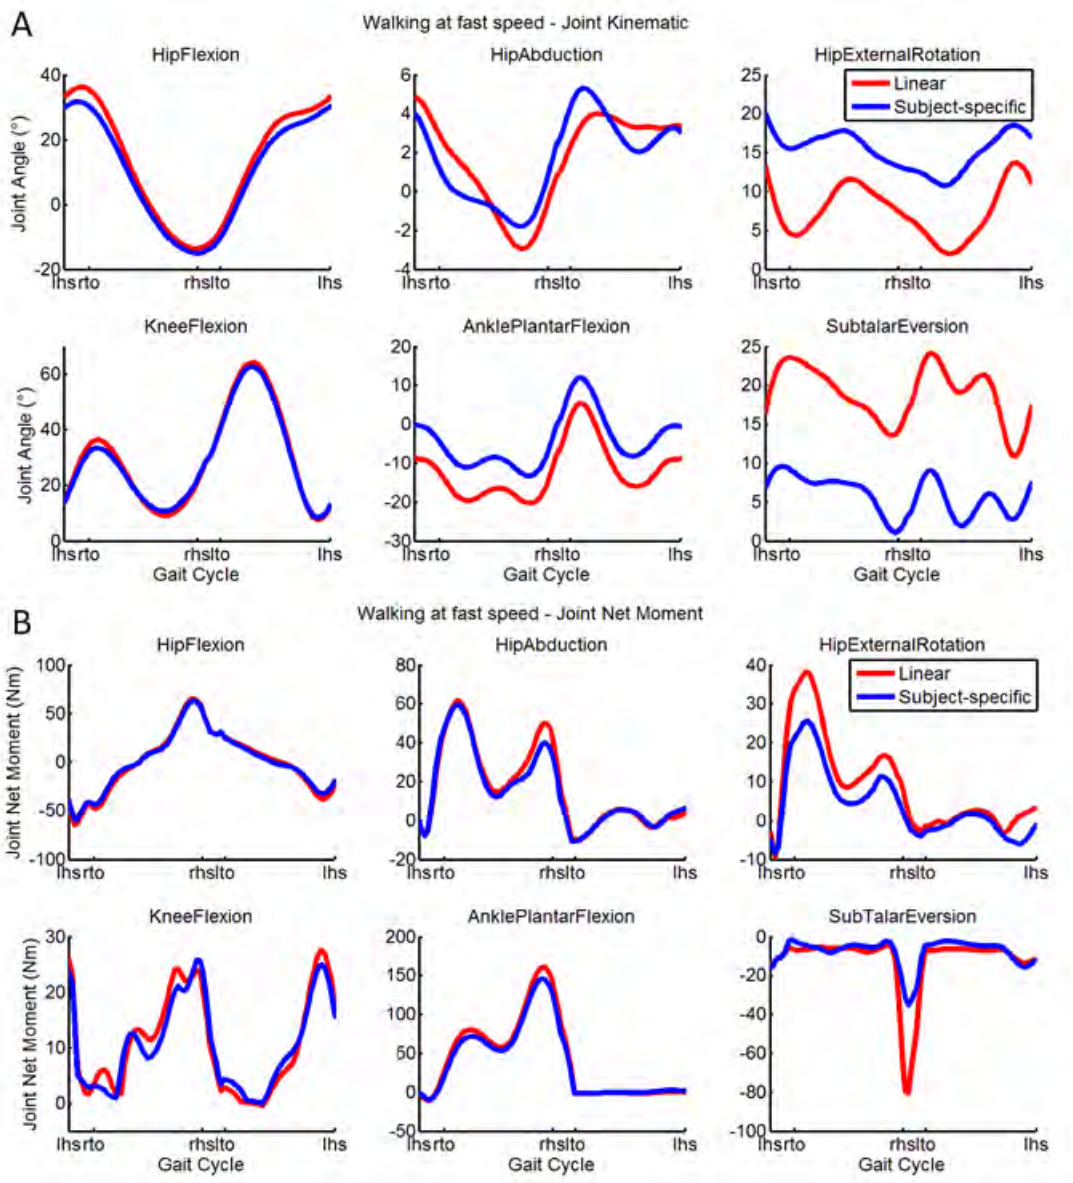
Using Mimics® 17.0 and 3-matic® 10.0 (Materialise N.V., Leuven, Belgium), bone surfaces of pelvis, femur, tibia and fibula were segmented from MRI scans, then joint geometry was estimated: hip joint center based on the best fitting sphere to the acetabulum and femur head, knee joint center and direction based on the best fitting cylinder to the femoral condyles. Ankle and subtalar joint were linearly scaled, based on the position of the medial and lateral malleoli. Finally, automatic morphing was applied to the segmented bone surfaces, under the assumption that muscles attachments sites follow the non-linear morphing transformation [2].

Ten subject-specific models were created combining the MRI-based personalized information with the recent Twente Lower Extremity Model 2.0 [3] implemented in the AnyBody Modeling System™ ver. 6.0.3 (AnyBody Technology A/S, Aalborg, Denmark). Inverse kinematics and inverse dynamics were used to calculate joint kinematics and joint net moment when reproducing the measured gait trials, then subject-specific model predictions were compared with linearly scaled models.

Results: Subject specific models allowed a sensible improvement of the accuracy of the musculoskeletal geometry information. Linear model presented errors larger than 10 mm in the estimated segment size, larger than 20 mm in the estimated position of hip and knee joint center, and larger than 10° in the estimated knee joint direction. Moreover, linear models presented errors larger than 10 mm in the estimated position of muscle attachment sites, in particular errors larger than 20mm for some of the most sensitive muscle, such as glutei, piriformis and biceps femoris [4].

Although reproducing the same gait trials, linear and subject-specific and models presented significant differences in the predicted joint kinematics (Fig. 1A), in particular for knee flexion and subtalar eversion (larger than 20°) and for hip flexion and hip external rotation (larger than 10°). Finally, subject-specific models predicted a reduction of joint net moment compared to linear models (Fig. 1B), in particular for subtalar eversion (larger than 10%), and for hip flexion and ankle plantarflexion (larger than 5%).

Figure:



Caption: Predicted joint kinematics (A) and joint net moment (B) during walking at fast speed, using linear and subject-specific model - Example showing one of the ten healthy subjects measured.

Conclusion: Subject-specific models, based on individual bone surfaces extracted from MRI, showed a sensible improvement of the accuracy of musculoskeletal geometry information (bone segment size, joints center and direction, position of muscle attachment sites) when compared to linearly scaled models. These improvements led to large

differences in the predicted joint kinematics, which eventually resulted in a reduction of the predicted joint net moment, indicating that subject-specific models are more efficient than linearly scaled models when reproducing the same task.

The subject-specific models analyzed in this study were obtained semi-automatically using the TLEM*safe* modelling workflow [1]. Application on a large scale of this workflow would permit to reduce errors in musculoskeletal geometry information and model predictions, achieving the validity and reliability necessary in specific applications such as clinical decision making.

FRONTAL PLANE ACHILLES TENDON MOMENT ARM CHANGES WITH FRONTAL PLANE MOVEMENT OF THE FOOT

Susann Wolfram [1,*] Emma Hodson-Tole [2] Islay McEwan [1] Christopher Morse [1] Keith Winwood [1]

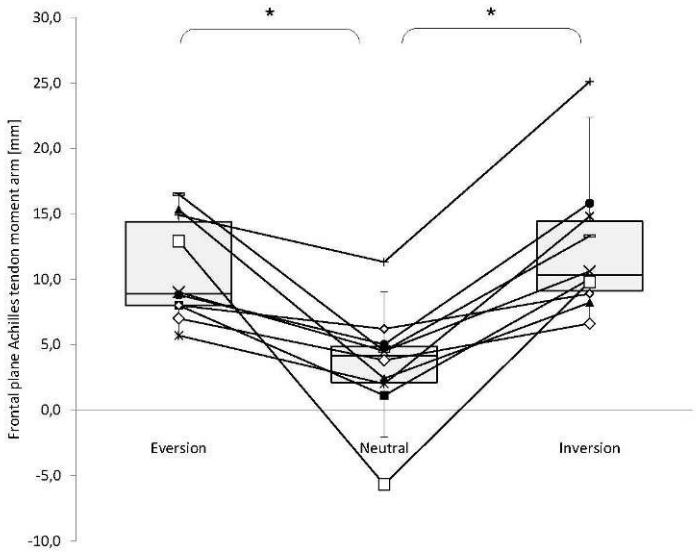
[1]Department of Exercise and Sport Science, Manchester Metropolitan University, Crewe, [2]School of Healthcare Science, Manchester Metropolitan University, Manchester, United Kingdom

Introduction and Objectives: Achilles tendon (AT) moment arms are frequently determined in order to estimate tendon forces in musculoskeletal models. Previously, AT moment arms have been determined in the sagittal plane using the centre-of-rotation method (COR) to estimate tendon forces during plantarflexion. However, the triceps surae muscle group and the associated Achilles tendon have also been found to contribute to both inversion and eversion movements. To date, little is known about the magnitude of Achilles tendon moment arms in the frontal plane and differences in AT moment arms in different frontal plane foot positions. The purpose of this study was to investigate the use of the COR method to determine AT moment arm in the frontal plane and to determine differences in AT moment arm in different frontal plane foot positions.

Methods: MR images of the left ankle were obtained from ten, supine, participants (five female, five male, age 26.3 ± 4.71 years), using a 0.2 T MRI scanner (TE/TR/flip angle of 16 ms/580 ms/75°). The field of view was 83.5 mm and contained 15 slices with a slice thickness of 5 mm and a gap between slices of 0.5 mm. A total of five scans were conducted with the foot positioned at 20° eversion, 10° eversion, 0°, 10° inversion or 20° inversion using a styrofoam wedge. In the obtained images, representative reference points were chosen on the lateral and medial side of the calcaneus at its posterior articulation with the talus. The COR method was then applied to find the centre of rotation, where the talus was assumed to be stationary and where the calcaneus rotates around the subtalar joint axis. The frontal plane AT moment arm was defined as the perpendicular distance from the bisection of the AT to the identified centre of rotation. Moment arms were obtained for the foot in 10° eversion, 0° neutral and 10° inversion. The angle of the AT bisection and the vertical was also measured to account for changes in moment arm. Differences in AT moment arm and the AT angle between the three foot positions were tested with a One-Way ANOVA. The level of significance was set to 0.05.

Results: The AT showed an eversion moment in all three positions. The moment arm in the neutral position was 3.5 ± 4.3 mm which was significantly smaller than the moment arm in eversion (10.6 ± 3.9 mm, $p = 0.005$) and inversion (12.3 ± 5.4 mm, $p = 0.001$) The difference in moment arms between eversion and inversion was not significantly different (Figure 1). AT angle was 85.3° ± 2.5°, 85.7° ± 2.1° and 86.0° ± 2.1° in eversion, neutral and inversion, respectively. Differences in AT angle were not significant.

Figure:



Caption: Figure 1. Box-and-whisker plots for the entire data set with each box plot representing the data distribution for one foot position (eversion, neutral, inversion). The line graphs show moment arm values for each individual subject in each of the three conditions with one line corresponding to one subject. *Significant difference between neutral and eversion, neutral and inversion.

Conclusion: This study showed that the COR method can be applied to determine frontal plane AT moment arms. One previous study reported frontal plane AT moment arms determined using the tendon excursion method [1]. Moment arm values obtained in the present study were considerably larger due to the fact that tendon displacement is generally underestimated with the TE method. Furthermore, the subtalar joint axis is not located perpendicular to the frontal plane but deviates from it. Therefore, the identified centre of rotation is also deviated, which results in a considerable overestimation of the AT moment arm. However, the present study does demonstrate that the AT moment arm varies considerably depending on foot position. This change cannot be attributed to a displacement of the AT as the AT angle was unchanged in all three positions. Therefore, changes in the magnitude of the AT moment arm in the frontal plane can be attributed to subtalar joint configuration. This information could be useful for examining musculoskeletal models of the lower leg and foot when estimating moment arms in more than one plane. Further investigation is necessary to determine frontal AT moment arms more accurately.

AS-0106

TRANSVERSE EXPANSION OF MUSCLE FIBRES DURING CONTRACTION

James Wakeling [1,*] Hadi Rahemi [1] Avleen Randhawa [1] Nilima Nigam [2]

[1]Biomedical Physiology and Kinesiology, [2]Mathematics, Simon Fraser University, Burnaby, Canada

Introduction and Objectives: Muscles come in a range of shapes and sizes, with different fibre lengths, cross-sectional areas and pennation angles, and the muscle size and structure is an important determinate of muscle function. During contraction the muscle fibres can shorten and rotate to greater pennation leading to changes in the length and cross-sectional area of the muscle belly. Due to the ability of the fibres to rotate, their shortening velocity can become uncoupled from the velocity of the muscle belly in a process known as belly gearing. Gearing can change in response to the contractile conditions and may be important in shaping the force, power output and function of the muscle during contraction.

The extent to which the muscle bellies bulge and the fibres rotate is different between the medial and lateral gastrocnemii, despite them being anatomically and functionally similar. It has been suggested that the way in which the fibres increase in girth during contraction may be different and this may lead to the differences in the shape changes in the muscle bellies during contraction [1]. However, until recently we have been without the experimental or conceptual framework to test such predictions. The purpose of this study was to test whether there are asymmetries in the transverse expansion of muscle fibres during contraction, and to investigate the mechanisms for and consequences of such an effect.

Methods: In order to quantify the transverse expansion of muscle fascicles during contraction we developed new image processing techniques to extract the fascicle width from B-mode ulrasound images of muscle contraction [2]. Ultrasound images of contracting medial and lateral gastrocnemii were collected for 6 subjects. The muscle belly region was segmented and pre-processed with multiscale vessel-enhancement filtering. 2D Discrete Fourier Transforms of these images revealed the spatial frequencies within the image in the x and y directions, and these were converted into wavelengths and resolved into the component transverse to the longitudinal axis of the fascicles within the mid-longitudinal plane of the muscle.

In order to test mechanisms that cause the asymmetries in the transverse expansion of the muscle fascicles, we developed a 3D finite element model of the muscle belly based on the continuum theory for fibre-reinforced composite biomaterials [3]. The material properties of the base-material were isotropic and the fibre properties only acted along the longitudinal axes of the muscle fascicles. The model was used to simulate contractions in the gastrocnemii (a unipennate geometry with superficial and deep aponeuroses), and was tested for aponeuroses of different stiffnesses.

Results: During muscle fascicle shortening the fascicle width increased but to a lesser extent than had been expected, giving a Poisson's ratio of 0.09 [2]. These results indicated that a greater fascicle expansion likely occurred in the transverse direction that was orthogonal to the mid-longitudinal plane than in the scanning plane that was parallel to the mid-longitudinal plane. This was confirmed on a further 10 subjects by simultaneously imaging the muscle from two orthogonal directions.

Despite the radial symmetries in the material properties of the muscle fascicles in the finite element model [3], an asymmetry occurred in the transverse expansion of the fascicles during contraction. The Poisson's ratio in the mid-longitudinal plane was 0.089 and matched the experimental findings, and the transverse expansion was greater in a direction orthogonal to this plane. The transverse expansion of the muscle fascicles depended on the stiffness of the aponeurosis and affected their rotations to higher pennation as the contractions progressed.

Conclusion: The abilities of the muscle fibres to shorten and change pennation depend on their transverse expansion and their interaction with the aponeuroses. Pennation of the muscle fibres results in an asymmetry to the structure of the muscle belly that in turn causes anisotropy in the transverse fibre expansion, despite their material properties being transversely isotropic. The structural properties of the muscle tissue combined with the stiffness of the connective tissues thus affect the differences in the transverse fibre expansion during contraction. This in turn affects fibre shortening, force development and thus muscle function.

COMPLETE OPENSIM SUBJECT-SPECIFIC LOWER LIMB JOINT-SKELETAL MRI-BASED MODEL

Simao Brito Da Luz [1,*] David Saxby [1] Luca Modenese [1] Peter Mills [1] Belinda Beck [1] Thor Besier [2] David Lloyd [1]

[1]Center for Musculoskeletal Research, Griffith University, Gold Coast, Australia, [2]ABI, University of Auckland, Auckland, New Zealand

Introduction and Objectives: OpenSim [1] is commonly used for musculoskeletal simulation, representing bones and joints while enabling inverse kinematics (IK) and dynamics (ID) solutions to movement. OpenSim can be employed for clinical purposes e.g. simulate the effects of joint replacement [2] or understand the aetiology of osteoarthritis [3].

OpenSim uses pre-defined joint-skeletal models. Tibiofemoral (TFJ) and patellofemoral (PFJ) kinematics are 2D sagittal planar joints, talocrural (TAJ) and subtalar (STJ) are hinge joints, while the hip joint (HJ) is a ball-and-socket. However not all joints degrees of freedom (DOFs) are defined e.g. no tibia Int-External (IE) or Abd-Adduction (AA) rotations. These models were obtained from a limited set of cadaveric data. For each subject joints kinematics and bones are generically scaled from motion capture (MOCAP) external markers. Joint-skeletal system might not be accurately represented, possibly leading to overestimation of measured TFJ contact forces. In contrast other studies showed improved results when using subject-specific 1) TFJ and PFJ models [4] or 2) hip geometry and hip joint center (HJC) [5]. Therefore, methods are needed to readily create such subject-specific models.

Different models have been used to represent subject-specific joints: 1) TFJ, PFJ and TAJ kinematics are well predicted using 3D parallel mechanisms [6,7]. These models are constrained by the bones, ligaments and tendon geometries, 2) STJ hinge axis can be defined by spheres fitted to the talus [8] and 3) HJC approximated by center of sphere fitted to femoral head.

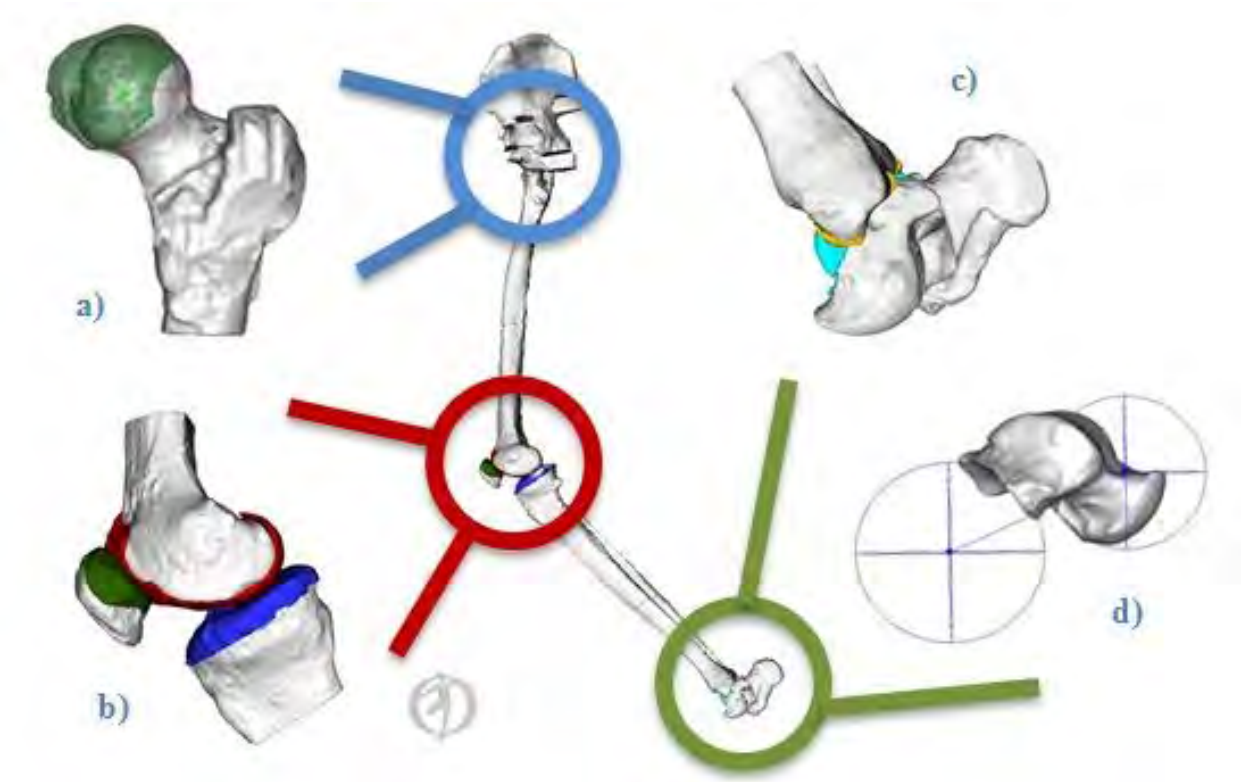
We aimed to use MRI images of *in vivo* joint tissues to generate subject-specific HJ, TFJ, PFJ, TAJ and STJ models to be used in OpenSim. For the same subject we compared the TFJ and PFJ model results, HJC location and STJ hinge axis orientation with those from generic scaled OpenSim.

Methods: MOCAP data and MRIs were acquired from 14 participants. Each subject's MOCAP marker 3D positions were used to scale the generic OpenSim model's 1) HJC location, 2) STJ hinge axis location and orientation, and 3) TFJ and PFJ locations and kinematics. Alternatively, subject-specific models were created using the geometries from their MRIs. The TFJ, PFJ and TAJ locations and kinematics were estimated using 3D parallel mechanisms [6,7,9]. The STJ axis location and orientation were created from the centers of two spheres fitted to the calcaneal and sustentaculum talus facets, while the HJC was the center of a sphere fitted to the femoral head (Fig.1).

Subject-specific TFJ and PFJ kinematics were compared to those from scaled OpenSim using Pearson's correlation and root mean square differences (RMSD). Both models estimated TFJ Ant-Posterior (AP) and Prox-Distal (PD) translations while PFJ models estimated also FE rotations and Med-Lateral (ML) translations. The differences between the HJC location and STJ axis orientation estimated using each model were also calculated.

Results: Differences in HJC location between the two models were 36.7, 0.033 and 7.7 mm at X, Y, Z respectively with 37.4 mm total difference. STJ axis orientation differences were 0, 0.1 and 0.25 at X, Y, Z. High correlation values (Table 1) and similar STJ axis orientation suggests that for common DOFs the two models estimated similar kinematic patterns.

Figure:



Caption: Figure 1- Subject-specific models a) HJC from femoral head sphere, b) TFJ and PFJ, c) TAJ, d) STJ axis from talus spheres.

Conclusion: Complete OpenSim subject-specific lower limb joint-skeletal models can be created using 3D mechanisms and parameters from MRI. We suggest that OpenSim model scaling can be improved, indicated by the large differences in the HJC location and large RMSD for TFJ and PFJ particularly PD. However generic OpenSim models do not include all DOFs and therefore a complete comparison is not possible. Our ongoing IK and ID analyses using each type of model suggest subject-specific models may be more repeatable.

Table:

	Correlation / RMSD			
	FE	AP	PD	ML
TFJ	-	0.85 / 1.7	0.98 / 62.5	-
PFJ	-0.55 / 7.4	0.99 / 4.4	0.88 / 21.3	0 / 10.2

PASSIVE AND ACTIVE SOLEUS MUSCLE FORCES IN CHRONIC HEART FAILURE

Fausto Antonio Panizzolo [1,*] Andrew J. Maiorana [2] Louise H. Naylor [1] Lawrence Dembo [3] David G. Lloyd [4] Daniel J. Green [5] Jonas Rubenson [1]

[1]School of Sport Science, Exercise and Health, University of Western Australia, CRAWLEY, [2]Advanced Heart Failure and Cardiac Transplant Service, Royal Perth Hospital, [3]Advanced Heart Failure and Cardiac Transplant Service, Royal Perth Hospital, Perth, [4]Centre for Musculoskeletal Research, Griffith University, Gold Coast, Australia, [5]Research Institute for Sport and Exercise Science, Liverpool John Moores University, Liverpool, United Kingdom

Introduction and Objectives: Reduced skeletal muscle strength has been linked to the compromised exercise capacity characterizing chronic heart failure (CHF) (1). However, it is not clear if the reduction in peak voluntary strength in CHF is associated primarily with reduced muscle size. This shortcoming might stem from the reliance on net joint moment-based measurements that reflect activity in all synergist and antagonist muscles crossing a joint. Therefore, the aim of this study was to investigate the size-specific active voluntary force (force per muscle physiological cross sectional area, PCSA) and passive force in a single muscle, the soleus (SOL), of CHF patients and age- and physical activity-matched control participants. The SOL was selected as it is a key muscle for postural control and locomotion (2), and its muscle architecture is severely affected by CHF (3).

Methods: Twelve patients with CHF (63.5±10.9 yo, 168.2±9.6 cm, 67.9±14.8 kg) in the class II-IV of the New York Heart Association and 12 age- and physical activity-matched control participants (62.7±5.6 yo, 173.3±6.1 cm, 69.7±8.5kg) who were free from musculoskeletal disorders and lower limb musculoskeletal injuries were recruited for this study. Voluntary active and passive SOL forces and PCSA were obtained by means of a novel approach combining experimental data (dynamometry, electromyography, muscle imaging) with a musculoskeletal model (4).

Results: We found reduced absolute peak voluntary SOL forces (~25%) as well as reduced passive forces (~30%) (at equivalent levels of muscle stretch) in CHF *vs.* healthy individuals. These differences were eliminated when force was normalized by PCSA, indicating that reduced peak voluntary force and passive force may be strongly associated with muscle size. Fascicle lengths at which the peak active forces were generated () as well as the passive fascicle lengths were shorter in CHF *vs.* controls.

Conclusion: Our results showed that a main determinant of muscle strength in CHF is muscle size. These findings, which might be in contrast with previous investigations on different muscle groups (5), reinforce the specificity of the SOL muscle in the CHF syndrome and further suggests its possible use as a predictor of the disease (3).

The differences reported in length at, as well as the passive fascicle lengths, might also offer additional insight into the altered gait mechanics of CHF patients (6). A combination of the shorter SOL muscle fascicles in CHF patients and their greater dorsiflexion during mid-stance of gait (6) may cause significantly greater SOL strain. This might place the muscle on to the descending limb of the force-length curve where large passive forces develop (4). In this scenario CHF patients would rely more on their passive forces to support the plantarflexion moment during walking, which has the benefit of

reducing metabolically expensive active force development. This may help explain why CHF patients rely proportionately more on their ankle for powering walking as speed and metabolic demand increases (6).

These findings raise the importance of exercise rehabilitation targeting an increase in muscle hypertrophy, and for the calf muscles, exercise that promotes muscle lengthening.

HIP POWER ANALYSIS IN INDIVIDUALS WITH TRANSFEMORAL AMPUTATION: A DIFFERENT STRATEGY FROM STABILISATION DURING GAIT STANCE

Raphael Dumas [1 2 3,*] Laurent Frossard [4 5] Catheryne Robert-Leblanc [6] Pierre-Marc Beaulieu [6] Rickard Branemark [7 8]

[1]Université de Lyon, Lyon, [2]Université Claude Bernard Lyon 1, Villeurbanne, [3]Laboratoire de Biomécanique et Mécanique des Chocs , IFSTTAR, Bron, France, [4]Queensland University of Technology, Brisbane, [5]University of the Sunshine Coast, Maroochydore, Australia, [6]University of Quebec In Montreal, Montreal, Canada, [7]Department of Orthopaedics, University of Gothenburg, [8]Centre of Orthopaedic Osseointegration, Sahlgrenska University Hospital, Gothenburg, Sweden

Introduction and Objectives: Joint moments and joint powers during gait are widely used to determine the effects of rehabilitation programs as well as prosthetic fitting. Following the definition of power (dot product of joint moment and joint angular velocity) it has been previously proposed to analyse the 3D angle between both vectors, α_{Mw} [1].

Basically, joint power is maximised when both vectors are parallel and cancelled when both vectors are orthogonal. In other words, $\alpha_{Mw} < 60°$ reveals a propulsion configuration (more than 50% of the moment contribute to positive power) while $\alpha_{Mw} > 120°$ reveals a resistance configuration (more than 50% of the moment contribute to negative power). A stabilisation configuration (less than 50% of the moment contribute to power) corresponds to $60° < \alpha_{Mw} < 120°$.

Previous studies demonstrated that hip joints of able-bodied adults (AB) are mainly in a stabilisation configuration (α_{Mw} about 90°) during the stance phase of gait [1, 2]. Individuals with transfemoral amputation (TFA) need to maximise joint power at the hip while controlling the prosthetic knee during stance.

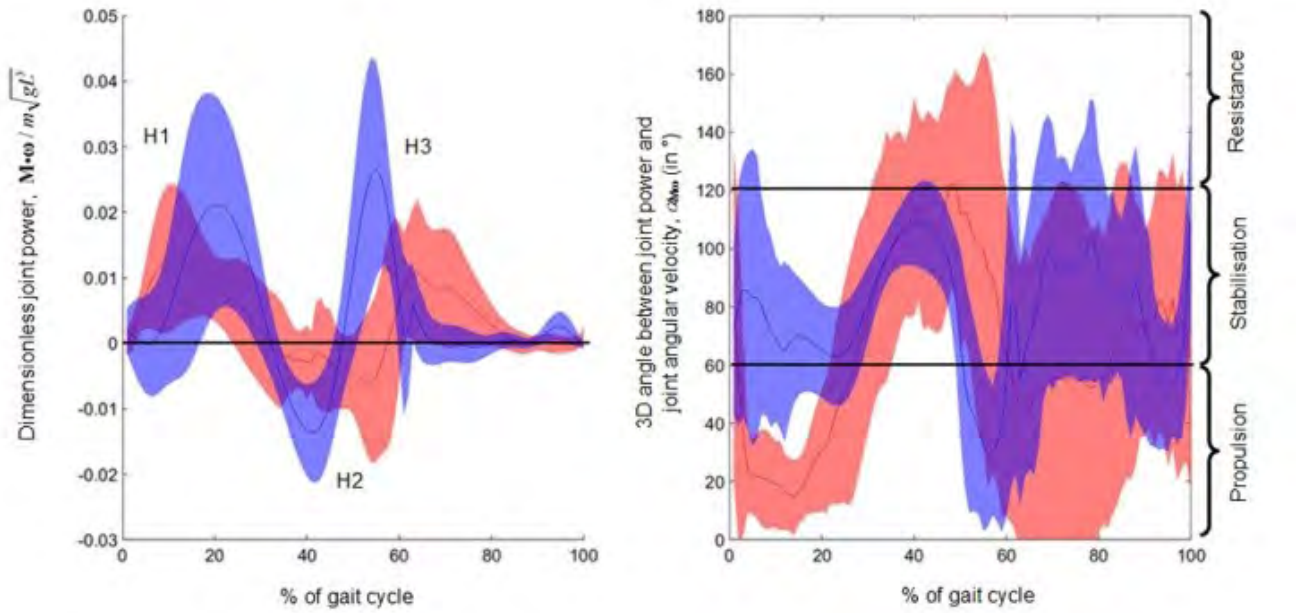
Therefore, we tested the hypothesis that TFAs should adopt a strategy that is different from a continuous stabilisation. The objective of this study was to compute joint power and α_{Mw} for TFA and to compare them with AB.

Methods: Three trials of walking at self-selected speed were analysed for 8 TFAs (7 males and 1 female, 46±10 years old, 1.78±0.08 m 82±13 kg) and 8 ABs (males, 25±3 years old, 1.75±0.04, m 67±6 kg). The joint moments are computed from a motion analysis system (Qualisys, Goteborg, Sweden) and a multi-axial transducer (JR3, Woodland, USA) mounted above the prosthetic knee [3, 4] for TFAs and from a motion analysis system (Motion Analysis, Santa Rosa, USA) and force plates (Bertec, Columbus, USA) for ABs. The TFAs were fitted with an OPRA (Integrum, AB, Gothengurg, Sweden) osseointegrated implant system and their prosthetic designs include pneumatic, hydraulic and microprocessor knees. Previous studies showed that the inverse dynamics computed from the multi-axial transducer is the proper method considering the absorption at the foot and resistance at the knee [4].

Results: The peak of positive power at loading response (H1) was earlier and lower for TFA compared to AB. Although the joint power is lower, the 3D angle between joint moment and joint angular velocity, α_{Mw}, reveals an obvious propulsion configuration (mean α_{Mw} about 20°) for TFA compared to a stabilisation configuration (mean α_{Mw} about 70°) for AB.

The peaks of negative power at midstance (H2) and of positive power at preswing / initial swing (H3) occurred later, lower and longer for TFA compared to AB. Again, the joint powers are lower for TFA but, in this case, α_{Mw} is almost comparable (with a time lag), demonstrating a stabilisation (almost a resistance for TFA, mean α_{Mw} about 120°) and a propulsion configuration, respectively. The swing phase is not analysed in the present study.

Figure:



Caption: Dimensionless hip joint power (m is the body mass, g is 9.81 m/s2 and L is length length) and 3D angle between joint moment and joint angular velocity: Red and blue lines and areas are means ± standard deviations for individuals with transfemoral amputation (TFA) and able-bodied adults (AB), respectively.

Conclusion: The analysis of hip joint power may indicate that TFAs demonstrated less propulsion and resistance than ABs during the stance phase of gait. This is true from a quantitative point of view. On the contrary, the 3D angle between joint moment and joint angular velocity, α_{Mw}, reveals that TFAs have a remarkable propulsion strategy at loading response and almost a resistance strategy at midstance while ABs adopted a stabilisation strategy.

The propulsion configuration, with α_{Mw} close to 0°, seems to aim at maximising the positive joint power. The configuration close to resistance, with α_{Mw} far from 180°, might aim at unlocking the prosthetic knee before swing while minimising the negative power.

This analysis of both joint power and 3D angle between the joint moment and the joint angular velocity provides complementary insights into the gait strategies of TFA that can be used to support evidence-based rehabilitation and fitting of prosthetic components.

IS THE RESULTANT MOMENT A MORE SENSITIVE METRIC OF STRUCTURAL OSTEOARTHRITIS PROGRESSION THAN INDIVIDUAL MOMENTS?

Kerry E. Costello [1,*] Cheryl L. Hubley-Kozey [1 2 3] Janie L. Astephen Wilson [1]

[1]School of Biomedical Engineering, [2]School of Physiotherapy, [3]School of Health and Human Performance, Dalhousie University, Halifax, Canada

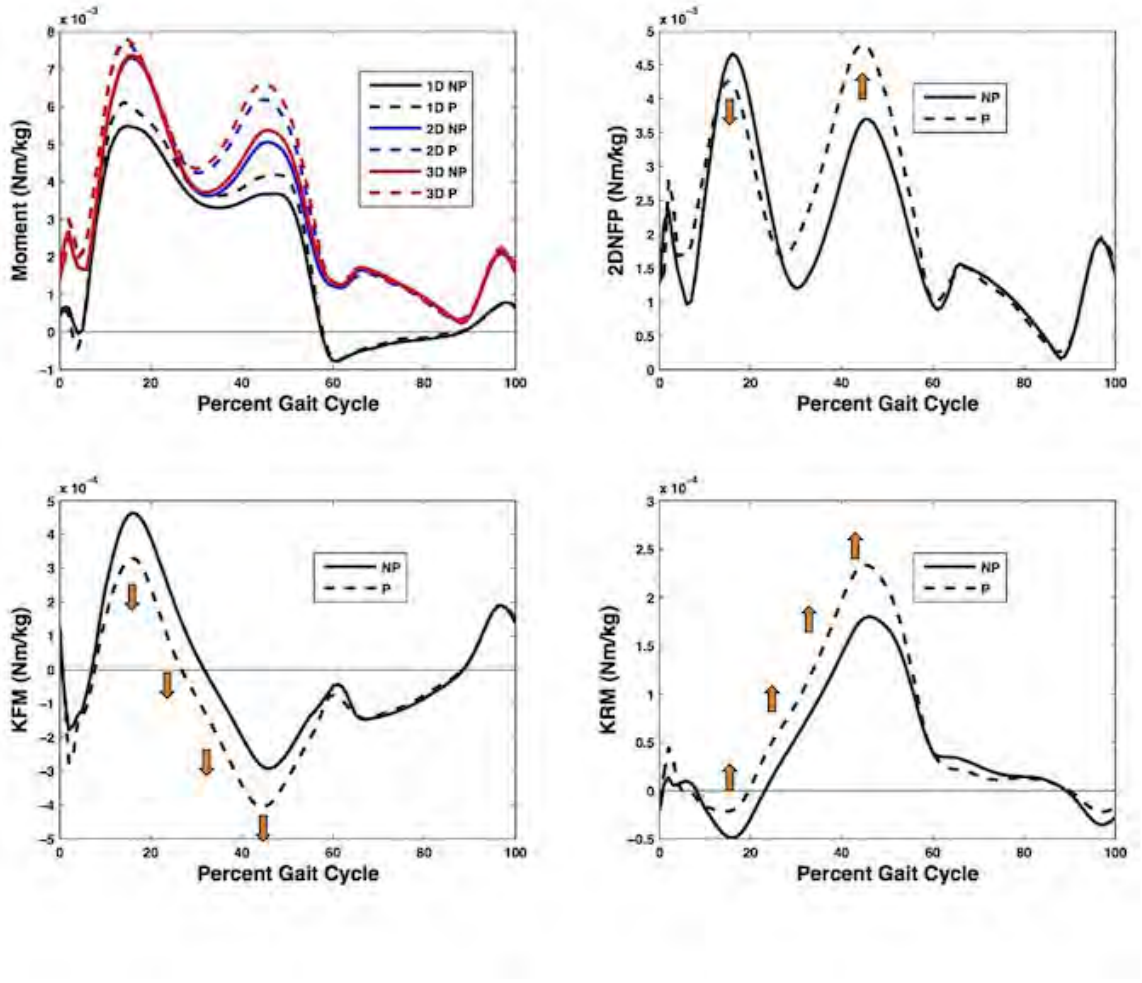
Introduction and Objectives: Measuring joint loads directly or implementing modeling techniques may provide better estimates of joint contact forces in the context of knee osteoarthritis (OA) progression, but these techniques are often not feasible. Developing better estimates of loading exposure from gait data might be more practical. Research on medial compartment knee OA progression has focused on the knee adduction moment (KAM) as it is considered a surrogate of medial:lateral compartment loading ratio. Recent studies have also linked non-frontal plane loading metrics (knee flexion and rotation moments, KFM & KRM) with OA progression [1-2]. Total loading exposure depends on all three dimensions, thus resultant moments that combine the various dimensions into a single measure may provide a more sensitive OA progression metric. The purpose of this study was to compare the ability of single plane moments versus resultant moments to distinguish between individuals with medial compartment knee OA who will progress structurally and those who will not.

Methods: Three dimensional motion (100 Hz) and ground reaction forces (2000 Hz) were recorded for self-selected speed walking in 46 individuals with moderate medial knee OA (high function, non-surgical candidates). Standard anterior-posterior radiographs taken at baseline and 5-10 years later were scored for medial joint space narrowing (JSN) [3] by a single orthopedic surgeon. Progression (P) and no progression (NP) groups were defined based on whether or not the JSN grade increased in 5-10 years. Knee angles (joint coordinate system) and external moments (normalized to body mass, Nm/kg) were calculated from inverse dynamics and time-normalized to a single gait cycle. A two-dimensional resultant moment (2D) was calculated as the vector sum of KAM and KFM, and a three-dimensional resultant moment (3D) was calculated using all three planes. A non-frontal plane resultant moment (2DNFP) was calculated from KFM and KRM. Five separate analyses were performed. A 2-way mixed model ANOVA was run using scores calculated from principal component analysis (PCA) [4] of the set of KAM (1D), 2D, and 3D waveforms with model (1D, 2D, 3D) as a within subjects factor and group (P, NP) as a between subjects factor. PCA allows each participant's waveforms to be scored (PCscores) for shape and magnitude features (PCs) extracted from the set of waveforms. A separate PCA was run for each of the following: 2DNFP waveforms, KAM waveforms, KFM waveforms, and KRM waveforms. Student's t-tests were used to identify between-group PCscores differences (Mann Whitney U tests used in cases of non-normal PCscores distributions)(α=0.05).

Results: There were no between-group baseline differences in age, body mass index (BMI), speed, Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), or strength ($p>0.05$, Table 1). The two-way ANOVA showed main effects of model (1D, 2D, or 3D) but no main effect of group for any PC ($p>0.05$). A PC capturing the difference between mid and late stance moment had a significant interaction effect ($p=0.044$). Post-hoc tests showed 1D was different from

2D (p=0.045) and 3D (p=0.043), but no group differences. In contrast, 2DNFP had one between-group difference with P having higher 2DNFP in late stance compared to early (p=0.018). Additionally, when investigating the individual moments (KAM, KFM, & KRM), two between-group, non-frontal plane differences were found: P had greater extension and internal rotation moments throughout stance than NP (p=0.044 and p=0.017, respectively). No between-group differences were identified for KAM.

Figure:



Caption: Mean moment waveforms (1D (KAM), 2D, 3D, 2DNFP, KFM, and KRM) with JSN Progression (P) and No JSN Progression (NP) group differences indicated with arrows ($p<0.05$)

Conclusion: KAM moments alone or resultant moments incorporating KAM did not discriminate between baseline data from individuals with OA who progressed structurally versus those who did not. A non-frontal plane resultant moment and individual non-frontal plane moments did discriminate between groups. While KAM was not significantly different between groups, it tended to dominate the resultant moment, masking differences between groups in the non-frontal planes. Care should be taken when combining different planes into a resultant moment that includes KAM, as group differences in individual planes can be lost in the process.

A COMPARISON OF HUMAN WALKING USING A CONVENTIONAL GAIT LABORATORY AND THE MOTEK MEDICALA COMPUTER ASSISTED REHABILITATION ENVIRONMENT WITH VARYING LEVELS OF "IMMERSIVNESS"

Andre Attard [1,*] Andrew J. Murphy [1]

[1]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

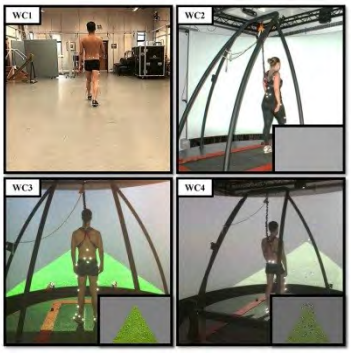
Introduction and Objectives: Treadmills provide a convenient and controlled environment which promotes ease of motion analysis data due to the lesser spatial volume used, however such configurations lack visual feedback from the surrounding environment which has a detrimental effect on the users' gait (Sloot *et al.*).Virtually realistic optic flow during treadmill based rehabilitation has been recently introduced as a novel alternative to conventional over ground laboratories. Sloot *et al.* stated that imposing an immersive virtual reality environment during a fixed speed treadmill modality will elicit walking that is closer to that which is obtained during over ground walking (Sloot *et al.*). The primary objective of this project was to add to the growing body of literature which quantifies differences between over ground walking, and walking conducted in a virtual reality based environment with varying levels of complexity in the so called "optic-flow".

Methods: Motion capture was carried out using a 12 camera Vicon T-series for over ground walking and a 12 camera Vicon Bonita10 system which was installed within a Computer Assisted Rehabilitation ENvironment (CAREN) extended suite (Motekforce Link, Amsterdam). Following ethical approval, 7 healthy participants volunteered (age = 27.6 ± 3.8). A repeated measures design was followed for four walking conditions, over ground (WC1), treadmill (WC2), treadmill with a virtually generated grass pathway (WC3), and treadmill with a grass pathway and a simplified avatar (WC4, Figure 1). Participants walking speed was individualised inter participant but not inter walking condition.

Primary outcome measures which were assessed for the four walking conditions were walking speed (m/s), cadence (steps/min), stride length (m), maximum hip flexion angle (°), maximum knee flexion angle (°) and maximum ankle dorsiflexion angle (°). Data was exported to IBM SPSS, where it was checked for normality. A non-parametric approach was implemented to compare for inter walking condition effects using the Wilcoxon Signed Ranked Test, with a Bonferroni Correction.

Results: Refer to Table 1.

Figure:



Caption: The four walking conditions. In the bottom right corner of WC2 to WC4, the VRE rendered for each condition is shown.

Conclusion: The fixed speed modality used during the treadmill ambulation reflected on the measured results. This modality affected the participants' temporal spatial parameters (TSPs) across the different virtual reality (VR) scenario. This provided evidence that with increasing immersiveness of the VR during treadmill walking (WC2 - WC4), the TSPs converge to those measured during WC1. The relatively high immersiveness of the VR used during WC4 increased the participants' confidence which led to a faster walking speed, but due to the fixed treadmill speed modality the participants unconsciously altered their cadence and stride lengths. This occurs as a result of the TSPs' intra-dependency which states that when walking speed is decreased, cadence is decreased while the stride length is increased.

The statistical study reported statistical differences between over ground walking and treadmill walking conditions, within five out of six of the outcome measures. This shows that these outcome measures are affected by the walking speed. Statistical differences between the different treadmill walking conditions were noted, within five out of six of the outcome measures investigated. This shows that the optic flow has an impact on these parameters, mainly the maximum knee and ankle flexion angles.

Conclusion: Although the gait parameters investigated in this study showed statistically different values amongst a number of cases, the differences were within the range of repeatability of the gait parameters' variability, hence considered clinically insignificant. Thus, treadmill walking for motion analysis purposes in conjunction with virtually realistic optic flow systems is deemed acceptable to utilise instead of over ground walking as long as a high quality VR environment is used and the motion analyst is aware of the variability that occurs within the parameters.

HIP JOINT CENTRE MODELS IN FAI POPULATION

Giulia Mantovani [1,*] K.C. Geoffrey Ng [2] E. Paul Beaulé [3] Mario Lamontagne [1 2]

[1]School of Human Kinetics, [2]Department of Mechanical Engineering, [3]Division of Orthopaedic Surgery, University of Ottawa, Ottawa, Canada

Introduction and Objectives: An accurate location of the hip joint center (HJC) is crucial for motion analysis and musculoskeletal modelling. HJC misplacement of just 3cm can cause up to a 22%>difference in hip flexion-extension moment, and can considerably affect muscle moment arms [1]. When imaging data are not available, the HJC can be estimated using regression equations that incorporate anthropometric measurements [2,3], with recent studies suggesting that Harrington's regression equations provide higher accuracy than Davis model [4]. No study has investigated the accuracy of these regression equations applied to special populations such as cam-type femoroacetabular impingement (FAI) patients. Cam FAI is the result of a femoral head deformity characterized by an elevated alpha angle and the alteration of other pelvic anatomical parameters [5]. Because of this, it cannot be assumed *a priori* that the same regression equations can properly locate HJCs in individuals with FAI. Therefore, the objective of this study was to evaluate the accuracy and reliability of Harrington and Davis HJC regression models for FAI and non-FAI populations.

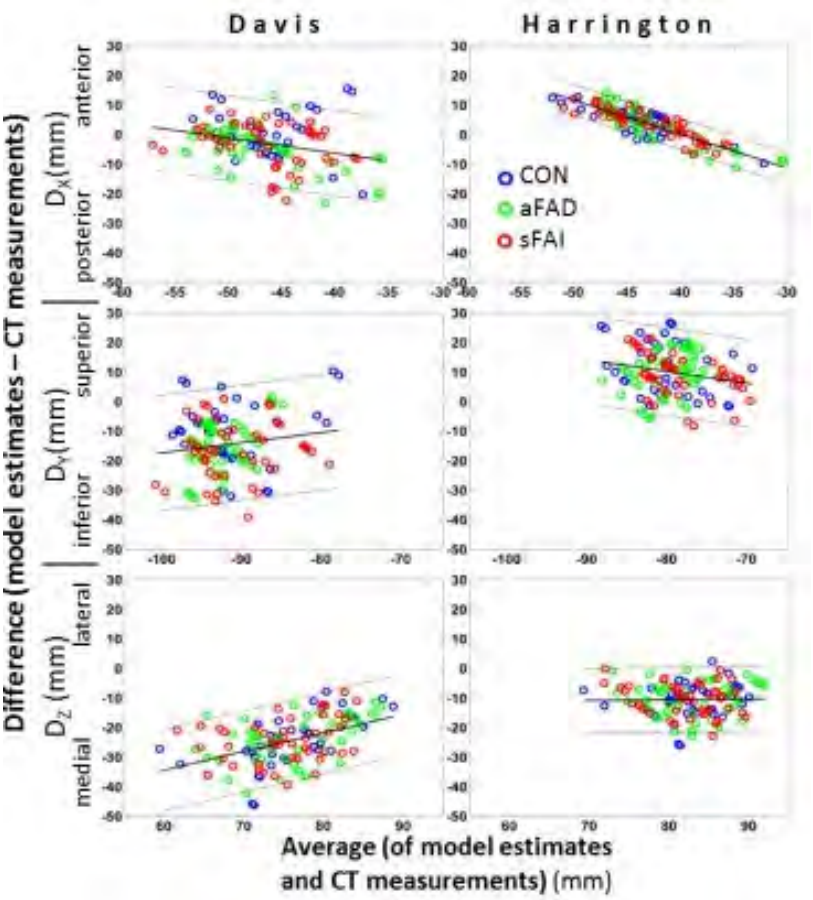
Methods: Sixty-six participants took part in the study: 18 control participants (CON), 25 with an asymptomatic femoroacetabular deformity (aFAD), and 23 with symptomatic FAI (sFAI) (Table 1). Bilateral anterior and posterior iliac spines were identified from each participant's blinded CT data, using ITK-SNAP 2.4 (PICSL, USA), to define the pelvic local reference system and estimate HJC from the regression models. The hip geometric centers were also located on CT images and considered as the actual HJC. The measurements were completed by three readers, each performing three readings, with near-perfect inter- and intra-observer reliability (ICC>0.90).

The errors between the estimated and the actual HJC were calculated in the three orthogonal directions (D_x, D_y D_z) together with the Euclidean distance (D_L). HJCs from each regression model were directly compared to the actual HJC, using Bland-Altman test [6]. A one-way ANOVA was used to identify significant differences among the participant groups. A paired t-test compared the average error between the two models.

Results: No differences were found among the three groups and between sides (symmetry between hips), therefore, participants and sides were pooled together for a total of 122 samples per regression method. Paired t-tests showed a significantly lower error for Harrington's equations (D_L = 16.9±7.6mm) than Davis's (D_L = 31.3±9.3mm, $p<0.001$).

The Bland-Altman limits of agreements (LOA) were corrected to adjust the linear relationship between average and difference. Less than 5% of the samples fell outside the LOA (Figure 1).

Figure:



Caption: Bland-Altman scatter plots for estimated vs. actual HJC coordinates. Black lines represent the regression line and corrected limits of agreements (b0 + b1•avg ±1.96 residual std)

Conclusion: The anatomical differences in the FAI population do not significantly alter HJC location, with respect to a healthy population. Interestingly, the marginal differences between groups were non-significant and beyond the accuracy of the prediction methods. Therefore, motion analyses on FAI populations (asymptomatic and symptomatic) can use the same HJC regression equations, used for the healthy population.

Since less than 5% of the samples fell outside the LOA in both regression models (Figure 1), the HJC model estimates were in statistical agreement with the actual CT HJC. However, Bland-Altman tests showed a linear relationship between errors and coordinate magnitudes, such as for Harrington's D_X, where the best estimation (i.e. smallest error) was achieved when HJC_x coordinate was near -40mm, but was increased when deviating from this range. A clear bias was seen in D_Z, where the average error was larger than 20mm for Davis and 10mm for Harrington throughout the whole range. While the linear dependency is harder to correct, the bias could be added to the regression equations to reduce the estimation error.

The average errors in HJC estimations were consistent with previous studies [2, 3]. Davis model produced double the error respect to Harrington model, thus confirming the superiority of Harrington's equations in predicting accurate HJC. The reduced error can improve inverse kinematics and dynamics calculations and muscle force estimation.

Table:

	N (male/female)	Age (years)	Height (cm)
CON	18 (15/3)	34±6	174±9

A COMPARISON BETWEEN FOUR FOOT MODEL PROTOCOLS: THE EFFECT OF WALKING ON A TREADMILL

Roberto Di Marco [1 2,*] Stefano Rossi [3] Vitomir Racic [4] Paolo Cappa [1 5] Claudia Mazzà [2 6]

[1]Department of Mechanical and Aerospace Engineering, 'Sapienza' University of Rome, Rome, Italy, [2]Department of Mechanical Engineering, The University of Sheffield, Sheffield, United Kingdom, [3]Department of Economics and Management, Industrial Engineering, University of Tuscia, Viterbo, Italy, [4]Department of Civil Engineering, The University of Sheffield, Sheffield, United Kingdom, [5]Laboratory of Movement Analysis and Robotics (MARlab), Children hospital 'Bambino Gesù', Fiumicino, Italy, [6]INSIGNEO Institute for in silico medicine, The University of Sheffield, Sheffield, United Kingdom

Introduction and Objectives: The interest on the foot ankle complex modelling is increasing in the last years. In gait analysis, the most widespread models are those proposed by Stebbins *et al.* [1], Leardini *et al.* [2], Sawacha *et al.* [3], and Saraswat *et al.* [4], which segment the foot-complex in three bodies, coherently with the anatomy. To the Authors' knowledge, a comparative exam of the performances inherent with the previously indicated models is not available. The main goal of the research project is the comparison of the foot models described in [1–4] by applying the four marker sets simultaneously on the subject.

Considering the significant number of markers to be applied (i.e. 27) and to facilitate marker tracking and labelling, the trials were conducted on a treadmill. However, kinematic and kinetic variables obtained in treadmill or overground walking might show different values [5]. Thus, as a prior study toward a comparison of the model outputs on a larger sample of individuals, this work investigated the comparability of treadmill and overground walking conditions in terms of main joint kinematics variables obtained for the four examined foot models.

Methods: The right lower limb and pelvis of four healthy adults with no ankle impairments were simultaneously equipped with the four marker sets [1-4] (4 mm hemispherical markers), Figure 1. The data collection was performed using a Vicon system (T 10-camera-workstation, Nexus 1.8.5 software, 100 Hz, Vicon Motion Systems, Oxford - UK).

A static trial was collected to define the local coordinate systems (CS), and five strides were then collected on a treadmill and overground. The treadmill speed was set at 3 m/s, whereas in the overground condition subjects were asked to walk at a self-selected speed.

Each model was analysed by properly selecting the relative marker set to obtain the kinematic angles. Joint kinematic angles were first expressed as a percentage of the gait cycle and then the sagittal range of motion (ROM) and the maximum plantar flexion and dorsiflexion for all the joints defined in the models were extracted using MATLAB (MathWorks, Natick - USA). The mean values were calculated along the five strides. The output of each model was tested with a repeated measure ANOVA ($p=0.05$) to investigate the differences between the two walking conditions (IBM SPSS Statistics v21, IBM Corporation, Armonk - USA).

Results: As a qualitative result, we can report the difficulty in tracking the marker trajectories when walking overground, while the tracking was simple enough in the case of using the treadmill. The statistical analysis shows that none of the joint kinematic variables significantly changed between the two conditions ($p>0.05$). We found the lowest *p*-values for the

plantar/dorsiflexion ROM of the forefoot relative to calcaneus in the Saraswat's model (p=0.16) and for the maximum dorsiflexion of the mid-foot relative to calcaneus in the Sawacha's model (p=0.23). The largest value (p=0.99) has been obtained for the plantar/dorsiflexion ROM of the forefoot relative to tibia in the Stebbins model, for the foot relative to tibia both in the Leardini and Sawacha models, and for the maximum plantar flexion of the forefoot relative to tibia in the Saraswat model.

Figure:

Caption: Figure 1 – The full marker set obtained by fusing the four foot protocols: 13 markers for the Stebbins' model [1], 14 markers for the Leardini's model [2], 13 markers for the Sawacha's model [3] and 16 markers plus the triad on the hallux for the Saraswat's model [4].

Conclusion: Since that to the Authors' knowledge there are no articles on the described comparison considering a segmented foot model as the ones proposed in [1–4], in the present study we achieved an evaluation of the kinematic variables defined on the sagittal plane from four subjects equipped with the four foot models. The same variables were extracted both from a walking trial collected asking the subjects to walk on a treadmill and to walk overground.

While Riley *et al.* [5] asserted the differences on the hip, knee and ankle angles on the sagittal plane considering the two walking conditions, the 21 variables here examined indicate that no significant differences were observed between the two walking conditions (p always ≥0.16).

This finding allows the Authors to develop a methodology in the on-going phase of the research project for quantifying the goodness of the models in terms of repeatability, reproducibility and reliability that include the use of the treadmill for the walking trials.

However, it has to be noticed that the number of subjects involved in the study might have affected the results.

ESTIMATION OF FORCE, STIFFNESS AND ELASTIC ENERGY BASED ON KINEMATIC DATA WHILE RUNNING

Didier Staudenmann [1,*] Jacques Robadey [1] Silvio Lorenzetti [2] Wolfgang Taube [1]

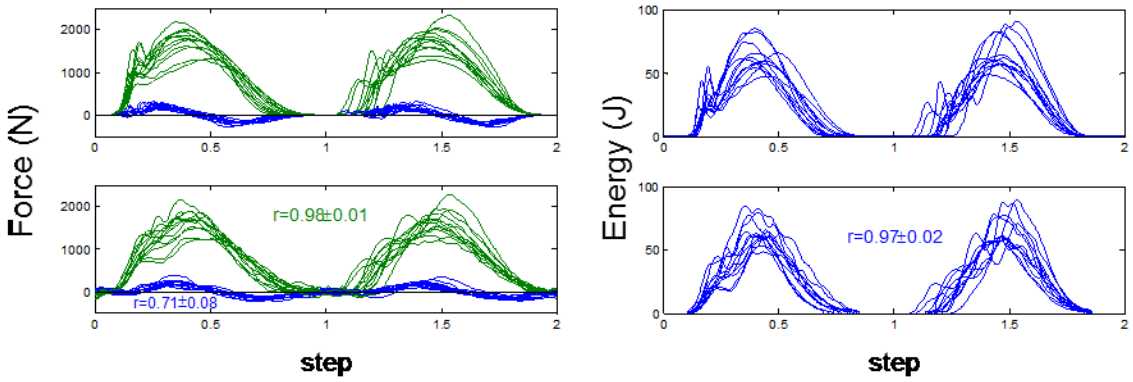
[1]Movement and Sport Science, Department of Medicine, University of Fribourg, Fribourg, [2]Institute for Biomechanics, Department of Health Sciences and Technology, Swiss Federal Institute of Technology , Zurich, Switzerland

Introduction and Objectives: Recording of ground reaction forces (GRF) provides crucial information to evaluate the running pattern. Furthermore, in combination with kinematic data, GRF can be used to determine the leg stiffness [1] and its elastic energy (Ee). However, although the assessment of these parameters is important, force recordings during running require complex laboratory settings with multiple imbedded force plates or instrumented treadmills. Consequently, this kind of approach is limited in its applicability. The aim of this study was to investigate the accuracy of estimating force, stiffness and Ee based on kinematic data of the COM, in comparing these values against GRF data.

Methods: In 13 subjects we measured full body kinematics and GRF of two steps (two force plates) during running (v=3.0±0.3m/s). From the kinematics we assessed the COM in sagittal plane, which was low-pass filtered (Savitzky-Golay) and differentiated to obtain acceleration and – after taking into account the respective body mass – force F. During the stance phase we estimated the "leg length" as the distance between COM and the center of pressure and considered its length change (Δl) in sagittal plane during foot strike and maximally flexed leg [cf. 1]. During the same interval we considered the change in sagittal force (ΔF), which allowed quantifying leg stiffness during stance as $k=\Delta F/\Delta l$. Based on force and stiffness we estimated the elastic energy in sagittal plane as $Ee=1/2\cdot(F_1^2/k_1 + F_2^2/k_2)$ for leg1 and leg2. The accuracy of F, ΔF, k, and Ee was estimated by comparing kinematic-based to GRF-based data using correlation coefficients.

Results: The kinematic approach estimated vertical force better (r=0.98±0.01) than the horizontal force (r=0.71±0.08, see Figure). The change in "leg length" Δl was 6.8±1.1 cm. The kinematic-based ΔF was significantly lower (9%) than the measured GRF (1.4±0.3kN vs. 1.6±0.3kN, $p<0.01$) and the kinematic-based leg stiffness-k was also significantly lower (10%) than the GRF-based data (22±5kN/m vs. 24±6kN/m, $p<0.01$). The kinematic-based Ee showed a considerable congruence with the vertical GRF-based values (r=0.97±0.02; see Figure).

Figure:



Caption: Result of force (left) and elastic energy (right) for two steps of 13 subjects. Upper panels show GRF-based outcomes and lower panels show kinematic-based outcomes. The correlation coefficients between the kinematic-based and the GRF-based values provide information about the accuracy of this approach.

Conclusion: Force, stiffness and elastic energy represent important parameters to evaluate running. The present study shows that these parameters can be estimated based on kinematic data. When considering the accuracy of this force estimation, the horizontal force was more difficult to estimate than the vertical force and strongly depended on the filter settings. However, as the vertical force is considerably larger than the horizontal force it will have a stronger effect on the further outcomes (k, ΔF, Ee). In this sense, Ee showed indeed a comparable accuracy than the vertical force (see Figure). It can be concluded that force, leg stiffness, and elastic energy can be estimated with kinematic data but the accuracy of this estimation depends strongly on the filter settings that are applied to the COM kinematics.

CORTICAL MODULATION OF ABERRANT LOWER LIMB MUSCLE SYNERGIES FOLLOWING STROKE

Andrew Q. Tan [1,*] Yasin Dhaher [2]

[1]Neuroscience, [2]Biomedical Engineering, Northwestern University, Chicago, United States

Introduction and Objectives: Growing evidence demonstrates unique synergetic signatures in the lower limb(LL) post-stroke, with a specific across-plane and across-joint representations. Observations of such neural constraints include coupled cross planar kinetic outflow[1] and altered muscle synergy structure[2]. Recent findings from our lab illustrated that additional activation of the lesioned hemisphere (L-H) upregulates the expression of these aberrant muscle synergies in the LL [3]. While the inhibitory role of the ipsilateral hemisphere in the upper limb has been widely reported, examination of the role of the contralesional hemisphere (CON-H) in modulating these synergies in the LL following stroke is lacking. Accordingly, we test the hypothesis that stimulation of L-H and CON-H motor cortices will have differential effects on the motor evoked potential (MEP) patterns of the paretic LL. We proposed a novel TMS paradigm to identify patterns of MEPs across multiple LL muscles during a task where synergistic actions have been reported.

Methods: 10 control and 12 chronic stroke participants with single hemispheric stroke were recruited. Motor evoked potentials (MEP) were elicited in 8 LL muscles using single pulse TMS. Surface electromyography (EMG) were recorded from: vastus medialis (VM), vastus lateralis (VL), rectus femoris, adductor longus (ADD), tibialis anterior (TA), medial gastrocnemius, and biceps femoris. Single pulse TMS was delivered using a Magstim 200 stimulator via a 110 mm diameter double-cone coil. The coil position was incrementally adjusted to locate the ADD hotspot over L-H motor cortex contralateral to the test limb (stroke paretic limb). Optimal coil position and intensity was mapped as the lowest stimulation intensity required to evoke ADD MEPs of 50 μV in peak-to-peak amplitude in 3 of 5 consecutive trials. The hotspot for the test limb ADD was similarly mapped for stroke contralesional hemisphere (CON-H) or control ipsilateral hemisphere to test limb. Stimulator output for the CON-H was increased in order to match contralateral (cMEP) and ipsilateral (iMEP) ADD amplitudes.

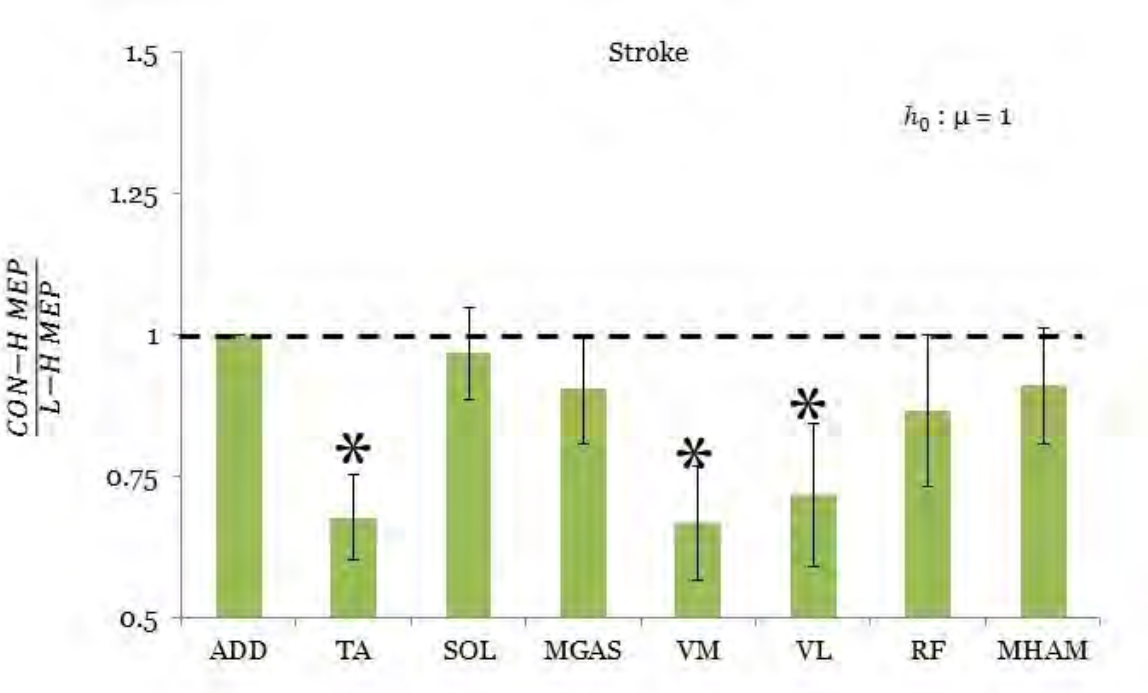
Participants were isometrically locked in the toeoff gait posture in an instrumented exoskeleton with 3 6-DOF load cells used to measure the interaction forces and moments. Participants matched isometric hip adduction torques at 40% of their maximum while receiving instantaneous visual feedback in the form of moving a circular cursor. A successful trial was considered if the participant matched the target torque within ±5% of the torque magnitude and direction and hold for a minimum of 200ms.

For each trial the TMS coil was placed over the hotspot location for either hemisphere. When the participants successfully matched the target adduction torque, the TMS device was triggered by software. Matched ADD MEPs together with nontargeted muscles were simultaneously recorded. 10-30 trials were performed for each hemisphere. An 80 ms window following the TMS pulse was searched for the MEP onset when 5 consecutive points in the EMG trace were above 3 standard deviations of the mean pre-TMS EMG activity. MEP amplitudes were measured peak-to-peak and calculated as the difference between the background activation and the average of a 20 ms window centered at the peak MEP rectified pulse. The ratio of the mean iMEP amplitude over the mean cMEP amplitude was quantified for each muscle. A statistical

value less than one indicate a reduction in iMEP amplitude relative to the cMEP amplitude following TMS of the ipsilateral hemisphere.

Results: By quantifying the CON-H / L-H MEP ratio across muscles, we characterized a significant inhibition of aberrant MEP coupling between ADD and VM (p=0.0078) and VL (p=0.047) following CON-H stimulation exclusive to the stroke group (ANOVA,p=0.028), an inhibition that was muscle dependent (ANOVA, p= 0.039). We find a significant reduction of TA MEPs in both groups following ipsilateral hemisphere stimulation (p=0.0014 stroke; p=0.015).

Figure:



Conclusion: Our results indicate that stimulation of CON-H reduced the expression of abnormal synergistic activations in individuals with stroke. Our observations seem incongruent with the notion of maladaptive motor output from CON-H post stroke suggested in the UL. Furthermore, a majority of the interhemispheric MEP onset latency differences occur below 3ms, consistent with the interpretation of ipsilateral corticospinal projections to the LL despite equivocal findings of their functionality the UL. Combined with the systemic inhibition of TA across groups, we argue that the ipsilaterally mediated MEP signature provides indirect evidence of inhibitory intracortical connectivity between abnormally synergistic muscles. This study takes an important step in exploring the relation between CON-H cortical reorganization and the modulation of abnormal LL muscle synergies post stroke.

DYNAMIC MOTOR CONTROL DURING WALKING PREDICTS TREATMENT OUTCOMES IN CEREBRAL PALSY

Michael Schwartz [1 2,*] Adam Rozumalski [2 3] Katherine M. Steele [4]

[1]Biomedical Engineering, University of Minnesota, Minneapolis, -, [2]James R. Gage Center for Gait & Motion Analysis, Gillette Children's Specialty Healthcare, St Paul, [3]Biomedical Engineering, University of Minnesota, Minneapolis, [4]Mechanical Engineering, University of Washington, Seattle, United States

Introduction and Objectives: Cerebral palsy (CP) impacts roughly 3 out of every 1000 individuals, impairing movement and coordination after an injury to the brain near the time of birth [1]. There are many treatment options to improve movement for individuals with CP; however, treatment outcomes are unpredictable, and not always satisfactory [2]. Since every brain injury is unique, each individual with CP has unique impairments, creating a challenge for clinicians to determine optimal treatment. Further, many treatments, such as orthopaedic surgery, focus primarily on musculoskeletal deformities and do not address underlying neural control. A long-held clinical belief is that part of the variability in outcomes after treatment is due to differences in neural control between individuals [3]. An individual with near-normal motor control may have greater improvements after orthopaedic surgery compared to an individual with more severely impaired motor control who, even after significant musculoskeletal correction, does not have the neurological capacity for unimpaired walking. In this study we sought to test this hypothesis by using EMG synergy analysis to quantify changes in dynamic motor control during walking and evaluate the effect of dynamic motor control on treatment outcomes.

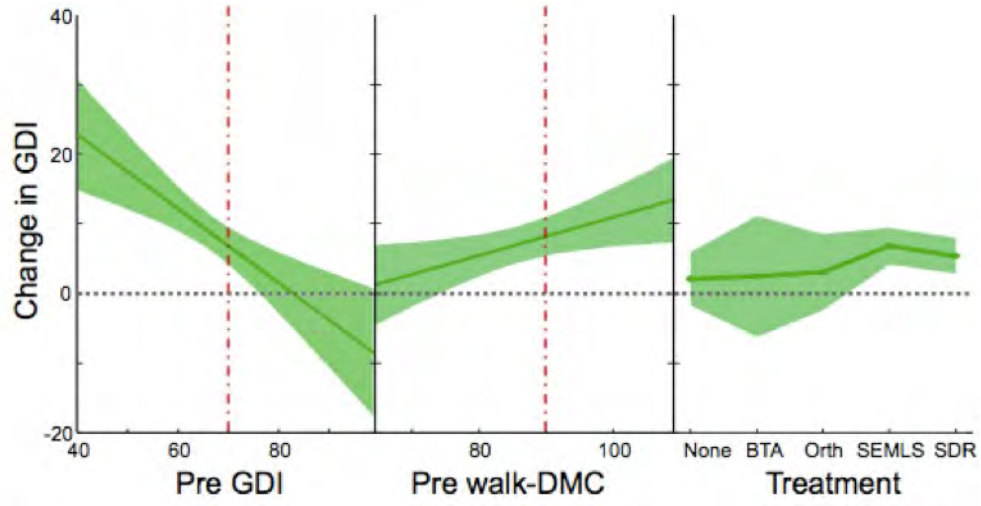
Methods: We retrospectively identified individuals with a diagnosis of diplegic CP, age < 21 years, who had previously received gait analysis including surface electromyography (EMG – rectus femoris, medial gastrocnemius, anterior tibialis, medial hamstrings) and a follow-up gait analysis 9-36 months later. For each individual, EMG data was processed using nonnegative matrix factorization [4] to identify weighted groups of muscles that are consistently activated together (synergies). The variance accounted for by one synergy was scaled to a z-score relative to a database of EMG from 84 typically-developing children to define the dynamic motor control index during walking (walk-DMC). Thus, a walk-DMC value of 100 equals the average variance accounted for by one synergy of typically-developing children and each 10 point increment represents one standard deviation. Values less than 100 indicate a more simplified control strategy in which a single synergy can describe greater variance in muscle activity than unimpaired individuals.

A stepwise linear regression model was computed predicting the change in gait kinematics (Gait Deviation Index, GDI, [5]) from initial to follow-up gait analysis. A constant model was initially assumed, with $p < 0.05$ for variable entry, and $p > 0.10$ for variable removal. Possible predictors included walk-DMC and measures previously shown to be associated with outcomes: initial GDI, age, prior surgery (yes/no), and treatment group.

Results: The analysis included 518 individuals with CP who met all inclusion criteria. Dynamic motor control was reduced in this population compared to typically-developing children with an average walk-DMC of 85.6 +/- 7.5 The final regression model to predict changes in gait kinematics included initial GDI, walk-DMC, treatment group, and an interaction term between initial GDI and treatment group ($r^2 = 0.31$, Fig. 1). The effect size for initial GDI and walk-DMC were similar in magnitude, but had opposite signs, such that individuals with dynamic motor control more similar to typically-developing

children (walk-DMC closer to 100) had better outcomes. More aggressive treatments (multi-level orthopaedic surgery and rhizotomy) resulted in larger positive GDI changes, but the magnitude of the treatment effect was significantly smaller than the magnitude of GDI and walk-DMC effects.

Figure:



Conclusion: Dynamic motor control was significantly associated with treatment outcomes, even after controlling for differences in gait pattern. For example, among individuals undergoing single-event multi-level orthopaedic surgery, those with the highest walk DMC improved nearly 12 GDI points more than those with the lowest walk-DMC. These results suggest that dynamic motor control plays a significant role in predicting gait outcomes after treatment and may provide a useful measure for treatment planning that can be calculated from currently available clinical gait analysis data.

Caption: Final regression model of change in gait deviation index (GDI). Regression lines show a slice through the regression surface at the average initial GDI and walk-DMC values (dotted red lines). Shaded area show 95% confidence interval for regression lines. Treatment groups included botulinum toxin/casting (BTA), single orthopaedic surgery (Orth), single-event multi-level orthopaedic surgery (SEMLS), and selective dorsal rhizotomy (SDR).

MODELING OF DYNAMIC RESPONSE OF CALF MUSCLES TO FUNCTIONAL ELECTRICAL STIMULATION

Hossein Rouhani [1 2,*] Michael Same [1 2] Ya Qi Li [1 2] Kei Masani [1 2] Milos R Popovic [1 2]

[1]Institute of Biomaterials and Biomidecal Engineering, University of Toronto, [2]Rehabilitation Engineering Laboratory, Lyndhurst Centre, Toronto Rehabilitation Institute - University Health Network, Toronto, Canada

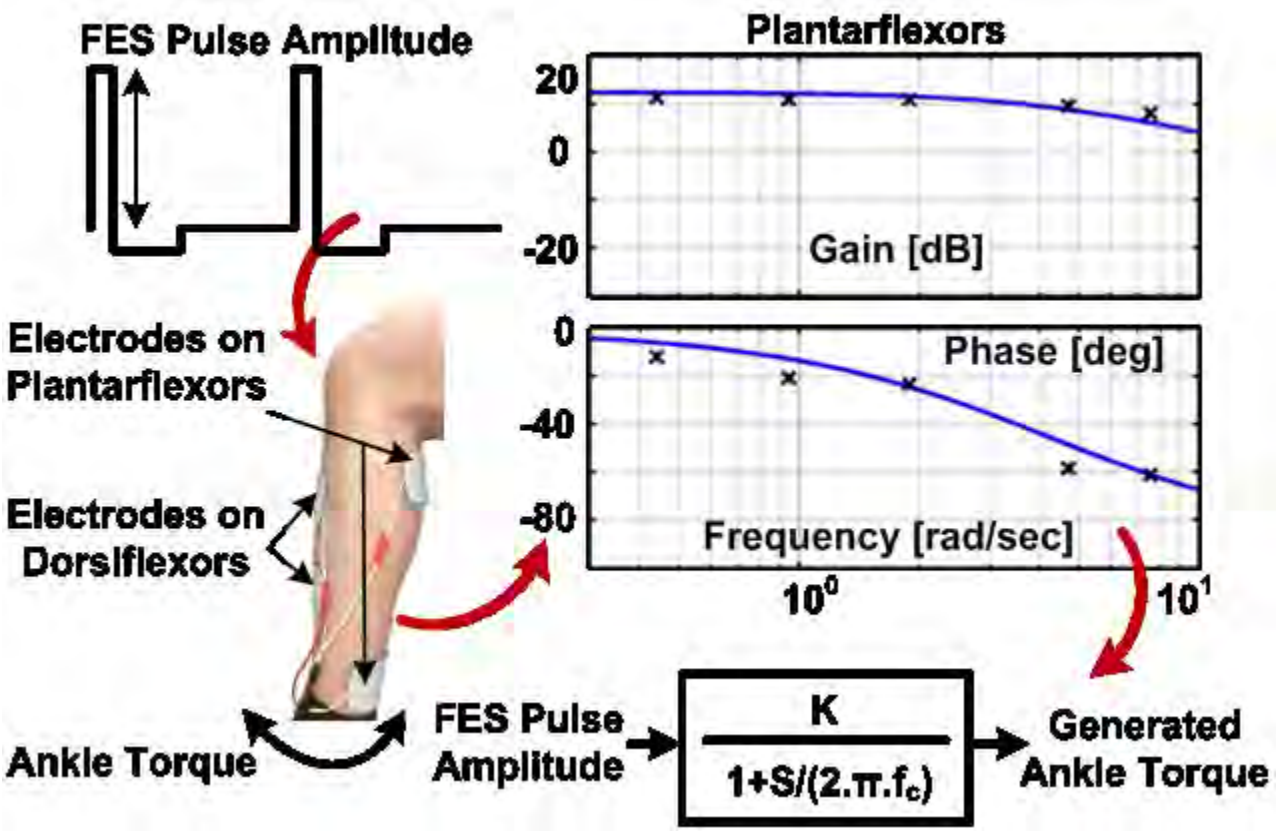
Introduction and Objectives: Functional electrical stimulation (FES) is referred to applying electrical pulses to intact motor neurons of paralyzed muscles to artificially induce muscle contractions and to restore functional motor tasks in individuals with spinal cord injury, traumatic brain injury, stroke or other neuromuscular impairments. FES can be utilized as neuroprosthesis for the purpose of permanently substituting lost motor function such as grasping, walking or standing [1,2]. The dynamic response of muscles to FES (as a transfer function) is an integral component of the closed-loop system controlling neuroprostheses, which is task-dependent and should be modeled before designing such neuroprostheses. Here we investigated the dynamic response of ankle muscles to FES in a standing posture, which can be implemented into closed-loop controlled FES system for standing balance. We applied FES pulse trains within a frequency range, and measured the dynamic response of the ankle dorsiflexors and plantarflexors to FES.

Methods: Eleven subjects (5 female, 25±4 years old, 172±9 cm, 68±9 kg) participated in the experiment. The subject stood on a standing frame with his/her extended knee and hip mechanically locked. The subject's feet, positioned horizontally, were fixed firmly to the foot-plates that were also locked. A programmable functional electrical stimulator (Compex Motion II, Compex SA, CH) was utilized to bilaterally stimulate the plantarflexors and dorsiflexors through surface electrodes. The stimulus waveform was rectangular, balanced, biphasic and asymmetric, applied at frequency of 20 Hz with pulse duration set to 0.3 msec. The pulse amplitude was modulated on sinusoids between 20 mA and 60 mA at frequencies of 0.07, 0.15, 0.3, 0.75, and 1.2 Hz. The plantarflexors and dorsiflexors were separately stimulated and the exerted isometric ankle torque was recorded using a torque transducer (TS11-200, Durham Instruments, DE) connected to the foot-plates. After discarding the first second of each trial, we fitted the generated ankle torque curves to at least two complete periods of sinusoids. The sinusoid of FES pulse amplitude and the fitted torque curve were considered as input and output, respectively. The amplitude gain, and phase lag between input and output were calculated on each frequency. We plotted a Bode diagram using amplitude gains and phase lags for all measured frequencies. We fitted a first-order linear model to the diagrams. Then, the parameters of the first-order linear model, i.e., gain (K) and time constant (T), were estimated for each subject (Figure 1).

Results: The gain (K) of the first-order model with FES amplitude as an input and ankle torque as an output was estimated to be 3.82±0.84 and 0.78±0.42 for plantarflexors and dorsiflexors, respectively (the mean ± standard deviation for the group of 11 subjects). Large inter-subject variability (coefficient of variation: 22% and 54% for plantarflexors dorsiflexors, respectively) in the estimated gains were observed. However, the estimated gain can be a function of muscle strength, electrode placement and skin-electrode contact conditions, and thus large variability among subjects was expected. The time constant of the first-order model with FES amplitude as an input and ankle torque as an output was estimated to be 0.31±0.05 and 0.27±0.05 for plantarflexors and dorsiflexors, respectively. Inter-subject variability of the estimated time

constant (coefficient of variation: 17% and 19% for plantarflexsors and dorsiflexors, respectively) was smaller compared to the estimated gain. This indicated similar muscle dynamics among subjects. Therefore, the identified cut-off frequency ($fc=1/(2.\pi.T)$) of the first-order filters, that modeled muscle dynamics, were 0.53±0.09 Hz and 0.60±0.12 Hz for plantarflexsors and dorsiflexors, respectively.

Figure:



Caption: Figure 1. Modeling dynamic response of ankle plantarflexors and dorsiflexors to functional electrical stimulation as a first-order model.

Conclusion: We identified the dynamic response of ankle muscles to FES in a standing posture. We successfully modeled the dynamic response of planterflexors and dorsiflexors using a first-order filter with FES as an input and the exerted isometric ankle torque as an output. However, higher order models and nonlinear components can also be investigated. Finally, this finding should be considered in the design of closed-loop controlled neuroprostheses when immediate torque generation is expected. The physiological interpretation of this modeling should be further studied.

BRAIN ACTIVATION DURING RHYTHMIC LOCOMOTOR TASKS IS COORDINATED WITH THE MECHANICAL DEMANDS OF THE MOVEMENT CYCLE

Hendrik Enders [1,*] Filomeno Cortese [2] Benno Nigg [1]

[1]Human Performance Lab, [2]Seaman Family MR Research Centre, University of Calgary, Calgary, Canada

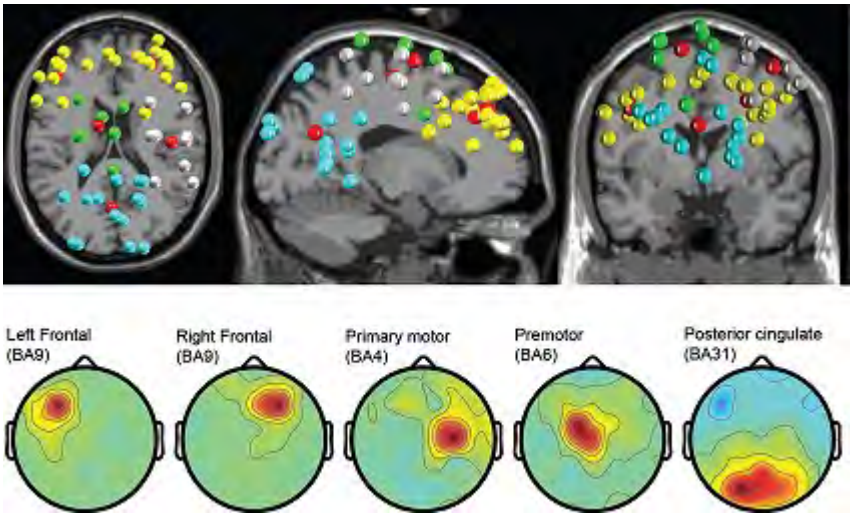
Introduction and Objectives: Coordinated movement is a complex process required for daily living, work and personal enjoyment. For individuals suffering from neuromuscular disorders, coordinated movement can be difficult if not impossible. Prosthetics and neuro-rehabilitation devices have been developed in order to improve movement for those with disability. Most studies have largely focused on the mechanics with less emphasis on the neuromechanical coordination between brain, the musculoskeletal system and the environment. This motor control problem, however, needs to be addressed in order to make rehabilitation devices and programs more efficient. Efficient rehabilitation for patient populations, however, requires a sound understanding of the underlying mechanisms in healthy humans first. Therefore, as a first step toward this goal, it is critical to understand healthy brain function during locomotor tasks in order to develop efficient devices that can mimic healthy human movement. The shortcoming in this area thus far is that real-time brain function and activity during unconstrained movement has rarely been assessed due to the difficulty of collecting noise-free data during dynamic tasks. Recent advances in hardware and software now allow researchers to image the brain in real time during dynamic situations [1]. Therefore, the purpose of this study was to investigate the time-frequency patterns of electrical brain activity during rhythmic movements in healthy individuals.

Methods: Ten healthy individuals were cycling at a constant intensity that was normalized to their maximum power output while real-time cortical activity was recorded using a 64-channel electroencephalography (EEG) and 7 muscles were collected using surface electromyography electrodes. Cycling serves as an excellent model for rhythmic locomotor type tasks in humans and has minimal head movement that interferes with the EEG recordings. This abstract will focus on the results obtained by the EEG analysis. Adaptive Mixture Independent component analysis (AMICA) was used to remove eye artifacts and non-cortical noise components [2]. The cleaned EEG signal was resolved into spatially independent components represented as two dimensional topographic maps. An anatomical head model consisting of the average of 152 MRI scans was used to perform source analysis in order to locate the origin of neural activity in brain space [3]. A k-means clustering algorithm was used to group the identified sources of neural activity across subjects. Time-frequency patterns of cortical activity were visualized as event-related spectral perturbations (ERSP) in order to quantify the oscillatory behavior of neural sources located in three dimensional brain space. Cluster-based permutation statistics were used to test if the ERSP data showed significant spectral perturbations from baseline ($P < 0.05$).

Results: Neural sources were spatially localized to Brodmann area (BA) 9 (left and right frontal cortex), BA 4 (primary motor cortex), BA 6 (Premotor cortex) and BA 31 (posterior cingulate cortex) (Figure 1). The ERSP showed significant changes in spectral power across the pedaling cycle with the strongest activity being present in the premotor cortex cluster, followed by activity in the frontal lobe and the primary motor cortex. We were able to show neural excitation in

primary and secondary motor areas prior to the down stroke of the pedaling cycle which corresponds to the phase where the musculoskeletal system needs to produce the majority of the mechanical power output.

Figure:



Conclusion: To the best of our knowledge this is the first study reporting intra-trial fluctuations of brain activity localized to specific cortical areas during cycling. Based on our results we suggest a cortical network model of cycling that includes executive brain centers (frontal cortex), the premotor area for movement planning and the primary motor area for descending motor commands and integration of sensory afferent feedback. Our results suggest that the temporal pattern of neural activity in the motor areas of the brain corresponds well to the time frame of mechanical power production by the lower limb muscles during the pedaling cycle.

EMG

AS-0119

USING SURFACE ELECTROMYOGRAPHY (SEMG) TO NON-INVASIVELY MONITORING THE ACTIVATION OF DEEP AND SUPERFICIAL EXTRINSIC FOOT MUSCLES

Cara Swanepoel [1,*] Yumna Albertus-Kajee [2] Lester John [1]

[1]MRC/UCT Medical Imaging Research Unit, Division of Biomedical Engineering, Department of Human Biology, [2]UCT/MRC Research Unit for Exercise Science and Sports Medicine, Department of Human Biology, University of Cape Town, Cape Town, South Africa

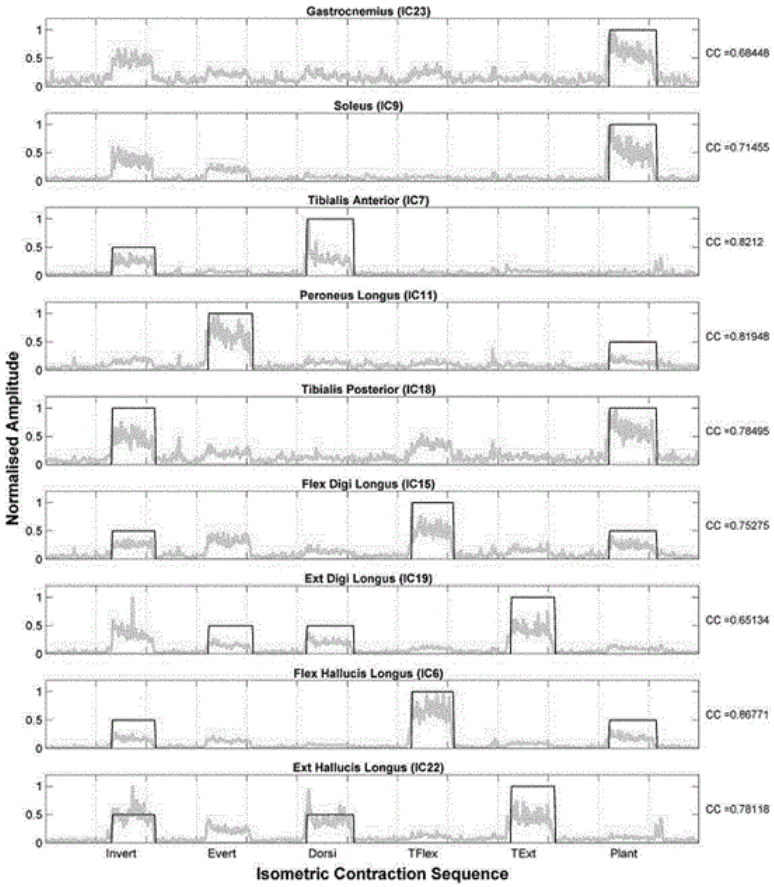
Introduction and Objectives: Using current methods of Electromyography (EMG) to measure the activity of both deep and superficial muscles would require a combination of surface and invasive intra-muscular electrodes, as present-day surface EMG (sEMG) is unable to distinguish between deep and superficial muscle activation. A novel technique utilising monopolar sEMG in conjunction with a separation algorithm (for example Independent Component Analysis) and muscle specific activation protocol[1] has previously been implemented to detect the activation of the deep Brachialis[2] and Tibialis Posterior[3] muscles. The technique was adapted and utilised to detect the activation of deep (Tibialis Posterior [TP], Flexor Digitorum Longus [FD], Flexor Hallucis Longus [FH], Extensor Hallucis Longus [EH]) and superficial (Triceps Surae [TS] (Gastrocnemius and Soleus), Tibialis Anterior [TA], Peroneus Longus [PL], Extensor Digitorum Longus [ED]) extrinsic foot muscles during a platform-guided isometric contraction sequence.

Methods: Four concentric rings, each consisting of 10 non-commercial application-specific electrodes, were placed around the lower segment of the right lower limb of 17 healthy male participants. The rings were arranged in 2 pairs, spaced 20mm apart and placed at 1/3 and 2/3 of the distance from the medial malleolus to the tip of the fibula. Monoploar EMG signals were recorded while the participants performed a specifically designed, platform-guided isometric contraction protocol, repeated 10 times with both the knee flexed at 90° and fully extended. The muscles within the capture area of the EMG electrodes were selectively activated by contractions of Toe Flexion (TFlex), Toe Extension (TExt), Plantar Flexion (PFlex), Dorsi Flexion (DFlex), Inversion (Inv) and Eversion (Evn), (40%of Maximum Voluntary Contraction- confirmed by strain gauges), randomised and interspersed with rest periods. ICA (fastICA) was applied to the sEMG signals to separate-out source activations, known as the Independent Components (ICs) which were Root Mead Square (RMS) smoothed (moving window of 250s) and normalised. A contraction sequence specific, anatomically defined[4], expected EMG activation patterns (with timing informed by strain gauges) for each muscle under investigation is compared to the ICs using Pearson's Correlation Coefficient. The ICs are ranked according to correlation coefficients (ρ) and the highest ranking IC for each muscle was considered to represent the EMG activity. (Typical example in Figure 1).

Results: The mean correlation between the expected EMG patterns and the detected Independent Components, for each muscle over the 10 repetitions for all 17 participants, were calculated for both the knee flexed at 90 degrees and fully extended. Good correlation values indicate that the ICs detected are highly likely to represent the EMG activity of the muscles under investigation. Lower correlation values could be due to poor adherence to the contraction protocol by participants or possibly co-contractions. In surface muscles these could be confirmed by extracting standard bi-polar

sEMG measurements from the measured signals. Limitations of the fastICA algorithm could account for incomplete separation of the ICs which could indicate activity when no activity was present.

Figure:



Caption: Typical expected EMG activation patterns (dark) and top ranked ICs (light) for each muscle from a single experimental run for 1 participant. Vertical divisions indicate transitions between contractions and rest periods.

Conclusion: The detection of EMG activity from deep and superficial extrinsic foot muscles using sEMG was possible as the ρ values indicate a correlation between measured activity and the expected activation patterns generated. Further verification of the technique and results is on-going.

DIAGNOSIS OF PATELLOFEMORAL PAIN SYNDROME IS POSSIBLE USING SURFACE ELECTROMYOGRAPHY

Deisi Ferrari [1,*]Fábio Azevedo [2]Nathalie Faria [2]Danilo Silva [2]Marcella Pazzinatto [2]Ronaldo Briani [2]Neri Alves [1]

[1]Bioengineering Postgraduate Program , University of São Paulo, São Carlos, [2]University of Sao Paulo State, Presidente Prudente, Brazil

Introduction and Objectives: Despite the high incidence and physical limitations caused by patellofemoral pain syndrome (PFPS), there is no consensus on diagnosis and etiologic factors. One hypothesis explains PFPS as alterations in the muscle activation or muscle inhibition of the vastus medialis (VM) and vastus lateralis (VM)[1], which can be visualized by changes in the spectral properties of the electromyogram [2]. In this context, the association between EMG and clinical findings might be a new method for the diagnosis of PFPS. The purpose of this study was to assess the diagnostic accuracy of surface EMG parameters associated with anterior knee pain for diagnosing PFPS.

Methods: To perform a study on diagnostic accuracy it is necessary to compare the index test, i.e., the test under evaluation, with the standard reference which is defined as the best-available method to determine the absence or presence of the condition of interest. 29 pain free subjects and 22 subjects with PFPS were recruited according to the standard reference and, posteriorly submitted to assessment using the index test. The index test in this case was the association between 2 clinical criteria and an electromyography parameter. The electromyography parameter should be reliable, precise and able to differentiate the groups. The clinical criteria were an anterior knee pain level of at least 2 cm on a visual analog scale in the preceding month and anterior knee pain whilst performing at least 2 functional activities (squatting, kneeling, running and stair climbing). The EMG signal was collected for the VM and VL muscle during the functional movement of stair climbing. The staircase used had seven steps, and coupled to the fourth step was a force plate to detect the exact moment that the individual touched the ground. The tests were run on two days, each test consisted of ten stair climbing trials. The EMG signals were processed in Matlab®. The Discrete Fourier Transform was used to calculate the median frequency (MF) and the normalized power spectrum was divided into three bands denominated low (15 to 45Hz), medium (45 to 96Hz) and high frequency (96 to 400Hz). The $ICC_{2,k}$ (intraclass correlation coefficient), SEM (standard error of measurement) and independent t test were calculated. Sensitivity, specificity, negative and positive likelihood ratios (LR- and LR+),and negative and positive predictive values (NPV and PPV) were calculated for diagnostic accuracy. To determine the cutoff of the EMG signal for diagnosis, several confidence intervals of the control group were considered. The confidence interval selected was the one that showed the best sensitivity and specificity.

Results: Table 1 presents the descriptive and relyabilty data of the EMG parameters. The outcomes of the diagnostic accuracy of the index test refer to the medium-frequency band (B2) because this parameter was reliable, precise and able to differentiate the groups for both muscles. The cutoff value determined corresponds to a 95% confidence interval. The interval was between 26.72 and 31.26 for the VM muscle and 24.75 and 29.01 for the VL muscle. The participants who reported values within these ranges were considered pain-free, and the participants with values outside these ranges

were considered as having PFPS. Diagnostic accuracy results were: sensitivity = 0.70, specificity = 0.87, PPV = 0.86, NPV = 0.72, LR- = 5.63 and LR+ = 5.63.

Conclusion: Our results showed that the medium-frequency band (B2) parameter was reliable, precise, and able to differentiate participants with and without PFPS. This study provides evidence for the use of the EMG signal for the diagnosis of PFPS.

DOES THE ABDOMINAL DRAWING-IN MANEUVER CHANGE THE LOCAL DYNAMIC STABILITY OF REPETITIVE SPINE MOVEMENTS IN A HEALTHY POPULATION?

Daniel Southwell [1,*] Nicole Hills [2] Linda McLean [2 3] Ryan Graham [1 4]

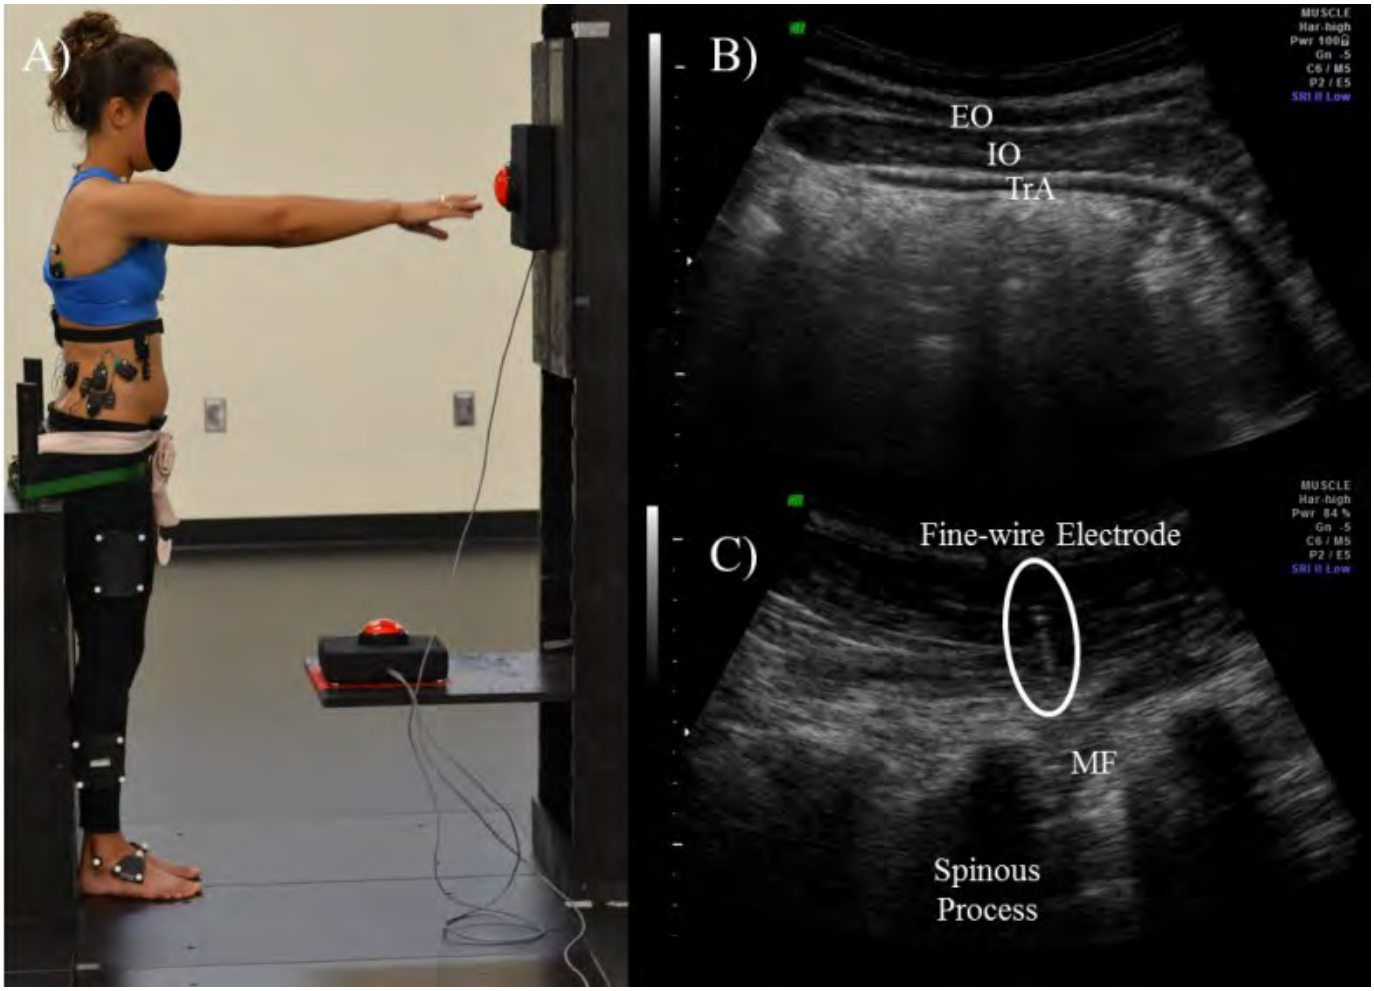
[1]School of Physical and Health Education, Nipissing University, North Bay, [2]School of Rehabilitation Therapy, Queen's University, Kingston, [3]School of Rehabilitation Sciences, University of Ottawa, Ottawa, [4]School of Kinesiology and Health Studies, Queen's University, Kingston, Canada

Introduction and Objectives: Selective activation of the transversus abdominis (TrA) through the abdominal drawing-in maneuver (ADIM), has been adopted as common clinical practice in the prevention and rehabilitation of low back pain (LBP) [1]. However, there is still a debate in regards to the role the ADIM has in maintaining a stable spine [2-3]. There is also limited evidence to support the use of the ADIM during dynamic movement tasks to enhance spine stability and currently no literature that shows spinal control is less optimal when activation of the TrA is changed [3]. Spinal control cannot be accurately tested in many current biomechanical models as few include contributions of intra-abdominal pressure and fascial tension [3]. One way to assess control and take into account all aspects of spine stability is to look directly at the outcome kinematics during repetitive movement using non-linear dynamic systems analyses [4]. Thus, the purpose of this study was to (i) examine whether TrA activation could be increased during dynamic movements following five minutes of training, and (ii) assess whether changes in TrA activation could alter dynamic spine control and stability.

Methods: Thirteen healthy participants (7M, 6F) performed two sets of 35 cycles of repetitive unloaded spine flexion with a constrained pelvis to the beat of a metronome at a rate of 15 cycles/min [4] (Figure 1). Between sets, participants were instructed by a Registered Physiotherapist on how to perform the ADIM in standing. Ultrasound (US) imaging (Voluson i, GE Health Care, UK) was used as biofeedback to ensure successful contraction of TrA. Surface EMG was recorded at 2000Hz from four muscles bilaterally: thoracic and lumbar erector spinae (TES and LES), and internal and external oblique (IO and EO) (Trigno, Delsys Inc., USA). Indwelling EMG was recorded synchronously from three muscles unilaterally (right side): IO, TrA, and multifidus (MF). Indwelling electrodes were inserted under US guidance to ensure correct positioning in each muscle (Figure 1). During all trials, 3-D kinematic data were collected at 50 Hz (Oqus 400+, Qualisys, Sweden), and Visual-3D was used to calculate 3-D spine kinematics (C-Motion Inc., USA). EMG data were processed and local dynamic spine stability was calculated using published methods [4]. The average peak EMG across all cycles and the local dynamic stability values were then compared between the baseline and trained trials using repeated-measures ANOVA's in SPSS 22 (IBM Corporation, USA).

Results: Average peak EMG and local dynamic stability results can be found in Table 1. Results indicate that following ADIM training, there were significantly greater ($p<0.05$) levels of activation in all of the tested abdominal muscles during movement. Conversely, there were no significant increases in activation of any of the back muscles tested. Moreover, no significant change in the local dynamic stability of spine movements was observed following training ($p=0.855$).

Figure:



Caption: Figure 1. A) Experimental set-up. B and C) Representative abdominal and lumbar spine ultrasound images.

Conclusion: The results indicate that in a healthy population, increasing activation of the TrA does not increase dynamic spinal control or stability. While this finding agrees with previous research [2], it may also be partly explained by participants' non-familiarity with activating their TrA during movement (although not reported, abdominal muscle activation variability was significantly greater during the trained trial). Previous literature has shown that focusing internally on the activation of a muscle rather than externally on the task at hand, can impair neuromuscular coordination and movement outcomes [5]. To assess such a motor learning effect, we are currently analyzing data from a second day of testing after participants performed a home exercise program of TrA activation and stabilization exercises for one week. Our future work will also investigate the effects of the ADIM on the dynamic stability of spine movements and TrA timing in LBP patients, since TrA training may be effective in reducing symptoms in such populations [3].

GAIT IMPROVEMENT INDUCED BY REAL-TIME FEEDBACK BASED ON DYNAMIC FOOT PRESSURE INDEX FOR DYNAMIC EQUINUS IN CHILDREN WITH CEREBRAL PALSY

Weiyan Ren [1 2,*] Fang Pu [1 2] Wei Chen [1 2] Deyu Li [1 2] Feng Zhao [1 2] Yubo Fan [1 2]

[1]School of Biological Science and Medical Engineering, [2]Key Laboratory of Rehabilitation Technical Aids of Ministry of Civil Affair, Beihang University, Beijing, China

Introduction and Objectives: Cerebral palsy (CP) children with dynamic equinus often walk on their toes, which can be treated with gait rehabilitation. Real-time feedback is considered to be helpful in improving gait training efficiency, but previous toe-walking gait monitoring systems had the problem of inaccurate feedback and insufficient analysis for patient ambulation. Dynamic foot pressure index (DFPI)[1] is an useful parameter to quantify the degree of toe-walking gait in children with CP. This study is to explore the impact of real-time feedback based DFPI on gait improvement during rehabilitation gait training for CP children with dynamic equinus.

Methods: Real-time feedback cue for toe-walking gait was generated by a wearable device based on DFPI. Ten CP children with dynamic equinus were tested their daily gait and training gait under real-time feedback by wearing the device with sound off and sound on respectively. The mean values of DFPI in normal gait (NORG) and in toe-walking gait (TOEG) were selected as parameters to evaluate walking performance in the two experimental stages for each subject.

Results: Compared with the walking performance of patient daily gait，testing results of training gait under real-time feedback have significant improvement in both NORG ($P = 0.011$) and TOEG ($P = 0.030$).

Conclusion: Real-time feedback training method based on DFPI can effectively correct toe-walking gait, which can contribute to improve walking abilities in CP children with dynamic equinus.

FORCE MANTAINANCE OF THE PELVIC FLOOR MUSCLES ARE INFLUENCED BY THE COMBINED ACTION OF HIP ABDUCTOR MUSCLES IN HEALTHY WOMEN

Amanda C. Amorim [1,*]Licia Cacciari [1]Anice Passaro [1]Simone Brandao [2]Isabel Sacco [1]

[1]Physical Therapy, Fonoaudiology and Occupational Therapy, [2]University Hospital, University of Sao Paulo, Sao Paulo, Brazil

Introduction and Objectives: The strength and coordination of the pelvic floor (PF) muscles are related to the severity of urinary incontinence and sexual satisfaction (1). Clinicians intending to facilitate the PF treatment commonly associate classical PF strengthening exercises with hip adduction/abduction activity, but to this date the benefits of this combination and the anatomical/ biomechanical rationale to adopt those associations in exercise treatments, are still unknown. The levator ani muscle inserts into the obturatorius internus muscle internal fascia (2), then if its tension increases by hip external rotation and/or abduction, one may improve the quality of PF contraction, contributing with its treatment. Here our aim was to investigate the effect of the association of hip adduction and abduction in the force production and maintenance of PF muscles.

Methods: Twenty continent and nulliparous young woman (28.5±5.3 years old, 56.0 ±10.1 kg, 1.61±0.10 cm) were assessed in supine with knees flexed (figure), with 2 dynamometers (figure) (into the vaginal cavity and around the tights to measure the hip add/abduction force) in 3 different conditions: (a) isolated PF contraction for 10 seconds; (b) associated with hip adduction (30% maximal voluntary contraction) for 10 seconds; and (c) associated with hip abduction (30% maximal voluntary contraction) for 10 seconds. The strain gauge data were sampled at 100Hz, filtered with a low-pass of 8Hz and subtracted from the passive force (assessed after one-minute accommodation period following the vaginal probe insertion). From the temporal series, we calculated the maximal force (N), endurance (N.s) (area under the curve – 8 seconds window) and force maintenance (N.s) (area of an 8s projected interval where the value is constant and equal to the first peak minus the force curve integral). Repeated measures ANOVAs followed by Newman-keuls post hoc tests were used to compare the conditions ($p<0.05$).

Results: The results showed a significantly reduced maximal force and endurance for the condition with hip adduction. This result means that this association do not improve the magnitude or maintenance of PF strength capacity and that the adductors muscles may not contribute with the PF muscles contraction. The force-time integral (endurance variable) was significantly greater for the isolated contraction, what means that this condition led to a greater magnitude of PF strength capacity. It is possible that in both dual-task conditions, the attention was shifted for the hip action goal (30% of maximum voluntary contraction), competing with the PF muscles contraction. Interestingly the condition with hip abduction showed significant positive strength maintenance when compared to the other two conditions. This result suggests that, during the hip abduction, the subjects were able to recover (or restore) their PF strength, in the time period evaluated (8 seconds). According to our hypothesis, it could mean there was a tension transmission through obturatorius internus muscle internal fascia optimizing the PF muscle function.

Figure:

Caption: Figure. Vaginal Dynamometer and tight dynamometers

Conclusion: The association of PF muscles contraction and hip abduction action have improved the force maintenance in young woman and could be used during sustained contraction practices and daily function.

EFFECTS OF HIP EXTENSOR MUSCLES STRENGTHENING ASSOCIATED WITH LANDING STRATEGY MODIFICATION IN AN ATHLETE WITH PATELLAR TENDINOPATHY: A CASE REPORT

Rodrigo Scattone Silva [1,*]Ana Luisa Granado Ferreira [1]Theresa Nakagawa [1]Lucas Aoki [1]José Mourão dos Santos [2]Fábio Serrão [1]

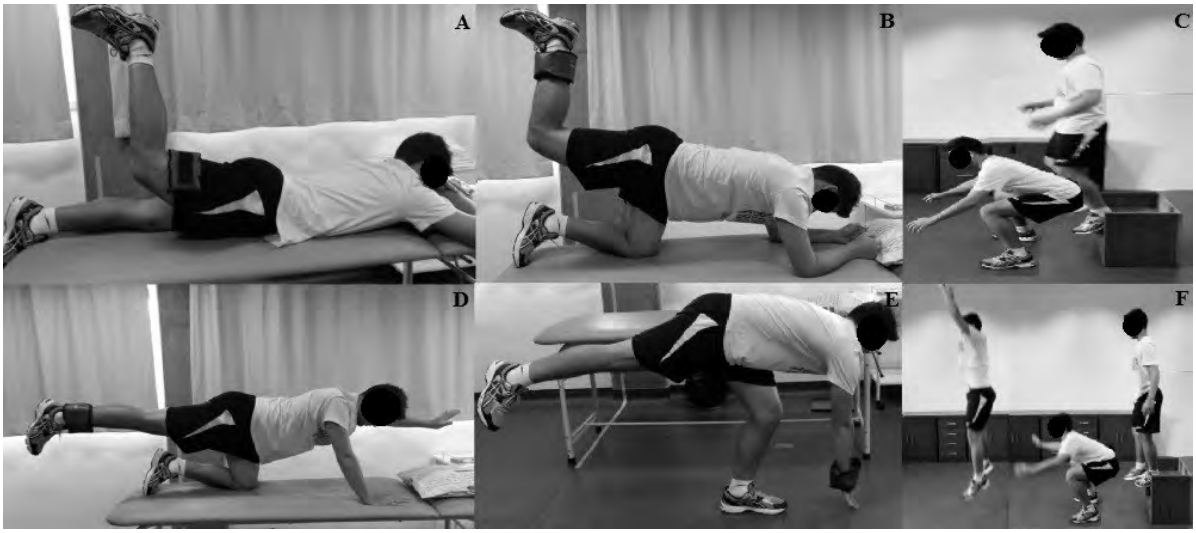
[1]Department of Physiotherapy, [2]Department of Medicine, Federal University of São Carlos (UFSCar), São Carlos-SP, Brazil

Introduction and Objectives: Patellar tendinopathy is one of the most common causes of anterior knee pain in the athletic population. Although eccentric exercises have been considered a cornerstone of patellar tendinopathy rehabilitation, the outcomes with this intervention are sometimes less than ideal. Bahr *et al.* [1] found that only 55% of elite athletes treated with eccentric exercises had a satisfactory return to sports practice 1-year after the intervention. Therefore, the effectiveness of other treatment options for treating this dysfunction should be investigated. A recent study has shown that athletes with patellar tendinopathy have diminished hip extensor torque when compared to asymptomatic controls [2]. Previous research has also shown that athletes with patellar tendon abnormalities have altered jump-landing mechanics in comparison to controls without such abnormalities [3]. Therefore, an intervention aiming to address these aspects might be effective for the rehabilitation of athletes with patellar tendinopathy. The purpose of this case-report was to verify the effects of an intervention involving hip muscles strengthening and jump-landing strategy modification on pain and lower limb biomechanics of an athlete with patellar tendinopathy.

Methods: The patient was a 21-years-old male volleyball athlete who presented with pain in the patellar tendon during tendon-loading tasks for 9 months and patellar tendon ultrasound abnormalities, being diagnosed with patellar tendinopathy. The subject's worst pain in the previous week was assessed using a 10cm visual analogue scale (VAS) and the severity of his symptoms was quantified with the Victorian Institute of Sport Assessment-Patella questionnaire (VISA-P). A handheld dynamometer (Lafayette Instruments, IN, USA) was used to measure hip extension strength during isometric maximal contractions. A force plate (Bertec Corporation, OH, USA) and the Qualisys Motion Capture system (Qualisys Medical, AB, SWE) were used to evaluate kinetics and kinematics while the subject performed a drop vertical jump task from a 31-cm box. After the baseline evaluations, the subject was submitted to an intervention of 8-weeks. In phase 1 (weeks 1–4), the subject performed open kinetic chain hip extension exercises (**Figure 1A–1B**) and a training aiming to increase trunk flexion during drop jumps (**Figure 1C**). In phase 2 (weeks 5–8) more demanding hip extensor strengthening exercises were performed (**Figure 1D–1E**) and the jump-landing training involved drop vertical jumps with emphasis on trunk flexion in both landings (**Figure 1F**). The subject was allowed to continue his sports participation during the intervention period. After 8 weeks, all baseline evaluations were repeated. The Visual3D (C-Motion, MD, USA) software was used for data analysis. Joint moments were calculated using inverse dynamics and the patellar tendon forces were calculated [4]. The primary outcomes of the jump-landing evaluations were the peak knee and hip flexion angles, internal knee and hip extensor moments and patellar tendon forces during the landing phase of the drop vertical jump task.

Results: A substantial decrease in the patient's symptoms occurred after the intervention, with important changes observed in the VAS (baseline=6.0; after intervention=0.0) and in the VISA-P scores (baseline=61; after intervention=95). The subject reported being completely asymptomatic during sports practice after the intervention. The subject's isometric hip extensor strength had a 77% increase in 8 weeks. In the drop vertical jump the subject presented a 31% increase in peak hip flexion during landing, with little difference on peak knee flexion, after intervention (**Table 1**). Also, a 21% decrease in the knee extensor moment, a 50% increase in the hip extensor moment, and a 26% decrease in the patellar tendon force were observed during landing after the intervention (**Table 1**).

Figure:



Caption: Figure 1 – A. Hip extension in prone-lying; B. Hip extension in quadruped position; C. Drop jump landing training; D. Bird Dog exercise; E. Single-leg deadlift; F. Drop vertical jump landing training

Conclusion: The results of this case-report indicate that an intervention involving hip muscles strengthening and jump-landing modifications can substantially diminish pain and improve lower limb biomechanics during jump-landings in an athlete with patellar tendinopathy.

Table:

	Baseline	After Intervention	% Change
Hip Flexion (deg)	70.45	92.14	+30.79
Knee Flexion (deg)	104.50	100.52	-3.81
Hip Extensor Moment (N.m/kg)	2.09	3.13	+49.76
Knee Extensor Moment (N.m/kg)	2.19	1.73	-21.00
Patellar Tendon Force (BW)	5.04	3.75	-25.59

Biofeedback

AS-0125

DEVELOPMENT OF A BESPOKE MOTION CAPTURE SYSTEM ALLOWING REAL-TIME BIOFEEDBACK OF MOVEMENT FOR USE IN THE CLINICAL ENVIRONMENT.

Lindsay Clarke [1,*] Andrew J Murphy [1] Phil Rowe [1]

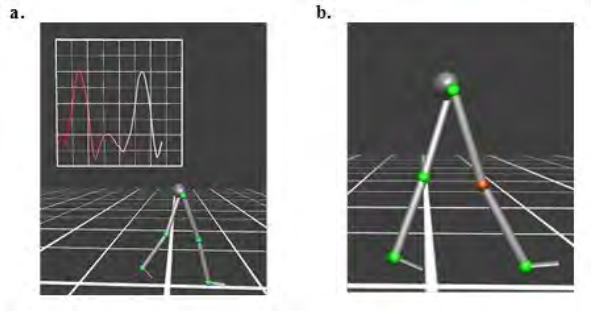
[1]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: The feedback of information to patients in the clinical environment is a key aspect to achieving a desirable outcome following a treatment intervention[1]. Biofeedback may be provided in many different ways. It has been suggested that providing patients with augmented visual feedback may have a positive effect on functional outcomes[2]. One of the easiest ways to provide this type of feedback is through motion capture technology. However, a high level of technical expertise is often required to operate motion capture systems and distil useful information from the results. Further, feedback to patients is limited by the technical nature of such systems and the data that they provide. This has limited their widespread use in the clinical environment to date[3,4]. The current study aims to develop a motion capture system which overcomes these issues and is capable of providing biofeedback to patients and clinicians in a clear and accessible manner.

Methods: A bespoke pelvis and lower limb cluster marker set combined with strategically placed anatomical markers was designed and implemented. Marker trajectory data was captured and labelled using Vicon hardware and acquisition software (Vicon Motion Systems, Oxford, UK). This data was streamed in real-time to an object-orientated application development package, D-Flow (Motek Medical, Netherlands). Bespoke scripting modules written in Lua programming code were used to create an avatar from tracked markers and calculated joint centres. The method described by Grood and Suntay[5] was used to calculate inter-segmental kinematics (figure 1). A colour coded joint system was developed to allow real-time feedback regarding hypermobility and pathological movements (figure 1).

Results: A biomechanical model was developed which removes an aspect of the technical inaccessibility of current commercially available motion capture systems. The model allows output of kinematics and visual feedback of movement to the patient and clinician. Currently, flexion/extension, internal/external rotation and ab/adduction angles can be displayed for all joints. Shank/thigh to vertical angle and pelvic, tilt, obliquity and rotation can also be displayed.

Figure 1. Biofeedback during walking. **a.** Avatar and knee flexion angle **b.** Hyperextension of the knee causes joint to turn red.



Conclusion: The need for technical expertise in motion capture is greatly reduced with the use of this model. Cluster markers reduce the need for accurate marker placement and visualisation and data feedback can be given in real-time. The use of real-time biofeedback will hopefully lead to increased patient understanding and an improved clinician-patient dialogue.

DETECTING CONTROL PRIORITIES WHEN REGULATING ANGULAR IMPULSE GENERATION IN WELL-PRACTICED GOAL-DIRECTED TASKS

Travis Peterson [1,*] Phillip Requejo [1 2] [3] Henryk Flashner [4] Jill McNitt-Gray [1 2]

[1]Biomedical Engineering, [2]Biological Sciences, University of Southern California, Los Angeles, [3]Rehabilitation Engineering, Rancho Los Amigos National Rehabilitation Center, Downey, [4]Aerospace and Mechanical Engineering, University of Southern California, Los Angeles, United States

Introduction and Objectives: Populations with balance-related impairments (older populations, persons with lower limb amputations, etc.) often have limitations in their ability to generate linear and angular impulse required in activities of daily living (ADL) such as fall recovery [1], stair descent [2], and gait termination [3]. For example, the inability to reliably regulate reaction forces (RF) generated with the prosthetic limb appears to affect the role of each leg in regulating the linear and angular impulse needed in a variety of weight bearing tasks [1–3]. The balance regulation strategies involved in effective performance of ADLs are also common to the golf swing. Participation in golf could improve an individual's capacity for coordinating impulse generation between legs and as a result, serve as an effective and engaging community-based intervention to assist in overcoming balance-related impairments.

During the course of play, players can use golf clubs of different length and club face angles to regulate the trajectory of the ball during flight. Previous research indicates that skilled players using a 6-iron modify shot distance by regulating the magnitude of the target and/or rear leg resultant horizontal reaction forces (RFh), with minimal changes in RFh orientation relative to the target [4]. These results suggest that angular impulse about the center of mass (CM) during the swing can be affected in a comparable way by regulating RFh magnitude and CM trajectory in relation to the point of wrench application (PWA). We tested this hypothesis by comparing the angular impulse generated about the CM when individual players hit a golf ball with a driver as compared to a 6-iron.

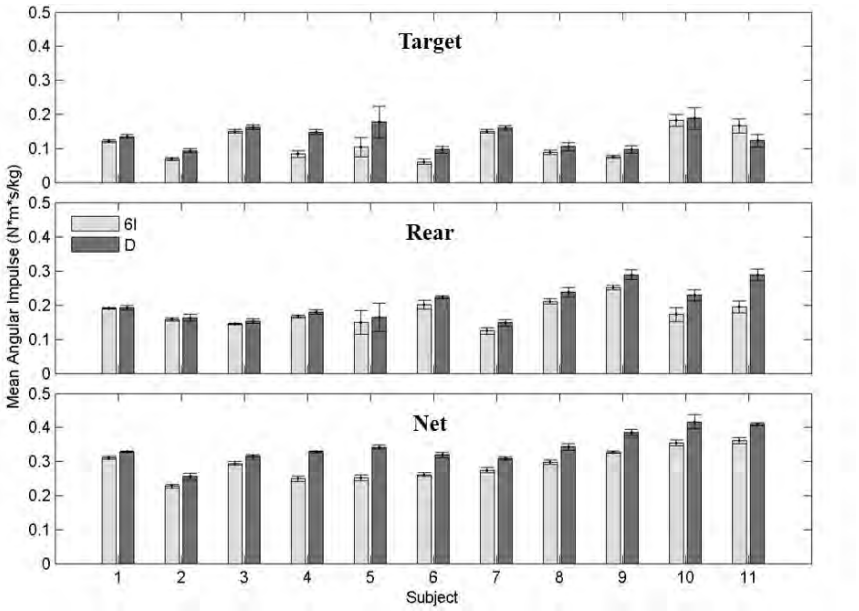
Methods: Skilled players (n = 11, handicap < 5) volunteered to participate in accordance with the institutional review board. Each player performed four shots towards a target with a 6-iron (6I) and a driver (D, Taylor Made adidas golf). Shots were initiated using their preferred address position with each foot fully supported by a force plate (Kistler, 1200 Hz). The magnitude and direction of the peak resultant horizontal reaction forces at the artificial turf/plate interface and PWA were computed for each leg [5]. Moments about the CM were calculated by the cross-product of the RFhs and distance between the CM and PWA for each leg. Angular impulse (AI) normalized by body mass was calculated as the area under the moment curves for each leg during the period of net positive AI beginning near transition and ending near ball contact. Statistical analysis estimated the probability that factors contributing to AI were less in trials with the 6-iron than with the driver [6].

Results: The net AI for swings with the driver were found to be greater than net AI for swings with the 6-iron for all players (**Figure 1**). Nine of eleven players increased target leg AI by more than 0.01 Nms/kg (up to 0.07). Eight of 11 increased rear leg AI by a comparable amount (up to 0.09).

All players increasing target leg AI increased the RFh (2.68-7.67% BW) while 4 of 11 experienced reductions in moment arm length (>0.01m). Less than half of the players increasing rear leg AI (5 of 11) increased RFh (1.03-3.51%BW), while 10 of 11 experienced increases in moment arm (0.03-0.19m).

However, player 11 chose to decrease target leg AI while increasing rear AI. As the target leg moment arm decreased at peak RFh, rear leg moment arm increased dramatically at peak RFh to achieve the increase of rear leg AI (**Figure 1**).

Figure:



Caption: Figure 1: Angular impulse of target and rear legs towards net AI for 6-iron and driver.

Conclusion: All players generated more angular impulse when using a driver as compared to a 6-iron. Target leg AI was increased primarily by increasing the RFh magnitude, whereas rear leg AI was increased primarily by increases in the moment arm. Some players increased rear leg peak RFh as a strategy to increase rear leg AI. Almost all players increased rear leg moment arm to increase AI to compensate for the lack of increased rear leg RFh.

These findings indicate that performance of a golf swing provides a unique opportunity to practice regulation of linear and angular momentum and promotes improvement in function at the whole body level. Regardless of technique, completing the golf swing allows for balance regulation skills to be practiced and honed by populations with balance impairments. Participation in golf related activities may prove to be an engaging rehabilitation intervention that can be effectively delivered in a community setting as part of the continuum of care where movement is medicine [7].

ADAPTATION OF CHONDROCYTES TO MECHANICAL COMPRESSION: ARE MEMBRANE RUFFLES UNFOLDED FOR CELL PROTECTION?

Eng Kuan Moo [1,*] Svetlana Kuznetsova [1] Walter Herzog [1]

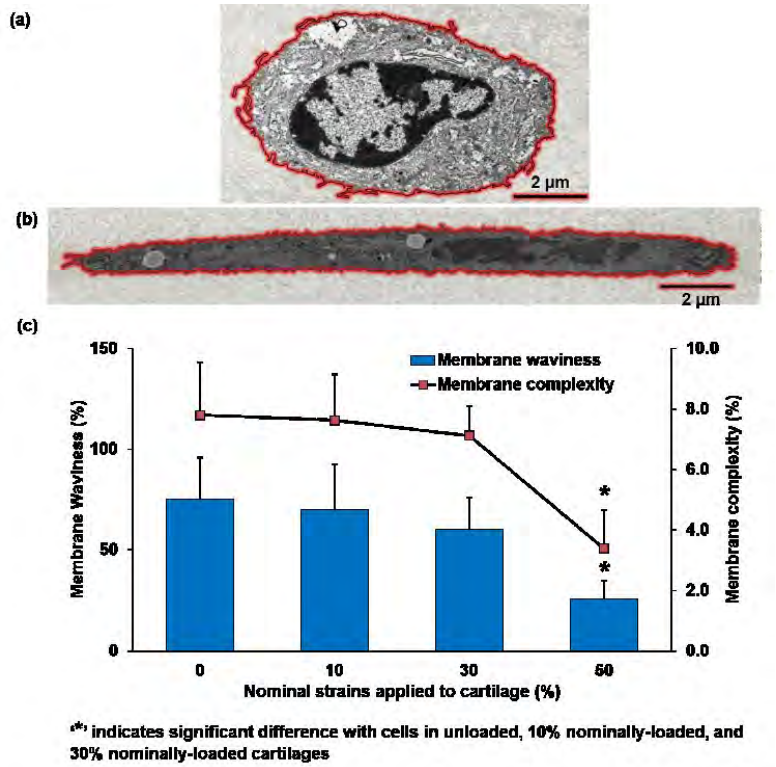
[1] Human Performance Laboratory, University of Calgary, Calgary, Canada

Introduction and Objectives: Impact/fast loading results in chondrocyte deaths [1]. Cell membranes can only sustain very small strains (3-4%) [2], but are thought to use membrane ruffles, also known as membrane reservoirs, to buffer tensile strains [3, 4]. We found that tensile strain rates in chondrocyte membranes may be crucial in deciding impact-induced cell deaths [5]. However, this hypothesis is based on the premise that cells can access their membrane reservoir effectively in their native environment at slow but not at high strain rates. Geometrically, it has been shown that isolated cells respond to hypotonic osmotic loading by unfolding their surface ruffles [6], and such unfolding events have also been documented in compressed agarose-seeded cells [7]. However, little is known about cell membrane behavior in an intact extracellular matrix. Therefore, the purpose of this study was to investigate changes in membrane topology of in situ cells during slow physiological cartilage compression. We hypothesized that cells unfold their membrane ruffles when loaded mechanically to protect the membrane from stretch.

Methods: Bovine cartilage-bone explants were loaded at 5μm/s to nominal strains ranging from 0-50%. After holding the final strains for ~60 min to allow tissues to approach a steady compressed state, the loaded cartilage was pre-fixed using Ruthenium Hexamine Trichloride fixative solution. The cartilage layer was then post-processed and stained with 0.5% Uranyl Acetate for visualization of cell ultrastructure using transmission electron microscopy (TEM, Hitachi H7650). The changes in surface topology in superficial zone cells by mechanical loading (strains of 0%, n=14; 10%, n=5; 30%, n=5; 50%, n=6) were quantified from the planar TEM image in two ways: (i) using the waviness of the surface ruffles, by measuring the difference in cell circumference between the manually-tracked cell boundary (represents cells with surface ruffles) and the boundary of the ellipse obtained by a best-fit to the manually-tracked cell area (represents cells without surface ruffles) [8], and (ii) using the complexity of the surface ruffles, by measuring the increase in box-counting fractal dimension (Image J, FracLac) of the manually-tracked cell boundary compared to the smoothened cell boundary. Cell shape is quantified by the aspect ratio (AR, defined as the ratio of major axis length to minor axis length) of the ellipse that best-fits individual cell.

Results: Compression of cartilage tissue resulted in corresponding deformation of the residing cells, as reflected in a load-dependent increase in cell aspect ratio (strains of 0%, AR=2.6 ± 1.2; 10%, AR=2.1 ± 1.0; 30%, AR=5.2 ± 2.4; 50%, AR=10.8 ± 3.3). Qualitatively, the cell surface ruffles that existed prior to loading (Figure 1a) disappeared when cartilage was loaded at 50% nominal strain (Figure 1b). Quantitatively, the waviness and the complexity of cell membranes decreased with increasing load magnitudes (Figure 1c), suggesting a load-dependent use of membrane reservoirs.

Figure:



Caption: Figure 1. Ultrastructure of chondrocytes in (a) unloaded cartilage, and (b) 50% nominally-loaded cartilage. (c) Membrane waviness (primary y-axis) and membrane complexity (secondary y-axis) as a function of nominal tissue strain.

Conclusion: During mechanical compression, pictorial observation of disappearance of membrane folds is confirmed by a decrease in waviness and complexity in cell membranes. We conclude from the results of this study that chondrocyte membranes unfold in a load-dependent manner when cartilage is loaded mechanically. This membrane unfolding is likely associated with no stretch of the cell membranes under physiologically meaningful conditions and suggests a protective mechanism used by chondrocytes during physiological mechanical loading via the membrane reservoir. This result can have influence on the pharmaceutical strategy used for cell injury prevention and treatment. Future tests will need to determine if the membrane unfolding is rate-dependent.

TRANSMISSION OF A MECHANICAL WAVE THROUGH THE LOWER LIMB DURING A DROP LANDING

Laura-Anne M. Furlong [1,*] Pui Wah Kong [2] Matthew T. Pain [1]

[1]School of Sport, Exercise and Health Sciences, Loughborough University, Loughborough, United Kingdom, [2]Nanyang Technological University, Nanyang, Singapore

Introduction and Objectives: During a drop landing, large ground reaction forces are observed which are subsequently transmitted through the body via mechanical waves. These waves have been observed using high speed footage, showing large amounts of soft tissue movement relative to the underlying rigid bone. Recent work suggests this movement may help dissipate force and energy (Zelik and Kuo, 2010). The characteristics of the wave can be quantified using markers on the surface of the segment, with changes indicative of the mechanical properties of the underlying soft tissues. In comparison with the skin the muscle-tendon complex has high stiffness, therefore the deformation wave due to an impulsive loading will not be due to skin motion as much as it is due to the motion of the underlying muscle because of the low stiffness of the skin at low strains not propagating forces well. The aim of this study was to investigate the characteristics of mechanical waves propagating through the shank during drop landings.

Methods: Following university ethical committee approval, six healthy, recreationally active males (age: 23 $\pm$ 3 years, height: 1.81 $\pm$ 0.08 m, mass: 81 $\pm$ 5 kg) provided written informed consent to participate in this study. All were familiar with the performance of a drop jump task. A total of 48 spherical retro-reflective markers, 7.9 mm in diameter, were attached around the shank in a 6x8 array using standard double-sided adhesive tape. A ten-camera motion analysis system (700 Hz, 612 series, 1.3 megapixel cameras, Oxford Metrics Group PLC., Oxford, UK) recorded the position of a 48 marker array on the shank (5-65% of shank length). A series of drop landings from box, where landing was heavily favoured onto the test leg, were performed from four different heights (0.3, 0.5, 0.7 and 0.9 m) onto a force plate sampling at 1200 Hz (Kistler 9281B-11, Amherst, NY, USA). All data pre-processing was completed using Vicon Nexus 1.4.116 with any incomplete marker trajectories reconstructed using the quintic spline gap filling procedure.

Marker data were subsequently analysed in Matlab (MathWorks, Natick, MA., USA)., to calculate the motion of the 48 markers, and the 40 sectors defined by the 48 markers, around the shank for data filtered at 50 Hz (with a second order, zero lag Butterworth filter). This gave eight columns with six markers in them, and eight columns with 5 sectors in them. The sector area was calculated from the three-dimensional co-ordinates to account for movement of the soft tissue in all three planes. The time delays between minima in local motion between markers and areas moving from the most distal to most proximal regions were calculated. This was repeated independently for the first maxima as well. This gives the speed at which the wave motion travels up the calf. The linear amplitude of the marker motion whilst undergoing a wavelike motion and the change in area of the sectors were also determined along with the frequency of the wave motion.

Results: Wave velocity was higher in the active compared to passive conditions. Average velocity for wave minima in the active condition was 8.7 $m.s^{-1}$ compared to 4.7 $m.s^{-1}$ in the passive. Similar average wave amplitudes were observed in the active (0.008 m) and passive (0.008 m) conditions. The dominant frequency of the wave was low-frequency (<5 Hz). Average change in the area of marker sectors was larger in the active (18.3%) compared to passive conditions (12.6%).

Conclusion: The results support the presence of wave motion in the soft tissues of the shank during a drop landing, the characteristics of which vary dependent on muscle activation conditions. Higher wave velocities were observed in the active contraction condition. Increased muscle activation increases the stiffness of the underlying muscle-tendon unit, with increased stiffness associated with increased speed of wave transmission. Wave amplitudes were similar in both contraction conditions, but it is possible that the amplitude of the wave is limited by the soft tissue itself.
The marker movement is dependent on the behaviour of the underlying soft tissues, which move with muscle contraction. Previous work has suggested increased muscle activation is associated with decreased soft tissue movement, to minimise the stress on the body (Wakeling et al., 2003). The results of this analysis show the opposite with increased tissue movement with increased activation, but results may be confounded by the greater impact forces exerted on the body during the active condition. Further work is required to determine the relationship between activation and area changes, and to further investigate the characteristics of the wave-like motion of the soft tissue during landing, to provide us with insight into the body's response to impact and potential injury risk.

REPRODUCIBILITY OF A NOVEL IN-SHOE ULTRASOUND METHOD FOR ASSESSING SOFT TISSUE BEHAVIOUR OF THE FOREFOOT DURING WALKING

Beverley O'Neill [1,*]

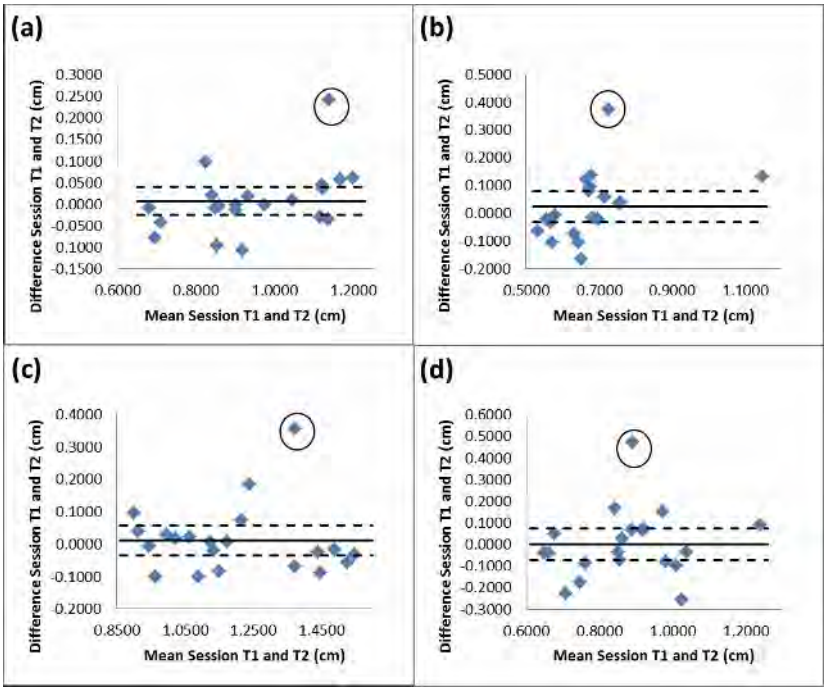
[1]School of Health and Life Sciences, Glasgow Caledonian University, Glasgow, United Kingdom

Introduction and Objectives: Diabetes is a major public health concern worldwide, and significantly contributes to risk of foot ulceration [1]. In healthy individuals, the plantar soft-tissues (PST) provide protection to bone, superficial connective tissue and skin. Changes in PST behaviour in people with diabetes may be a key factor in causal pathways for diabetic foot ulceration [2]. In vivo, monitoring the dynamic behaviour of PST during weight-bearing activities is difficult and existing techniques tend to be limited to unloaded indentation tests or single step methods. We have recently demonstrated the feasibility of using a shoe-embedded ultrasound (US) transducer to measure dynamic heel pad behaviour [3]. The aim of this study was to develop and assess the reproducibility of a novel protocol to measure forefoot PST behaviour during gait.

Methods: A modified shoe incorporating an US probe within a 3D printed insert was developed to enable US images of PST to be obtained from healthy participants. Data were collected at 2 sites ($2^{nd,}$ 5^{th} metatarsal heads, MTHs) on either foot (n=19/21 feet per site) during 25s treadmill walking trials. Maximum (unloaded) and minimum (loaded) PST thickness was subsequently measured from US cineloop files using Kinovea (version 0.8.15) open access software. Number of steps required to achieve the desired level of validity was evaluated by calculating coefficient of variation (CoV) for each incremental number of steps (2-10 steps). CoV of 2% was used as the threshold for acceptable within-trial variation. Measurements collected from participants by the same tester at two time points were used to evaluate between-session reproducibility. Intraclass correlation coefficients (ICCs), Bland Altman plots, and indices of changes in the mean and measurement variability (see Table 1 for description of statistics) were calculated for each PST variable.

Results: Six steps were found to yield acceptable within-trial variation (CoVs <2%) for all variables. Between-session ICC values were fair to good [4] for minimum (0.642) and maximum (0.559) PST thickness at the 5^{th} MTH, and excellent for minimum (0.906) and maximum (0.888) thickness at the 2^{nd} MTH. Bland Altman plots (Fig. 1) indicated no systematic errors between sessions. Outliers (Fig.1, circled data points) corresponded to unusually large between-session differences in PST thickness measures that were most likely due to tester inconsistencies (e.g. method and/or interpretation errors). Summary statistics are presented in Table 1. The mean absolute difference (d') between sessions ranged from 0.05-0.12cm for analysed variables, with measurements for minimum PST thickness tending to show smaller differences at both sites. CV% ranged from 4.69–12.25%, being larger at the 5^{th} compared to 2^{nd} MTH. For example, a mean minimum PST thickness of 0.95cm at the 2^{nd} MTH, with CV%=5.36, would produce a typical between-session variation of 0.05cm, thus a greater change would be required to indicate a clinically significant difference in this population.

Figure:



Caption: Figure 1 Bland Altman plots indicating 95% confidence interval (dashed lines) of the mean difference between two sessions (solid line) for (a) minimum PST thickness at 2nd MTH, (b) minimum PST thickness at 5th MTH, (c) maximum PST thickness at 2nd MTH and (d) maximum PST thickness at 5th MTH. Outliers are circled.

Conclusion: This novel method appears to enable good between-session reproducibility with acceptable levels of random error and measurement variability for PST measures at both 2nd and 5th MTH sites in a healthy population. As such, further evaluation of the use of this method in disease populations would be appropriate. Measurement of PST behaviours in people with diabetes may provide insight into causal pathways for diabetic foot ulceration.

Table:

	Change in Mean				Measurement Variability			
PST Variable/Site	*d*	SD_{diff}	SE	95% CI	ME	SEM	CV%	SEM %
Min PST, 2MTH	0.05	0.06	0.01	0.02-0.07	0.04	0.05	5.36	5.88
Min PST, 5MTH	0.08	0.08	0.02	0.05-0.12	0.06	0.08	12.25	14.33
Max PST, 2MTH	0.07	0.08	0.02	0.03-0.10	0.06	0.07	4.69	6.11
Max PST, 5MTH	0.12	0.11	0.02	0.07-0.16	0.08	0.11	8.66	12.82

INFLUENCE OF CAPSULAR PLICATION ON TRANSLATION IN A SIMULATED MDI SHOULDER

Andrew Kraszewski [1,*] Stephanie Mayer [2] Andreas Kontaxis [1] Russel Warren [2]

[1]Rehabilitation, [2]Orthopaedic Surgery, Hospital for Special Surgery, New York, United States

Introduction and Objectives: The glenoumeral capsule is a complicated shoulder structure that passively checks joint translation, but is susceptible to injury espcially in rigorous overhead activities. Symtopmatic glenonumeral laxity is common among young athletes, and when conservative management is often insufficient treatment typically regresses to orthopaedic intervention in the form of capsulorrhaphy, i.e. plication. In general, surgeons lack objectively-based clinical tools to judge the efficacy and performance of surgical interventions especially during surgery.

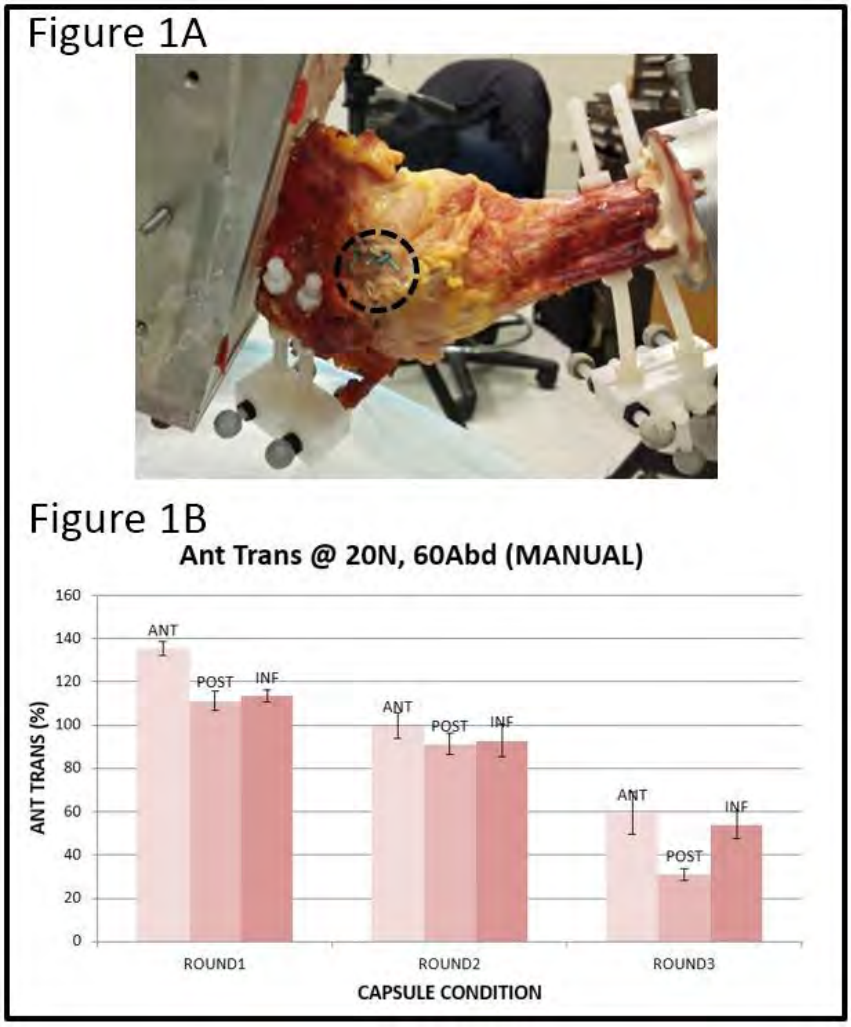
Our objective was to understand the effect of sequential regional plication on glenohumeral translation within and across multiple rounds of plication.

Methods: A cadaveric CT scan was taken and checked for significant degenerative pathology by an orthopaedic surgeon. At the time of thaw the specimen included a full scapula and humerus. All musculature was removed leaving only the glenohumeral capsule. Passive marker tracking clusters were fixed to each segment with two parallel trans-cortical rods per segment (see Figure 1A). Anatomical coordinate frames [1] were constructed from palpation and a functional joint method [2] and then rigidly embedded in the cluster tracking frames. The scapula and humerus were separately potted and fixed to a frame that allowed fixed glenohumeral orientation and full floating 3D translation. A 6DOF loadcell (MA1000, AMTI) was attached in series with the humerus to record external loads. Six optical motion cameras (Motion Analysis Corp) at 30 frames per second captured marker motion along with loadcell data at 300 frames per second. Model building and post-processing was done in Visual3D (C-Motion, Inc).

The capsule was preconditioned to reduce the effects of viscoelastic behavior. MDI laxity was simulated by stretching the capsule by internally and externally rotating the humerus based on a previous study [3]. The capsule was plicated over three rounds; within each round the capsule was plicated in a consistent order: first anteriorly (3:00), then posteriorly (9:00) and lastly inferiorly (6:00). Plication magnitude was larger each successive round: Round1 - 0.5cm, Round2 - 1.0cm, Round3 - 1.5cm. Glenohumeral orientation was fixed in neutral rotation and flexion with abduction at 60 degrees. External manual traction was applied to the scapula in the anterior, posterior and inferior directions, chosen randomly. Outcome measurements of interest were anterior, posterior and inferior glenohumeral translation at 20 Newtons of load. Descriptive statistics are reported.

Results: Outcomes are reported in Figure 1B and Table 1. On average anterior translation decreased per plication round, indicating increased capsule tightness as plication magnitude increased. The largest within-round changes occurred between anterior and posterior plications, whereas changes between posterior and inferior plication were much smaller. In Figure 3B, Round3 posterior translation is very low with repsect to both anterior and inferior directions, which was unexpected. This anomaly is believed to reflect negative pressure that was occasionally generated due to a temporary suction mechanism from the interaction of the joint cartilage and highly conforming joint geometry.

Figure:



Caption: Figure 1. A - Picture of potted and inverted humeral and scapula with tracking clusters; posterior plication sutures circled. B - Graph indicating changes in anterior translation within and across plication rounds.

Conclusion: The study is ongoing with one specimen collected to date. Lack of statistical power precludes inferential conclusions. However our results show, expectedly, that as plication magnitude increases translation decreases. More interestingly the data suggest that inferior plication may not influence anterior translation. Clinically, this may dissuade surgeons from plicating inferiorly in certain cases, as it may be unncessary.

CORNEA BIO-INSPIRED CONSTRUCTS BASED ON ORIENTED LONG COLLAGEN FIBERS BIO-COMPOSITES

Mirit Sharabi [1 2,*] David Varssano [3 4] Dafna Benayahu [2] Yehuda Benayahu [5] Rami Haj- Ali [1]

[1]School of Mechanical Engineering, The Fleischman Faculty of Engineering, [2]Department of Cell And Developmental Biology, Sackler School of Medicine, [3]Sackler School of Medicine, Tel Aviv University, [4]Department of Ophthalmology, Tel Aviv Sourasky Medical Center, [5]Department of Zoology, George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel Aviv, Israel

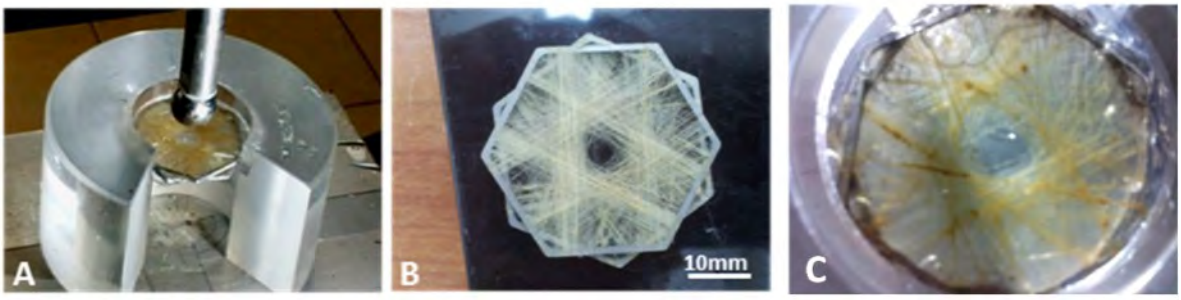
Introduction and Objectives: The cornea contains highly organized collagen fiber laminates, providing strong and durable structure that withstands inner and outer pressures. Here we present a biocomposite inspired for bio-mimetics of the construct based on structure-function needs towards engineering of cornea.

A novel bio-inspired constuct based on long collagen fibers bio-composite embbeded and crosslinked in polyacrylamide/alginate hydrogel (PAAm-Alginate) is made to mimic the human cornea. The research is focused on the fabrication of the biocomposite complexed structure and its non-linear mechanical behavior which is typical for the native cornea.

Methods: A novel fiber reinforced bio-composite was designed and fabricated based on our previous work [1], [2]. The construct included collagen fibers [3] aligned in varied directions (i.e. every 30 ^{o}) with clear center of 4.5mm diameter. The aligned fiber structure was embedded and cross-linked to hybrid gel double network of PAAm-Alginate) [4]. This composite was subjected to cyclic indentation, where the spherical indenter was pushed into the construct to simulate the physiological loading modes. In addition, three dimentional and hyperelastic finite element (FE model) was built for solving the inverse problem of calculating stress-strain values from the load-deflection experimental results using the measured material properties.

Results: A novel composite construct was fabricated from aligned collagen fibers embedded in PAAm-Alginate matrix. The anisotropic construct presented hyperelastic behavior with large deformations of about 20% strain. Effective hyperelastic stress-strain behavior of the indentation was calculated using the FE model and found to provide good fitting to the corneal tissue. The cornea's working range (10-20mmHg) was found in the initial part of the stress-strain curve of the bio-composite, allowing durabilty of the costruct in extreme cases of loading as injury or fall.

Figure:



Caption: Cornea bio-inspired construct. (a) Mechanical indentation of bio-composite. (b) Collagen fibers alignment. (c) Final cornea bio-mimetic construct.

Conclusion: Bio-inspired cornea construct can properly mimic the native cornea function providing hyperelastic behavior and mechanical durability, based on the novel collagen fiber–reinforced composite structure. FE modeling allows better understanding of the composite structure and thus to design custome-made bio-inspired cornea constructs, these *in silico* experiments enable saving time and resources in the engineering process.

MINIMUM INDENTATION DEPTH FOR CHARACTERIZATION OF 2ND SUB-METATARSAL HEAD AND HEEL PAD TISSUE PROPERTIES

Taeyong Lee [1] Jee Chin Teoh [2,*] Ying Bena Lim [2] Jaeyoung Park [3]

[1]Department of Medical Biotechnology, Dongguk University, Seoul, Korea, Republic Of, [2]Department of Biomedical Engineering, National University of Singapore, Singapore, Singapore, [3]Department of Leisure Sports, Dongeui University, Pusan, Korea, Republic Of

Introduction and Objectives: At present, there are several existing in-vivo indentation systems developed for the characterization of plantar soft tissue properties. Through using these devices, several studies have been conducted to investigate and quantify the relationship between plantar soft tissue properties and conditions that cause plantar soft tissue stiffening such as aging and diabetes(Chao, Zheng et al. 2010, Kwan, Zheng et al. 2010, Mickle, Munro et al. 2011).

The variable mechanical properties of plantar soft tissue depend on the extent of tissue deformation (Chao, Zheng et al. 2010) as well as the configuration of the metatarsophalangeal joint (MTPJ) (Garcia, Hoffman et al. 2008), specifically for the forefoot region. Thus, measurements of tissue stiffness should only be performed under a controlled environment with an appropriate degree of tissue deformation to obtain meaningful results.

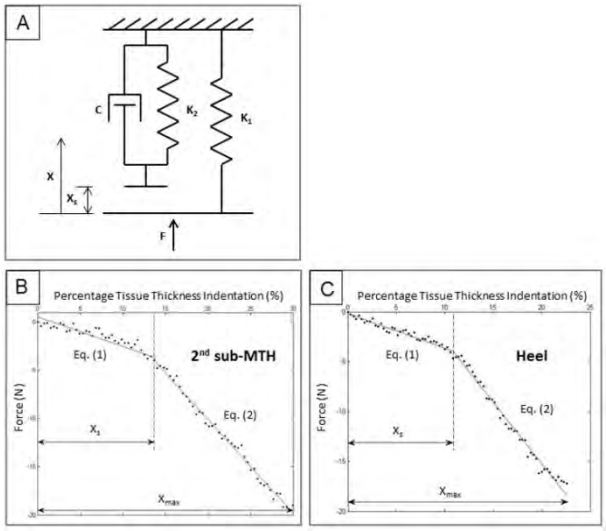
Most in-vivo indentation techniques are limited by the lack of adequate indentation into the plantar soft tissue. Moreover, there is a lack of consensus on the appropriate indentation depth, resulting in the inability to make unambiguous remarks from literature. Consequently, the purpose of this study is to investigate and determine the minimum indentation depth required to effectively characterize the biomechanical properties of plantar soft tissue under weight-bearing conditions.

Methods: Twenty young subjects (20-25 years) participated in this study. The test was conducted with equal weight borne on each of the participants' feet to mimic the static stance of the gait cycle. During the experiment, the indenter probed the 2nd sub-metatarsal head (MTH) and heel pad tissue at a constant rate of 12.3mm/s. The maximum tissue deformation induced was varied from 1.2mm to 6.0mm, in steps of 1.2mm. The tissue stiffness obtained from the tissue response curves was compared and fitted to the proposed viscoelastic model(Garcia, Hoffman et al. 2008) as shown in Fig. 1A.

Results: The viscoelastic model used in this is shown in Fig. 1A. K_1 and K_2 capture the elastic response of plantar soft tissue at the initial and subsequent phases of indentation. C characterizes the viscous behavior of tissue which is only prominent at the latter stage of indentation. X_s is the minimum indentation depth beyond which the tissue exhibits nonlinear viscoelastic behavior. The model suggests that there is a need to indent the tissue beyond X_s in order to assess both K_1 and K_2. This differs from the paper by Garcia et. al. (2010), where there is no mention of the reference value of X_s.

As the probe tip indents deeper into the plantar soft tissue beyond a threshold depth (i.e. X_s), the force gradient increases notably (Fig. 1B and 1C). As shown in Table 1, the absolute value of X_s was approximately 2.23mm and 2.14mm at the heel and 2nd sub-MTH respectively. Indentation depths which were less than this threshold depth might not be representative of the nature of plantar soft tissue nor reflect the critical deformation it experiences during physical activities that expose the tissue to risk of ulceration.

Figure:



Caption: Figure 1. (A) The viscoelastic model proposed by Garcia et al. (2010). Detailed tissue response of (B) 2nd sub-MTH and (C) heel pad.

Conclusion: The results of this study demonstrate the existence and significance of a minimum indentation depth (X_s) required for investigating plantar soft tissue properties. Adoption of an inappropriate indentation parameter may result in erroneous tissue stiffness measurements. Hence, a proper quantifiable reference helps provide valuable insights into plantar soft tissue behavior, which can be used for computational modeling to better understand complex foot mechanisms and pathologies. Furthermore, the tissue properties elicited provide valuable information and possible indication of disease (Jahss, Michelson et al. 1992). Hence, a rigorous description of plantar soft tissue behavior is crucial and has good potential for application in the diagnosis of foot abnormalities related to diseases such as diabetes.

Table:

	2nd sub-MTH	Heel	p-value
Average Tissue Thickness (mm)	13.80 ± 1.76	18.04 ± 2.42	< 0.01*

SINERGY-BASED TWO-LEVEL OPTIMIZATION FOR PREDICTING KNEE CONTACT FORCES DURING WALKING

Gil Serrancolí [1,*] Allison L. Kinney [2] Benjamin J. Fregly [3] Josep M. Font-Llagunes [1]

[1]Department of Mechanical Engineering, Universitat Politècnica de Catalunya, Barcelona, Spain, [2]Department of Mechanical and Aerospace Engineering, University of Dayton, Dayton, [3]Department of Mechanical and Aerospace Engineering, University of Florida, Gainesville, United States

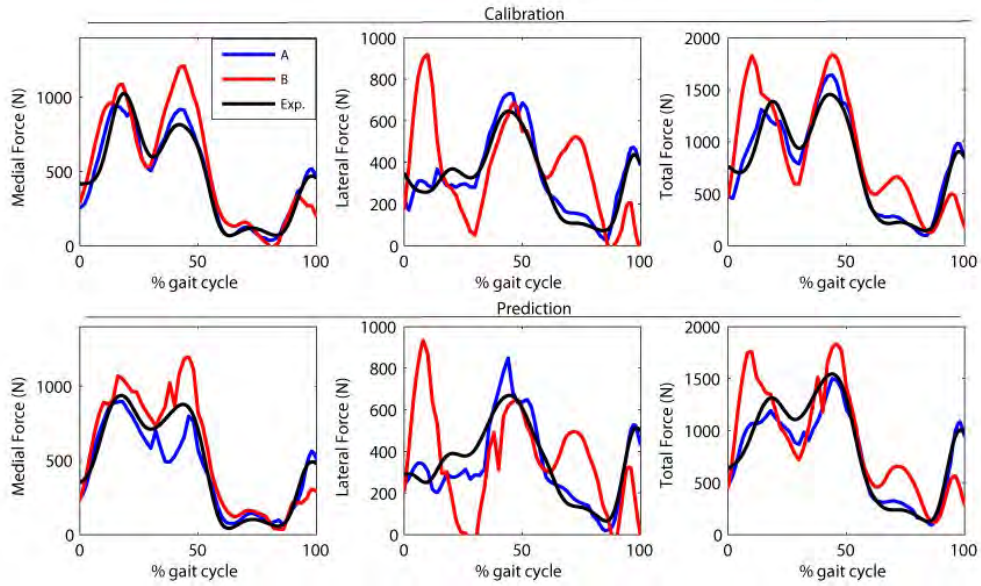
Introduction and Objectives: Musculoskeletal models and optimization methods are combined to calculate muscle forces. Some model parameters cannot be experimentally measured due to the invasiveness, such as the muscle moment arms or the muscle and tendon lengths. Moreover, other parameters used in the optimization, such as the muscle synergy components, can be also unknown. The estimation of all these parameters needs to be validated to obtain physiologically consistent results. In this study, a two-step optimization problem was formulated to predict both muscle and knee contact forces of a subject wearing an instrumented knee prosthesis. In the outer level, muscle parameters were calibrated, whereas in the inner level, muscle activations were predicted. Two approaches are presented. In Approach A, contact forces were used when calibrating the parameters, whereas in Approach B, no contact force information was used as input. The optimization formulation is validated comparing the model and the experimental knee contact forces. The goal was to evaluate whether we can predict the contact forces when in-vivo contact forces are not available.

Methods: The experimental data used in this study came from the 4th Grand Challenge Competition to Predict In Vivo Knee Loads [1]. The subject wore an instrumented knee implant in his right leg. An inverse dynamic analysis of six gait trials was carried out in OpenSim [2]. Muscle activations were obtained applying the muscle activation dynamics to the available EMG measurements for all six trials. A muscle synergy analysis was carried out to obtain Synergy Vectors (SVs_{exp}) and Neural Commands (NCs) from experimental activations. A unique set of SVs was obtained for all six trials and one NC for each trial represents the time-activation pattern. Three gait trials were used to calibrate the model. A two-step optimization formulation was developed to calibrate the muscle parameters in the outer level, and to calculate activations at the inner level. In the outer level, SVs of the muscles without experimental data (SV_{model}), scale factors for the SV_{exp}, moment arm deviations, scale factors for the muscle optimal length and the tendon slack length were calibrated. The outer cost function had terms to minimize the passive force and the residual activations and, only in Approach A, it had terms to track the knee medial and lateral contact forces. It also had bound terms to constrain SVs, moment arm deviations, the optimal muscle lengths and the tendon slack lengths. In the inner level, muscle activations were calculated by means of the resolution of a quadratic programming problem. Muscle activations were minimized while inverse dynamics muscle contributions were matched with the calculated ones. Three different gait trials were used to predict the knee contact forces. In this case, muscle parameters previously calibrated in the outer level were used to run the inner level.

Results: Table 1 shows the R^2 values (and RMSE in parenthesis) of the match between experimental and model knee contact forces (medial, lateral and total, respectively) when calibrating the model and when predicting the contact forces, using knee contact forces to calibrate the model (Approach A) and without using them (Approach B). Figure 1 shows the

knee contact force prediction in two trials (Approach A and B). The mean RMSE difference of the muscle parameters between Approach A and B for time varying quantities were computed: muscle activations 0.08, muscle forces 65.62, normalized length of the muscles 0.11. The mean absolute difference for muscle parameter values was 0.009 for optimal length of the muscles, 0.010 for slack length of the tendons and 0.290 for scale factors of the experimental activations.

Figure:



Caption: Fig. 1. Contact forces in one calibration and one prediction trial for both approaches and their experimental values

Conclusion: Medial contact forces were better predicted than lateral forces in both approaches, what is in agreement with other studies [3]. Overall, all muscle parameters are similar except some of them that would explain the differences in the contact force predictions. For instance, tensor fasciae latae, a muscle which crosses the knee, had a different activation in both approaches due to the lack of the knee contact force constrains in approach B. In Approach A, the contact force prediction were quite better predicted than in B, what means that for this subject the use of neural commands alone was not sufficient to calibrate the model such that predicted good contact forces.

Table:

	Approach A	Appoach B
Calibration	0.97 (56.97), 0.84 (64.18), 0.95 (110.39)	0.69 (194.64) / -2.07 (284.33) / 0.44 (363.88)
Prediction	0.91 (96.38), 0.76 (85.36), 0.91 (145.13)	0.68 (185.01) / -1.75 (288.64) / 0.44 (353.04)

FORWARD-DYNAMICS TRACKING WITH REACTION FORCE TARGETS

Benedikt Sagl [1,*] Ian Stavness [1] Rudolf Slavicek [2]

[1]Department of Computer Science, University of Saskatchewan, Saskatoon, Canada, [2]A.E.R.S Dental Medicine Organisations, Vienna, Austria

Introduction and Objectives: Forward-dynamics assisted tracking has become a widely-used tool for analyzing muscle contributions to dynamic human movements. This type of analysis has been developed in a number of simulators, notably as Computer Muscle Control (CMC) in OpenSim [1]. Tracking simulations use optimization to predict a trajectory of muscle forces that will drive a 3D dynamic musculoskeletal model to closely follow a target action. CMC simulations use kinematics as the target variable to track and require that external reaction forces between the model and the external world be prescribed. For example, in gait simulations, ground-to-foot reaction forces measured by force plates in the floor or treadmill are “played back” and applied to the model’s feet during the gait simulation. Many human actions, however, involve reaction forces with the external world that are difficult to measure or infer. Examples include the force applied by one’s hand to a tool or the forces that arise between opposing teeth during chewing. In these cases the standard CMC analysis is inappropriate. To solve this problem, our objective is to create a tracking simulation that includes reaction forces as a dynamic target, rather than as a fully prescribed quantity.

Methods: We have extended the well-known forward-dynamics assisted tracking algorithm to include reaction-force targets in addition to kinematics targets. This allows tracking simulations to predict muscle forces that cause a model to simultaneously slide (or roll) along a surface while applying a force normal to that surface. Our approach relies on a standard formulation of musculoskeletal dynamics that includes rigid bilateral constraints to enforce reactions between the model and the external world or between two internal contact surfaces within the model. In this formulation, the addition of reaction-force targets to a tracking simulation with kinematics targets results in negligible additional computational cost because the model’s velocities and reaction force magnitudes (Lagrange multipliers) are already computed simultaneously. We have implemented our reaction-force target tracking method within the open source ArtiSynth biomechanics simulation platform (www.artisynth.org).

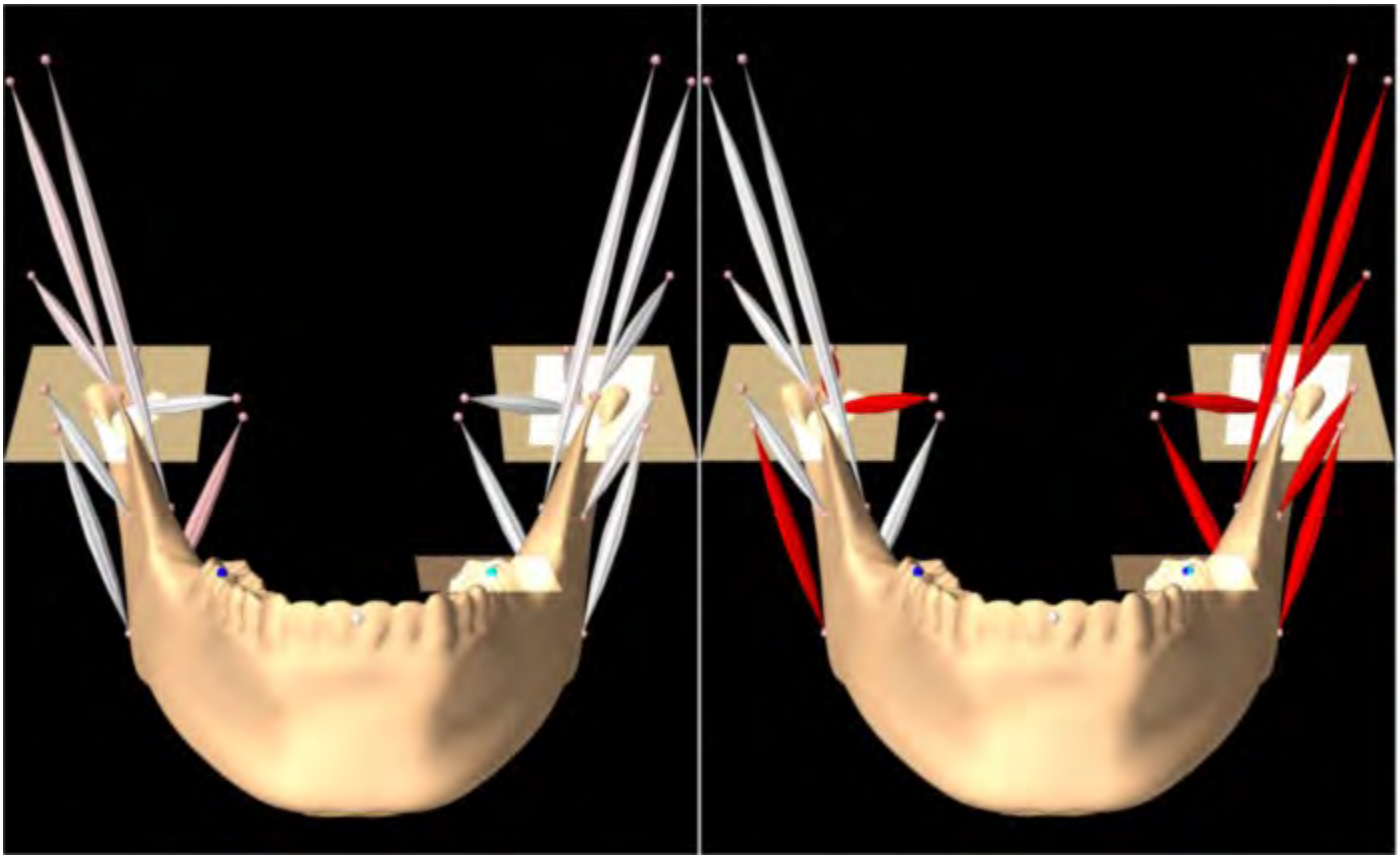
We have demonstrated our reaction-force tracking simulation in the context of teeth grinding. It is difficult to accurately measure contact forces between the teeth during clenching and grinding actions because the introduction of any material between the teeth, even a very small or thin force transducer, will alter a patient’s biting action and trigger a reflex response to reduce bite force. Therefore, the standard CMC algorithm is not appropriate for simulating teeth grinding because the tooth-to-tooth reaction force cannot be prescribed from experimental measurements. Without a reaction-force target, we expect that a tracking simulation will activate a set of muscles that fulfills the kinematics target using a minimal level of muscle forces and will barely create any closing force. We expect that the inclusion of a reaction-force target will elicit larger muscle forces and consequently a larger force between tooth facets during the grinding action.

We simulated a 2.5 mm inward grinding movement with a dynamic multibody jaw model [2] and a tooth-to-tooth frictional force that opposed sliding movements. The simulation started with the jaw in a 2.5 mm left lateral position and moved the

jaw inward toward a neutral jaw position. This movement simulates a left chewing-like power stroke that is typical of tooth grinding. We performed two simulations: (1) without a reaction-force target and (2) with a reaction-force target of 350 N.

Results: For the simulation with no reaction-force target, the kinematics target was fulfilled with very low muscle activations (Figure, left panel). Consequently, virtually no force was applied between the opposing teeth during the sliding movement. The inclusion of a target tooth-to-tooth reaction force of 350 N resulted in much higher activation of the jaw closing muscles (Figure, right panel), and the simulation was able to track both the sliding kinematics simultaneously with a 350 N force between the teeth.

Figure:



Caption: Two tracking simulations of tooth grinding with a dynamic multibody jaw model: one with no reaction-force target (left) and the other with a 350 N reaction-force target between opposing teeth (right). Muscle color denotes activation level from 0% activation (white) to 100% activation (red).

Conclusion: At ISB we will report our results on muscle contributions to teeth grinding and demonstrate that the reaction force-tracking approach is a useful augmentation to the standard CMC-style analysis tool for musculoskeletal research.

COMPARISON OF GEOMETRIC APPROXIMATION AND ANATOMICALLY SEGMENTED MODELS OF THE AORTA USING FINITE ELEMENT METHOD

Francisco Carrasco-Hernandez [1,*] Alan Parish [1] Richard Brooks [1] David Richens [2] Donal McNally [1]

[1]University of Nottingham, [2]The Trent Cardiac Centre, Nottingham, United Kingdom

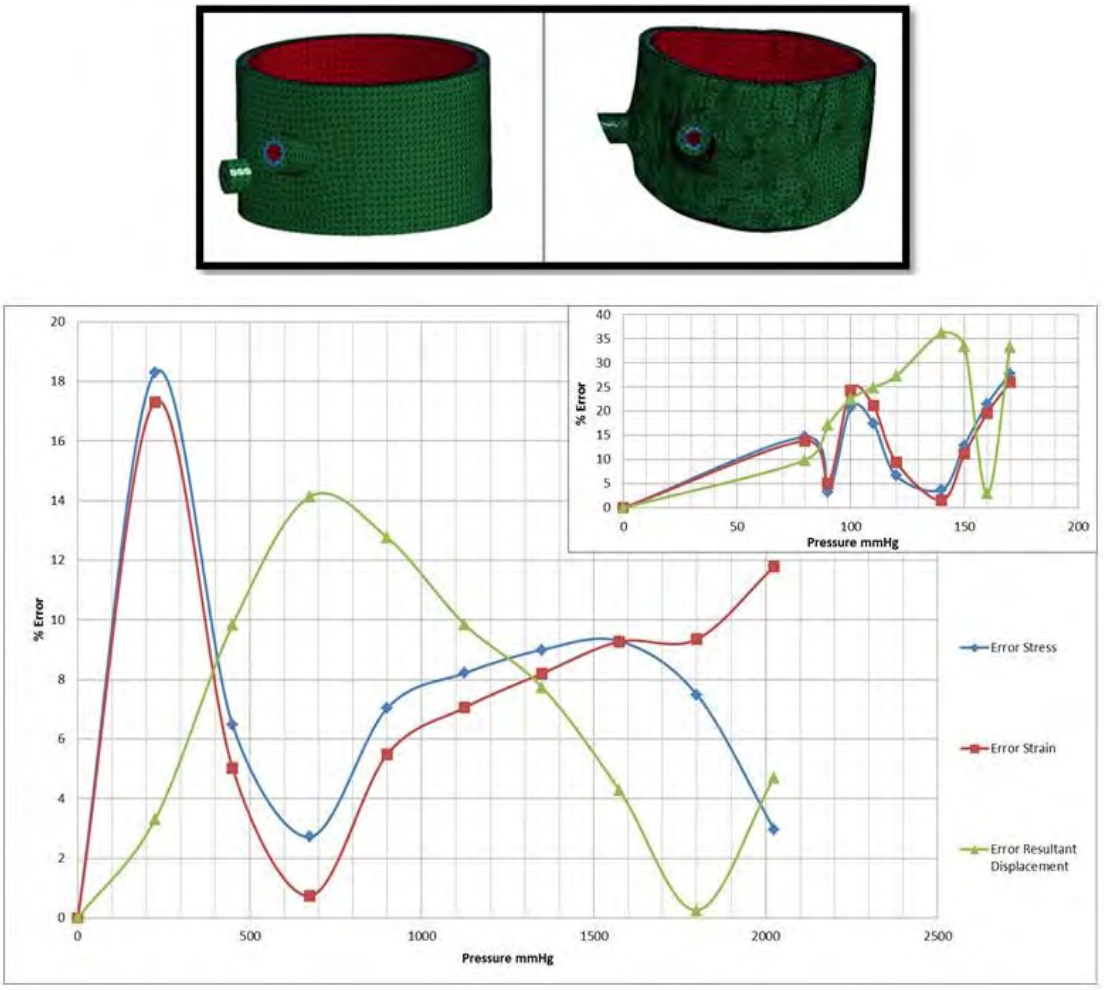
Introduction and Objectives: Simulation utilizing Finite Element Method (FEM) of organic tissues has become important in the design of medical devices. To design a specimen for FEM the simplest way is to approximate the geometry of it is using a Computational Assisted Design Software (CAD), or by segmenting out the specimen form medical data [1]. The advantages of using an approximated geometry specimen, includes the simplicity of its creation and also the increased speed in FEM due to its symmetry and uniformity. The segmentation of 3D medical images, can be used to generate an anatomically precise model of a specific human anatomy (SM), this more accurately shaped specimen, requires significantly more computational power for FEM than the approximated geometric specimen (GM). This study tests the hypothesis that a numerical simulation with a geometric approximation is less accurate than using a segmented model.

Methods: In order to find how advantageous the use of this methodology is in cardiovascular biomechanics, this paper presents the comparison of these two models. The anatomical model was created by segmenting the blood within the aorta from a 3D dataset using Mimics V17.0 (Materalise) and then wrapping the blood with three aorta layers using 3-Matic V9.0 (Materalise), while the simple geometric model was created in PTC CREO Parametric 2.0. Both model a 10mm long segment of human aorta, with three tissue layers, with hyper-elastic rubber-like mechanical properties taken from published literature, and confirming in a bubble bi-axial inflation test. These models were subjected to a variable internal pressure in FEM (LS-Dyna), to simulate the reaction of this tissue to the beating of the heart. Using two different pressure curves, first a High pressure of 0 – 2025mmHg (0 – 270KPa) [Pearson] representing rupture and secondly a normal physiological pressure values of 0 – 170 mmHg (0 – 23KPa) [2].

Results: The results can be observed in separate values for stress, strain and resultant displacement, obtaining errors between the two models, highlighting the first value of the high pressure curve, i.e. 225mmHg (30KPa), which is where an error of 18.3% in stress values is presented, and then drooping meanwhile the pressure is increasing.

With this reaction on the models, the normal physiological pressure is introduced, highlighting the sixth step (140mmHg – isolated systolic hypertension), where the SM changes shape into a circle, approaching to the GM as the strain error of 1.6% and displacement error of 36.2% represents

Figure:



Caption: Figure 1. Error between Geometric Approximation V.S. Segmented Model in High and normal physiological pressure

Conclusion: It is important to verify the feasibility of first create a geometric approximation of a biological tissue in order to give an idea of the mechanical reaction of the tissue using a FEM simulation. But more importantly to stablish the methodology to follow, as the GM specimen is less time consuming than the SM specimen. After stablishing a methodology for the simulation, the generated SM sample can be used to validate results.

Table:

Pressure (mmHg)	Error Stress	Error Strain	Error Resultant Displacement
90	3.27%	5.02%	17.19%
140	3.76%	1.59%	36.20%
170	27.77%	25.96%	33.38%
225	18.30%	17.31%	3.31%
675	2.72%	0.74%	14.14%
2025	2.97%	11.79%	4.71%

A COMPUTATIONAL STUDY OF STENT DEPLOYMENT INSIDE A DISEASED ARTERY WITH VARIABLE DEGREES OF STENOSIS, ASYMMETRY AND CURVATURE

Alessandro Schiavone [1,*] Liguo Zhao [1]

[1]Wolfson School of Mechanical and Manufacturing Engineering, Loughborough University, Loughborough, United Kingdom

Introduction and Objectives: Angioplasty and stenting are commonly used to treat cardiovascular diseases such as atherosclerosis. So far, research on stents is largely focused on the development of new materials and designs for better scaffolding, drug delivery and bioabsobability [1]. However, stent deployment and performance are also strongly affected by the thickness and asymmetric nature of plaque layers as well as the curvature of arteries, which has not been well studied yet. With this work, we aimed to understand how these biological factors influence the stent deployment and also to identify their possible connections with arterial damage [2, 3] and chest pain [4] caused by stenting.

Methods: Abaqus/Explicit has been used for finite element simulation of stent deployment. A model of Xience stent with 6mm in length and a crimped diameter of 1.5mm was meshed into 111380 incompatible brick elements. The folded balloon consisted of 7791 4-node shell elements. The artery (with separate intima, media and adventitia layers) had a length of 40mm, an inner diameter of 4mm and a thickness of 1mm. It was meshed into 72576 brick elements with reduced integration. Both straight and curved arteries (bended by 30^o and 60^o) were modelled.

The stenotic plaque had a length of 6mm, and its thickness was chosen to be 1.6mm (40% stenosis), 2.0mm (50% stenosis) and 2.5mm (60% stenosis), respectively. For asymmetric plaque layer, the ratio between the maximum and the minimum thickness was chosen to be 7:3 and 9:1, respectively. The plaque layer was meshed into around 25000 brick elements with reduced integration.

Elastic-plastic material properties were assigned for the stent material Co-Cr alloy L605. The balloon was modelled as a linear elastic material. The arterial layers and the stenotic plaque were all simulated using the Ogden hyperelastic model. The ends of the artery and the balloon were fully constrained to remove rigid body motion. The pressure applied on the inner surface of the balloon was linearly increased (up to 1.4MPa) during inflation and decreased to zero during deflation. Hard contacts were defined between the artery, the stent and the balloon.

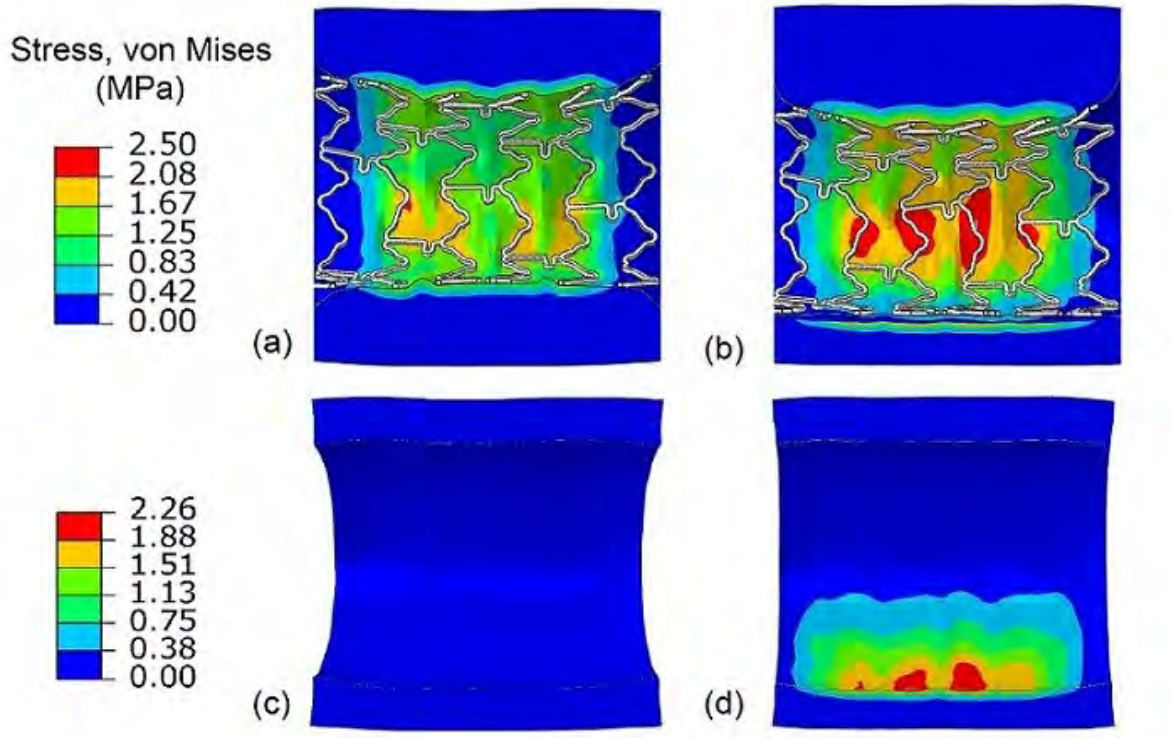
Results: Results showed that it was more difficult to open arteries with severe stenosis via the expansion of stent. The diameter achieved at the maximum expansion for arteries with 40%, 50% and 60% stenosis was 4.2mm, 4.1mm and 3.7mm, respectively. Also, both the recoiling and dogboning effects increased with the increased level of stenosis. Almost twice higher stress was obtained on the stenotic plaque when the stenosis was increased from 40% to 60%, indicating a potential for plaque rupture.

The asymmetry of plaque did not affect the overall stent expansion and recoiling effect, but the stresses in the plaque-artery system increased for asymmetric plaque. For the plaque, the maximum stress was 2.27Mpa in the symmetric case and 2.58MPa in the asymmetric case (ratio 9:1) (Figure 1a and b). For the artery, the stress was 0.08MPa in the case of

symmetric plaque and 2.26MPa when the plaque layer had an asymmetric ratio of 9:1 (Figure 1c and d) localised in the regions with relatively thin layer of plaque as a result of overstretch.

For curved arteries, stent expansion became non-uniform in the circumferential direction, which was also the case for development of dogboning. For a curved artery, the diameter change against pressure did not have a sustained period of expansion as that for straight arteries. However, results confirmed that the levels of stress developed in the plaque and arterial layers were comparable for stent deployment in curved and straight arteries.

Figure:



Caption: Figure 1. Contour plot of stress on (a) symmetric stenotic plaque, (b) asymmetric (ratio 9:1) plaque, (c) arterial wall with symmetric plaque and (d) arterial wall with asymmetric plaque (ratio 9:1).

Conclusion: This study suggests that future stent designs may need to be patient specific with expansion that can be tuned circumferentially according to the thickness of plaque layer. This will help protect the arterial layers from being overstretched and damaged by stenting, which is potentially associated with chest pain.

FREEWARE IS A VIABLE ALTERNATIVE TO COMMERCIAL SOFTWARE WHEN CREATING SUBJECT-SPECIFIC FE MODEL GEOMETRY

Jennifer L. Boyd [1,*] Cameron Brown [1] Andrew Price [1]

[1] Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, University of Oxford, Oxford, United Kingdom

Introduction and Objectives: Subject-specific finite element (FE) models are gaining popularity within personalized medicine. These models represent a specific individual and situation, and offer the possibility of simulating variations of treatments before selecting the optimal procedure for the individual. Subject-specific geometry is crucial to subject-specific models; using idealized geometries overestimates contact areas and underestimates stresses [1].

Subject-specific geometry is derived from medical scans. Geometry structures are segmented based on voxel grayscale values. Then any gaps or spikes in segmented surfaces are smoothed. Finally, structures are assembled into the FE model geometry. Commercial software provides efficient yet costly purpose-specific segmentation and smoothing workflows. Multiple freeware alternatives are also available. The objective of this study was to create subject-specific geometry using both commercial and free software. We then compared the volumes of the commercial and freeware segmented geometries and of the commercial and freeware smoothed geometries.

Methods: A 3T MRI scan (T1-weighted, sagittal-sliced, resolution=0.230mm^3) was taken of a healthy male's knee (47yrs, 108kg). Nine structures [bones (femur, tibia, patella), cartilage (femoral, medial tibial, lateral tibial, patellar), and menisci (medial and lateral)] were segmented using both commercial software (Mimics 14.01, Materalise, Leuven, Belgium) and freeware (ITK-SNAP 2.4.0, Cognitica Corporation and National Library of Medicine, USA). The 2D slice segmentations were combined to create 3D surfaces. Each structure's volume (including voxels internal to the surface) was calculated. The nine commercial and nine freeware segmentation volumes were compared.

Each structure was then smoothed. Commercial segmentations were smoothed using commercial software (Geomagic Studio 11, Geomagic, Inc., Research Triangle Park, NC, USA); freeware segmentations were smoothed using freeware (Blender 2.68a, Stichting Blender Foundation, Amsterdam, The Netherlands). The volume of each smoothed structure was calculated. The nine commercial and nine freeware smoothed volumes were compared.

The smoothed structures were then assembled into the FE model geometries (SolidWorks 2010, Dassault Systèmes SolidWorks Corp., Concord, MA, USA; Academic License cost $150/£100). Structures were automatically imported based on the original MRI scan coordinates. Therefore, structure orientations and positions matched those in the MRI scan. The knee assemblies created using commercial and free software were visually compared.

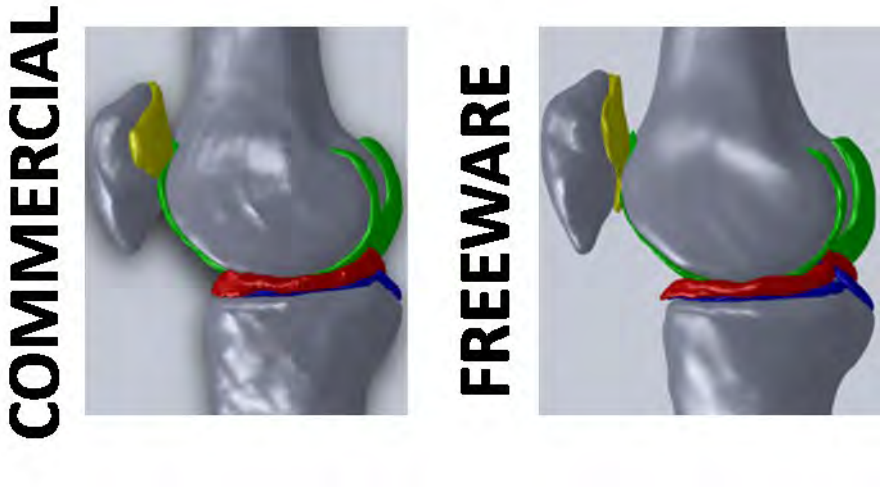
Results: Volumes of the nine structures segmented using commercial and freeware differed by 3.0% ± 3.7%. Commercial and freeware smoothed volumes differed by 7.1% ± 10.3%. Both segmented and smoothed structures tended to have slightly larger volumes when created using commercial software. This trend was at least partially explained by different segmentation and smoothing strategies used in the commercial and free software.

During segmentation, the user identifies pixels which represent a specific structure; the pixels are then used to define the structure boundaries. Therefore, structure boundaries will not be smooth, but stepped, due to the pixels. The commercial software used in this study artificially added material to avoid excessively-stepped surfaces, whereas the freeware used in this study did not add material. The material added by the commercial software led to larger volumes.

The larger commercial volumes persisted after smoothing. The commercial software automatically smoothed the structures, only removing volume in areas with geometric spikes. The freeware did not automatically remove spikes; the entire surface of each structure had to be smoothed to remove any potential spikes. Therefore, areas without spikes were also smoothed, resulting in smaller freeware volumes.

Visually comparing the knee assemblies showed that the gross morphologies of the commercial and freeware geometries were similar, with the details of the freeware geometry appearing smoother. There were some differences between the two assemblies: patellar cartilage (yellow) extended further distally and the anterior medial meniscus (red) was thinner when freeware was used. These differences were user-dependent and reflect the subjective nature of segmentation/smoothing, rather than systematic differences in software choice.

Figure:



Caption: Geometry created using (left) commercial and (right) free software.

Conclusion: Both commercial and free software were capable of creating morphologically similar subject-specific geometry. Therefore, we conclude that freeware provides a viable alternative to commercial software. We do not think one is “better” than the other. Users should understand the trends associated with using either commercial or free software. Freeware structures tended to be smoother with less volume; users must be careful to avoid over-smoothing surfaces.

THE RELATION BETWEEN CLINICAL DIAGNOSED MECHANICALLY INDUCED METATARSALGIA, INCREASED PLANTAR PRESSURE, AND REACTION FORCES AT THE FOREFOOT.

Katrin Schweizer [1,*] Sebastian Krapf [1] Jacqueline Romkes [1] Marie Freslier [1] Christian Wyss [1]

[1] Laboratory of Movement Analysis, University Children's Hospital, Basel, Switzerland

Introduction and Objectives: Metatarsalgia is defined as forefoot pain beneath the second, third, and fourth metatarsal heads [1]. Diseases, such as rheumatoid arthritis or neuralgia, but also altered forefoot biomechanics can cause metatarsalgia [2]. *Mechanically induced metatarsalgia* is a common medical diagnosis based on a clinical examination. The logical treatment approach is to reduce the mechanical forefoot load, either with orthotic devices or by surgery. However, these treatments can be expensive and often do not successfully relieve the pain [3]. The unsatisfactory treatment outcomes of patients with metatarsalgia lead to our research question: Can clinical examination diagnose a biomechanical overload beneath the forefoot?

A mechanical forefoot correction is only appropriate if there actually exists a biomechanical overload of the forefoot. Therefore, the main research objective was to evaluate the sensitivity and specificity of the clinical examination to diagnose mechanically induced metatarsalgia beneath the second metatarsal head. This was done by comparing the clinical diagnosis to the peak plantar pressure and the estimated reaction forces beneath the second metatarsal head.

Methods: Plantar pressure data of 340 subjects diagnosed with mechanically induced metatarsalgia beneath the second metatarsal head and 207 subjects without metatarsalgia were retrospectively compared. All subjects were examined by one experienced clinician. Plantar pressure of the second step was measured when walking over a pressure platform (EMED SF, Novel, Munich) at floor level. Five trials per subject were averaged and analysed.

The peak pressure beneath the second metatarsal head was calculated for each step using MATLAB. The estimated reaction forces at the second metatarsal head were calculated for each foot with the modified [4] inverse dynamics model of Jacob et al. [5]. Thresholds for normal pressure and reaction force values were derived by confidence interval of the subjects without metatarsalgia.

To compare the clinical examination with the peak pressure and the reaction forces, the sensitivity, specificity, positive and negative likelihood ratios together with the associated 95% confidence intervals (CI) were calculated from contingency Tables 1a and 1b.

Results: The sensitivity (true positive rate), meaning that metatarsalgia was diagnosed and the pressure is increased, was 65.5 % (CI: 58.5 % - 72.0 %). The specificity (true negative rate); hence, the probability that no metatarsalgia was diagnosed when the pressure is normal was 39.8 % (CI: 34.6 % - 45.2 %). The positive likelihood ratio was 1.09 (CI: 0.95-1.24), the negative likelihood ratio 0.87 (CI: 0.69-1.09).

Compared to the reaction force at the second metatarsal head the sensitivity of the clinical examination was 67.3 % (CI: 60.7 % - 73.3 %). The specificity reached 41.4 % (CI: 36.0 % - 47.0 %). The positive likelihood ratio was 1.15 (CI: 1.01 - 1.31) and the negative likelihood ratio 0.79 (CI: 0.63 - 0.99).

Figure:

A		Peak plantar pressure		
		+ increased	- normal	N
Clinical diagnosis	+ Metatarsalgia	133	207	340
	- No metatarsalgia	70	137	207

B		Reaction force		
		+ increased	- normal	N
Clinical diagnosis	+ Metatarsalgia	152	188	340
	- No metatarsalgia	74	133	207

Caption: Table 1: Contingency tables of diagnosis: (a) peak plantar pressure at second metatarsal head vs. clinical diagnosis and (b) reaction forces vs. clinical diagnosis.

Conclusion: Our sensitivity values indicate that clinicians diagnose a mechanically induced metatarsalgia beneath the second metatarsal head in less than 68 % correctly. Even worse, in less than 42 % (specificity) they can correctly declare a subject for healthy considering the forefoot loading. The positive likelihood ratios were below 2 where above 10 is considered a good value [6]. Our negative likelihood ratios of above 0.75 were too high, as values below 0.1 are considered as good [6]. Consequently, it is hardly possible to correctly diagnose a mechanically induced metatarsalgia by clinical examination. We conclude that biomechanical measurements, such as plantar pressure or estimated reaction forces at the forefoot can reduce the number of wrongly treated patients, especially when a metatarsalgia is accompanied by a missing mechanical overload. In this sense the benefit of the biomechanical measurements is the false-positive detection because these patients are unlikely to benefit from any orthotic or surgical treatment to unload the forefoot.

AS-0140

DO STATIC FOOT MEASURES PREDICT MEDIAL LONGITUDINAL ARCH MOTION DURING RUNNING?

Ben Langley [1,*] Mary Cramp [2] Stewart Morrison [1]

[1]School of Health, Sport and Bioscience, University of East London, London, [2]Centre of Health and Clinical Research, University of the West of England, Bristol, United Kingdom

Introduction and Objectives: Static assessment of the structural alignment and/or characteristics of the foot are commonly advocated by running shoe manufacturers and retailers to classify the foot, with a view to recommending the appropriate type of running shoe. Despite this, the extent to which static measures predict dynamic foot motion during running is unsubstantiated, with findings from previous research producing conflicting results [1, 2, 3]. The purpose of this work was to determine whether static foot assessment could predict medial longitudinal arch (MLA) motion during running.

Methods: Fifteen physically active males (27 ± 5 years, 1.77 ± 0.04m, 80 ± 10kg) participated in the study. Foot Posture Index (FPI-6), MLA and rearfoot angles were measured in a relaxed standing position. Static MLA and rearfoot angles, and dynamic MLA motion were calculated from the position of retro-reflective markers tracked by a VICON motion analysis system. Markers were attached to the medial malleolus, navicular tuberosity and the first metatarsal head in order to calculate the MLA angle and to the base of the calcaneus, the Achilles tendon attachment, the centre of the Achilles tendon at the height of the medial malleoli and the centre of the posterior aspect of the shank to calculate the rearfoot angle. Participants ran barefoot on a treadmill at a self-selected pace (2.8 ± 0.5m.s^{-1}) during dynamic trials. Bivariate linear regression was used to determine whether the static foot classification measures predicted MLA range of motion (ROM) and MLA angles at initial contact (IC), midsupport (MS) and toe off (TO).

Results: All three foot classification measures were significant predictors of MLA angle at IC, MS and TO ($p < .05$) explaining 40-91% of the variance (Table 1). None of the static foot classification measures were significant predictors of the range of MLA motion during the stance phase of running (Table 1).

Conclusion: The findings of this study revealed that all selected static classification measures were significant predictors of MLA angles at discrete time points within the running gait cycle. Static MLA angle explained the greatest amount of variance in dynamic MLA angles at discrete time points within the running gait cycle, accounting for 91%, 87% and 84% of the difference in MLA angles at IC, MS and TO respectively. However, the importance of being able to predict MLA angles at discrete time points is questionable, as angles at discrete time points provide only limited information as to the dynamic functioning of the foot. In contrast, MLA ROM during the stance phase of running gait gives an indication as to the dynamic flexibility and function of the foot, which have theoretical links to the development running related injuries [4, 5]. The absence of a significant relationship ($p > .05$) between the foot classification measures and MLA ROM during running has implications for both clinicians and the running community, specifically running shoe retailers, who commonly use static foot classification measures to recommend running shoes.

The findings from this work suggest that static foot classification measures do not predict MLA motion during running. This finding lends support to the view that static foot assessment may not be an appropriate approach to classify the foot with a view to recommending footwear interventions designed to reduce injury risk.

Table:

	Dynamic MLA motion			
	ROM	IC	Midsupport	TO
FPI-6	-.03	-.68*	-.76**	-.73**
MLA angle	.07	.95***	.93***	.92***
Rearfoot angle	-.46	.68*	.76**	.64*

* $p < .05$ ** $p < .005$ *** $p < .001$

Caption: Table 1. Coefficient of determination (r) for static foot classification measures and aspects of dynamic MLA motion throughout the stance phase of the running gait cycle

INTRA-ARTICULAR PRESSURE DISTRIBUTION IN THE NATIVE AND PROSTHETIC ANKLE JOINT

Tassos Natsakis [1,*] Josefien Burg [2] Greta Dereymaeker [1] Jos Vander Sloten [1] Ilse Jonkers [2]

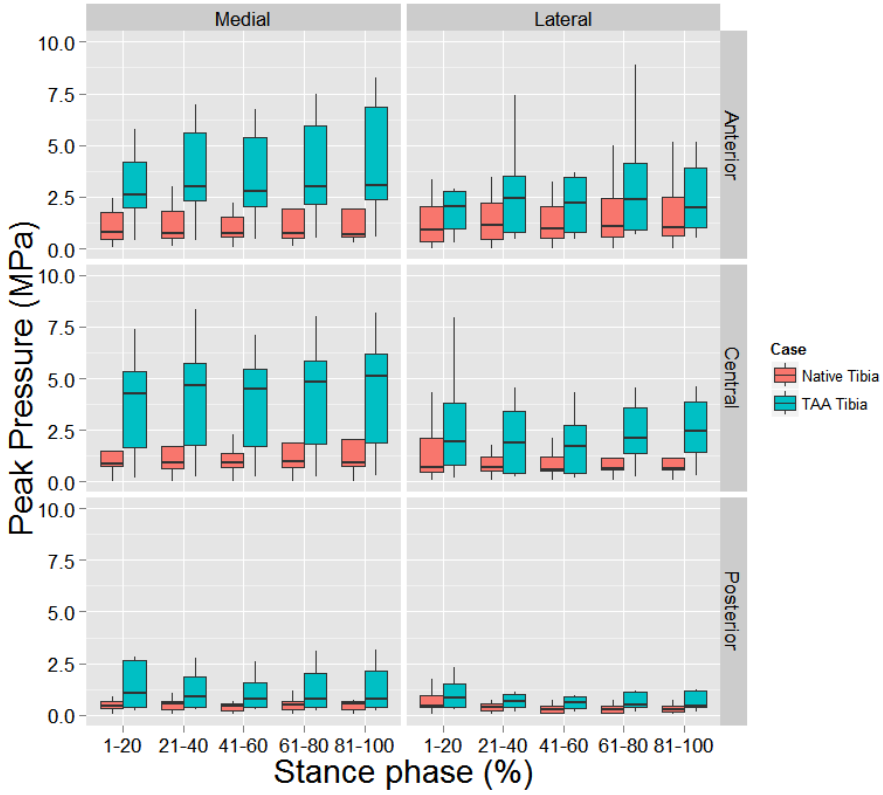
[1]Biomechanics section, [2]Faculty of Kinesiology and Rehabilitation Science, KU Leuven, Leuven, Belgium

Introduction and Objectives: Ankle osteoarthritis (OA) is a joint degenerative disease with high impact on quality of life. As ankle OA is often of post-traumatic nature, its onset has been linked to aberrant joint loading. When reaching end-stage (i.e. considerable lack of joint mobility, pain), the treatment options for ankle OA are limited to surgical interventions, such as Total Ankle Arthroplasty (TAA), which restores the mobility of the joint. However, TAA is associated with high failure rates, often related with bone resorption and cyst formation in the bone-implant interface or mechanical failure of one of the prosthetic components. To further investigate the link between joint loading and the development of OA, as well as the success of TAA, we quantified the topology joint loading conditions in the native ankle and TAA joint during gait.

Methods: Gait simulations were performed on 8 cadaveric foot specimens, amputated mid-tibially, by imposing tibial kinematics and applying muscle forces on nine tendons [1,2]. Intra-articular pressure distribution was measured with a Tekscan #5033 sensor (Tekscan Inc, Boston, MA) at 100 Hz in the ankle joint of the specimens before and after implantation of a Hintegra three component TAA (New Deal, Lyon, France). The peak pressure was calculated for five intervals of stance phase and six regions of the ankle joint. We tested for statistical significant differences between the native ankle and TAA joint with a non-parametric rank sum test (Wilcoxon) for each interval and region. The test was performed both for each specimen separately and for all the specimens grouped to differentiate individual and group response. Statistical significance was reported for $p \leq 0.05$

Results: For the native ankle, the highest peak pressures were measured in the anterior and medial regions of the joint. The maximum observed median pressure was 1.1 MPa and it occurred between 21%>40% of stance phase. For the TAA joint, the highest peak pressures were measured in the central and medial regions with the maximum observed median pressure being 5.11 MPa between 81%>100%. For most regions and stance phase intervals, significant increase in peak pressure was detected in five out of eight specimens, with only one specimen in most cases showing a significant decrease. No significant increase was detected for the grouped comparison in any interval or region, except for the anterior and medial region between 41%>60% (1.99 MPa increase, $p=0.038$) and posterior and lateral region between 41%>60% (0.29 MPa increase, $p=0.05$) and 61%>80% (0.31 MPa increase, $p=0.05$).

Figure:



Caption: Peak pressure distribution on the tibial articular surface before (red) and after (blue) TAA implantation. The peak pressure for six areas of the tibial articular surface is visible for five intervals of stance phase.

Conclusion: The regions that are more loaded in the ankle joint are coinciding with the regions that are often reported in literature with higher incidence of ankle OA [3]. This further supports the hypothesis that high joint loading and OA onset may be linked. Furthermore, a non-physiologic increase in joint loading is present in the joint after implantation of TAA, which might have a negative impact on the mechanobiology and bone growth of the distal tibia. This increase is significant in five out of eight specimens, however not significant for the group average; this indicates that even though the increase is significant in individual specimens, the amount of increase is not consistent.

CHANGES IN FOOT TEMPERATURE AS A FUNCTION OF WALKING SPEED

Prabhav Nadipi Reddy [1,*] Rhoda Sulaimon [2] Glen Cooper [1] Andrew Weightman [3] Emma Hodson-Tole [2] Neil Reeves [2]

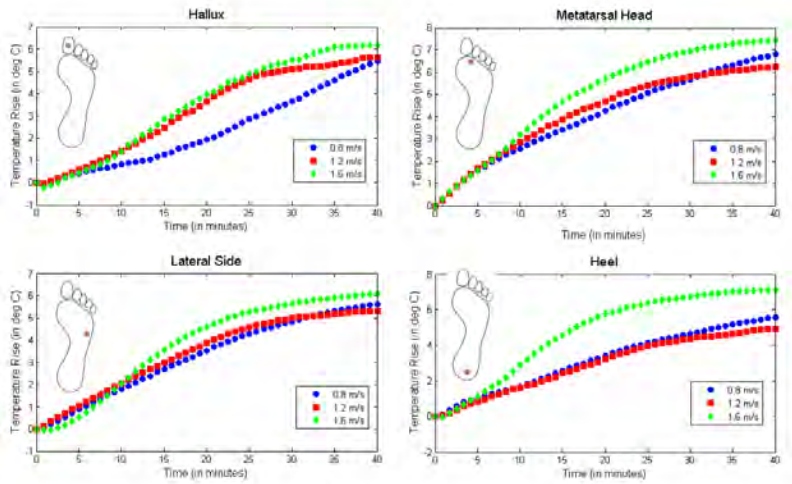
[1]Engineering, [2]Healthcare Science, Manchester Metropolitan University, [3]School of Mechanical, Aerospace and Civil Engineering, University of Manchester, Manchester, United Kingdom

Introduction and Objectives: Foot ulcers are a major concern for diabetic people. It has been shown that a difference of 2^0C or more between the same locations on the contralateral feet indicate a risk of ulceration in the foot with the higher temperature[1]. The mechanisms of this temperature rise are unknown. The first step to evaluating the role of temperature in ulceration is to understand the fundamental physiology of foot temperature changes with loading and walking. To this end, we studied the temperature of the feet of healthy human participants as they walked on a motorised treadmill at three different speeds.

Methods: 14 participants (21-40 years;13 male), without diabetes, foot problems or loss of sensation were recruited for the study. To record temperatures of the feet as participants walked we made insoles embedded with temperature sensors TMP35 (Analog Devices) at four locations: hallux, between the first two metatarsal heads, the lateral side of the foot, and the heel. The insoles were placed in standard 'Darco' shoes with the wiring from each sensor located under the insole to the lateral side of the foot. Temperature data were stored on a USB memory stick using the analog input channels of two myRIOs (National Instruments) – a reconfigurable input-output device – which digitised (12 bit resolution) and stored the data. We also recorded acceleration from an on-board (the myRIO) 3-axis accelerometer. All data were synchronously recorded at a sample rate of 100 Hz. During the experiment, the participants removed their shoes and rested with legs stretched out for 10 minutes, to ensure that the feet returned to their resting state. After the rest, temperature sensors were put on the feet and the subjects were asked to sit for 5 minutes followed by 10 minutes of standing. The subjects then walked on the treadmill at a fixed speed for 40 minutes. After walking, there was 15 minutes sitting while the temperature recording continued. It was intended that each participant walked on the treadmill three times at different speeds: 0.8 m/s, 1.2 m/s and 1.6 m/s. The order in which the participants walked at different speeds were randomized. For logistical reasons, not all participants walked all the speeds. Five participants walked all the three speeds. In total, the temperatures were recorded on 27 occasions.

Results: Fig. 1 shows the mean (over all participants) temperature rise profiles of the right foot while walking. The mean temperature rise over the duration of the walk are given in Table 1. We performed a factorial 3x4x2 ANOVA with speed, location of the foot and the two feet -right and left. It showed a significant main effect of speed on the temperature rise with walking, $F(2,190)=3.75$, $p=0.025$. There is a mild effect of location, $F(3,1279)=1.69$,$p=0.169$ and no effect of the foot, $F(1,1279)=0.937$,$p=0.749$. The interaction between location and speed was not significant, $F(6,1279)=0.35$,$p=0.912$.
The temperatures of the foot were lowest for the medium speed and highest for the maximum speed (Min-Med: $p=0.04$,CI–[0.04,1.38]; Min-Max: $p=0.02$,CI–[-2.16,0.15]; Max-Med: $p=0.002$,CI–[0.8,3.17]). We found that the temperature of the metatarsal head was significantly higher than the other locations (Met head-Hallux: $p=0.0002$,CI–[0.61, 1.0]; Met Head-Lateral Side: $p<0.0001$,CI–[0.66, 1.4]; Met Head-Heel: $p=0.0016$,CI–[0.38, 1.52]).

Figure:



Caption: Mean temperature rise curves during walking for different speeds and locations of the foot.

Conclusion: It is clear from our data that foot temperature increases as people walk. The temperature rise increases with increasing speed. The deviations from this trend may be due to the variations in the pressure-time integrals at different speeds. Temperature change also depended on the location of the foot, and likely reflects differences in loading at the locations. We are currently doing experiments to investigate these phenomena.

Since we sampled temperature from four different sites on the foot, we were able to identify some issues with two of the sensor sites that could be addressed by future changes to the measurement approach. Specifically, we found that the sensor under the hallux was not always touching the plantar tissue due to variations in foot size between participants. In addition, we found that in some cases the foot lifted off the sensors during walking.

Our study gives baseline data that we can use to inform our fundamental understanding of the mechanism(s) behind the rise in foot temperature as we move towards measurements in diabetics. We hope that this will help us to better understand the onset of diabetic foot ulceration.

Table:

	Hallux	Metatarsal Head	Lateral Side	Heel
0.8 m/s	2.01 ± 1.51	3.55 ± 1.36	3.16 ± 0.99	3.01 ± 0.89
1.2 m/s	2.80 ± 2.02	3.74 ± 1.43	3.14 ± 0.97	2.69 ± 1.29
1.6 m/s	3.12 ± 2.16	4.55 ± 1.39	3.70 ± 1.19	4.23 ± 2.50

TEST AND RE-TEST RELIABILITY OF ANKLE AND KNEE KINEMATIC VARIABLES DURING RUNNING

Andrea N. Onodera [1 2,*] Ana Paula Ribeiro [3] Licia Cacciari [1] Maria Isabel Roveri [1] Isabel C N Sacco [1]

[1]Physical Therapy, Speech and Occupational Therapy Dept. School of Medicine, University of São Paulo, São Paulo, [2]Dass Nordeste Calçados e Artigos Esportivos Inc, Ivoti, [3]Universidade de Santo Amaro, Universidade de Santo Amaro - Campus I, São Paulo, Brazil

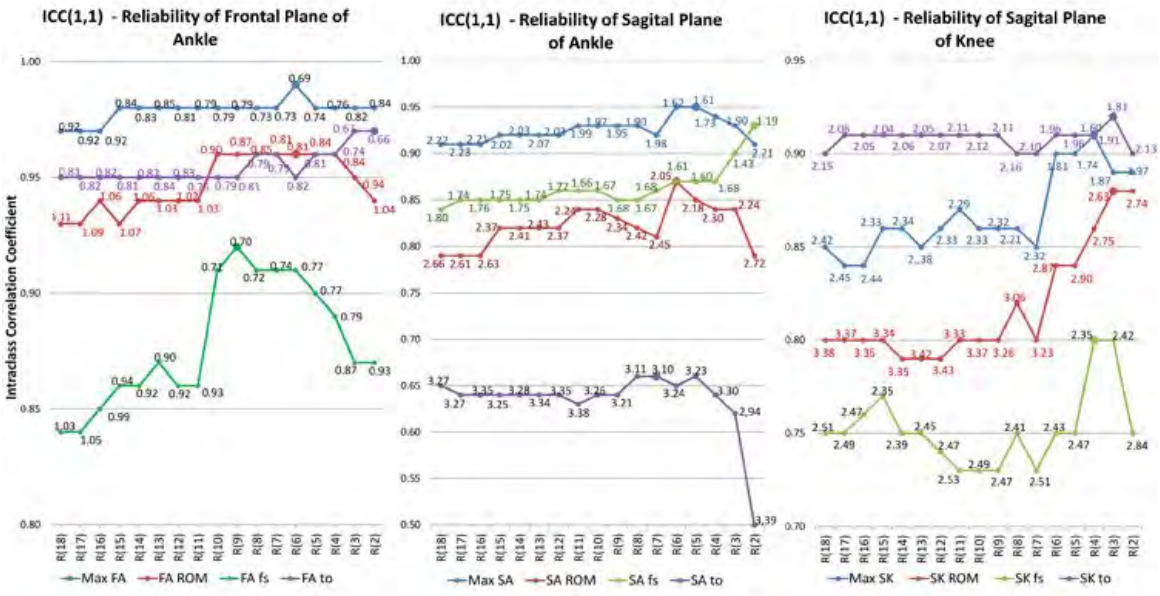
Introduction and Objectives: The Brazilian National Standards Organization[1] establishes 20 steps for determining the footwear pronation rate during walking and running.The data acquisition of 20 trials could imply discomfort for runners and more expenses for employees performing the biomechanical tests, especially for footwear studies in which two or more shoe models are compared in the same experiment.In addition, the number of analyzed trials has been considered of great importance for the reliability of locomotion measurements [2]. Some studies report 5 trials to assure good reliability of knee and ankle kinematics during running [3, 4, 5], however Ferber et al [3] and Diss [4] only analyzed Intraclass Correlation Coefficients (ICC) for 5 trials and Sinclair et al [5] analyzed the ICC and Standard Error of Measurements (SEM) for 5 trials.The ICC can provide the consistency between trials, while SEM quantifies the precision of scores in the test to define the ideal number of trials for the experiment.Therefore, the purpose of this study is to quantify the reliability of 12 kinematic variables using ICC and SEM across 18 trials, intending to optimize the biomechanical test protocols, yet assuring high confidence levels.

Methods: Ten healthy runners (39.0±9.3 yrs old, 70.0±6.1 kg, 170±6 cm) with rearfoot strike pattern ran over a 25 meters walkway in constant and natural velocity (2.64 to 2.92 m/s). All runners used the same commercially available sport shoe construction for the test. Eighteen valid trials were collected and the kinematics measured by 6 IR cameras at 300 Hz (VICON T-40, Oxford, UK). Sixteen reflexive markers (14 mm Ø) were attached according to Plug'n Gait marker set (Nexus, VICON) and sagittal knee and ankle angles and frontal ankle angles were analyzed. The right leg data was filtered at 12Hz using a Butterworth 4^{th} order zero-lag filter. Reliability tests were performed, after confirming that the data was normally distributed (Kolmogorov-smirnov), for 2 to 18 trials by intraclass correlation coefficients (ICC(1,1) = (MSb-MSw)/(MSb + (k-1)MSw)) and Standard Error of Measurements (SEM = SD$\sqrt{1}$-ICC). The means and standard deviations between subjects for all trials.

Results: For the knee kinematics in the sagittal plane, 3 to 4 trials are enough to get the best reliability and low SEM. For ankle kinematics in the frontal and sagittal planes, 6 trials result in a good reliability for ICC score and low SEMs. The only exception was the ankle extension during the toe-off, which did not achieve the acceptable classification even in the best ICC score. The ICC score should be carefully interpreted since the variability between subjects can interfere in the results. The ICC is very sensible to between-subjects variability [6]. That is why the SEM is also analyzed in these cases. The interpretation of SEM centers on the assessment of reliability within individual subjects and it is in the same units as the measurements of interest. The ankle extension during the toe-off had poor ICC score and also a high SEM probably because the take off can be performed with more or less ankle extension and is extremely variable among subjects. Our study shows that for all kinematic variables analyzed, more than 10 trials resulted in lower ICC and higher SEM. The

number of trials used for other authors [3,4,5] are better than the recommended by the Brazilian National Standards Organization, however, 6 trials for ankle kinematics and 4 trials for knee sagittal kinematics seems better than 5. The data acquisition of 20 trials would be a waste of experiment time and also would reduce the data consistency, probably explained by the increased chance of error.

Figure:



Caption: Ilustration of Intraclass correlation coefficient (lines) and Standard Error of Measurement (numbers above or under each mark) of ankle and knee kinematic parameters during 2 to 18 trials.

Conclusion: Six trials guarantee good reliability for almost all variables when analyzing ankle sagittal and frontal plane kinematics during running. For the sagittal plane of knee, four trials are necessary for a good reliability.

Table:

Variables	Mean	SD
Maximum Knee Flexion (º) – Max SK	49.9	6.0
Sagital Knee ROM (º) – SK ROM	31.6	7.1
Knee Flexion @ Footstrike (º) – SK fs	18.2	4.5
Knee Flexion @ Toe-off (º) – SK to	16.9	6.7

Maximum Ankle Flexion (º) – Max SA	36.4	7.4
Sagital Ankle ROM (º) – SA ROM	19.1	5.3
Ankle Flexion @ Footstrike (º) – SA fs	17.3	4.4
Ankle Flexion @ Toe-off (º) – SA to	0.6	4.6
Maximum Ankle Eversion (º) – Max FA	9.5	5.9
Frontal Ankle ROM (º) – FA ROM	9.1	4.3
Ankle Inversion @ Footstrike (º) – FA fs	-0.3	2.5
Ankle Inversion @ Toe-off (º) – FA to	-0.6	3.7

USING FINITE ELEMENT ANALYSIS TO IMPROVE THE DESIGN OF SOCCER SHOES OUTSOLES

Michel Behr [1,*] Sylvain Blanchard [1] Maxime Llari [1] Yves Godio-Raboutet [1] Lionel Thollon [1] Jerome Palestri [2] Jean-Luc Guer [2]

[1]Laboratoire de Biomécanique Appliquée, IFSTTAR/Aix-Marseille Université, [2]Wizwedge SARL, Marseille, France

Introduction and Objectives: Soccer is the most popular sport in the world, and also one of those with a particularly high injury rate per hours of play [1]. The shoe itself is suspected to be often involved and sometimes even responsible for this high injury risk exposure [2]. Among the various possibilities, custom-made shoes was identified as one promising way to improve players protection [3]. The current study aims at using numerical simulation to improve shoe design procedures in order to reduce players exposure to the most frequent pathologies occuring in soccer, and explore the possible benefits of the custom-made shoes approach.

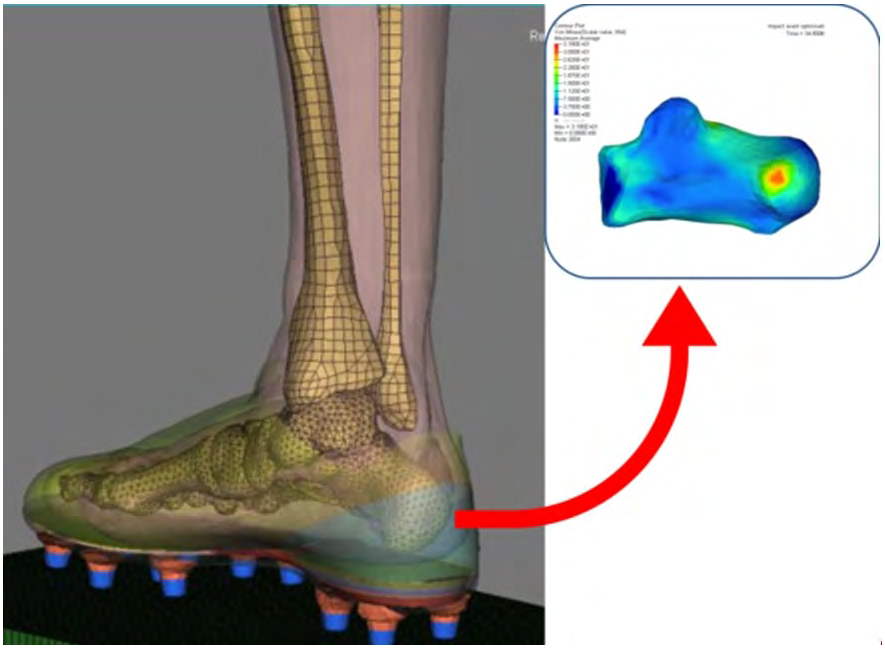
Methods: An parametric finite element model of the lower limb, derived form the LLMS model [4] was widely validated under quasi-static and dynamic loading conditions and afterwards coupled to a soccer shoe model. Particular attention was put on foot to shoe interactions and initial constraints. The shoe model includes an original outsole architecture offering the possibility to customize heel and footarch support geometry and materials according to each player characteristics.

A database of mechanical properties of 40 podiatric foams has also been build, by performing compression tests at 3 different energy levels and inverse analysis. Anti-vibration, shock-absorbing and propulsive properties of each tested foam were quantified by simulating hign energy impacts, in order to rate and classify each of these materials.

Finally, volunteer tests were performed on european first football leagues players in order to record plantar pressures and corresponding body kinematics in typical soccer movements such as jump landings or shootings. Recorded data would then define boundary conditions of these typical soccer movements, used as inputs for shoe structure and materials optimization. Optimization objectives were based on biomechanical criteria such as reduced vibrations and stress peaks at the major joints (see Figure 1).

Results: The characterization of foams revealed a great variety of visco-elastic behaviors. A classification of these foams into three groups (ie anti-shock, propelling and anti-vibration) could be proposed, with the most efficient materials identified in each of these groups. Optimization made it possible to achieve a combination of materials and define each layer thickness to reduce by up to 80 % vibrations transmitted to the bones and by 40 % the recorded peak stresses at joints.

Figure:



Caption: Figure 1. Example of jump landing simulation, and corresponding stress peak recorded on the calcaneus bone.

Conclusion: A modification of the outsole structure and materials significantly acts on the biomechanical response of lower limbs (and by extension on the entire human body). A significative improvement of lower limbs exposure to risk of injury can be considered from this type of approach.

CROSS CUT BIOMECHANICS ARE AFFECTED TO A GREATER EXTENT WHEN PERFORMED IN AN UNANTICIPATED CONDITION COMPARED TO A FATIGUED CONDITION

Enda Whyte [1,*] Kieran Moran [1 2] Chris Richter [1 2 3]

[1]School of Health and Human Performance, DCU, [2]Insight:Centre for Data Analytics, [3]Sports Medicine, Sports Surgery Clinic, Dublin, Ireland

Introduction and Objectives: Anterior cruciate ligament (ACL) are common in sports during landing, deceleration and cutting activities[1] particularly during the later stages of sporting activities[2]. This suggests that fatigue has a negative effect on lower limb biomechanics predisposing an athlete to injury. Further, many field sports produce relatively unanticipateable events, requiring participants to react with appropriate neuromuscular strategies[3]. This requires the integration of visual scanning and decision making with implementation of the appropriate neuromuscular strategy[4]. Non–contact ACL injuries tend to occur during sub-maximal activities in response to a sporting stimulus[1], suggesting that a chosen strategy may result in pathological loading.

Cutting activities are divided into side cutting where the participant plants one foot and cuts to the opposite side; and the cross cut where the participant plants one foot and cuts to the same side[5]. To the authors' knowledge, no studies have analysed the combined effect of fatigue and decision making on the biomechanics of the cross cut. Therefore, this study aims to examine the effects of fatigue and anticipation on the biomechanics of a cross cut.

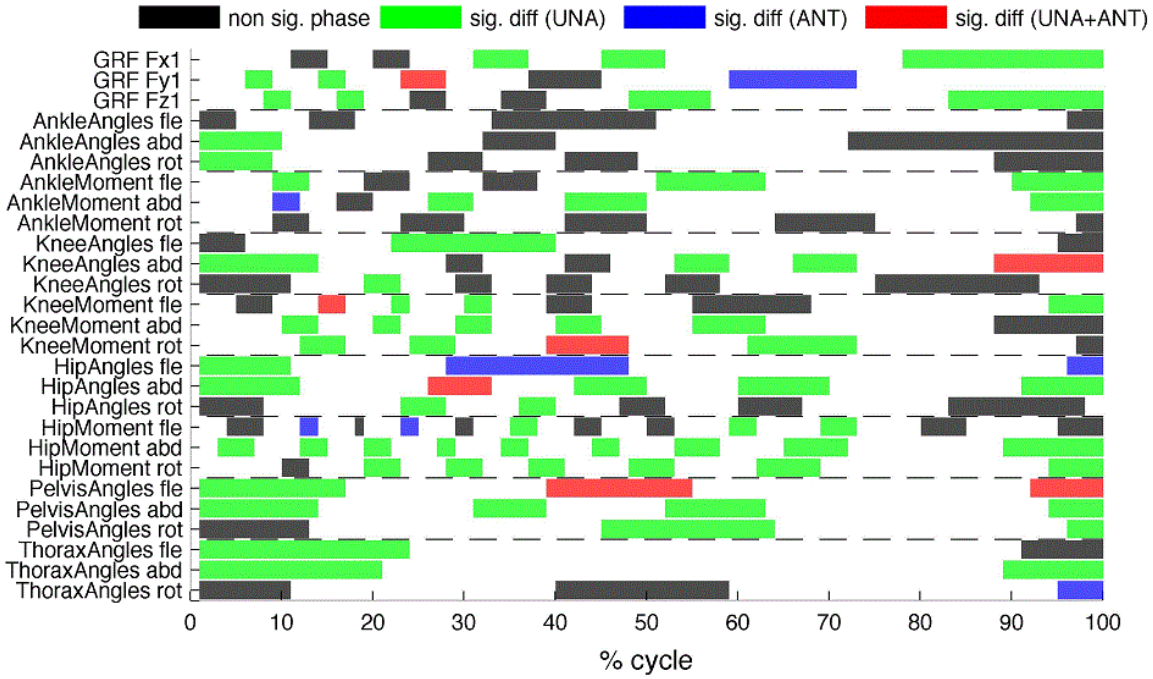
Methods: Kinematic and kinetic data were recorded for 30 healthy, male intervarsity athletes during a cross cut in anticipated (ANT) and unanticipated (UNANT) conditions, before (PRE) and after (POST) an exercise protocol[6]. Participants jumped forward 70% of their maximum jump, landed on their dominant leg and performed a cross cut at 45º. This was employed to limit the variable effect of a 'free run' approach. In the ANT condition, a light indicated the direction of the cut five seconds prior to the task. For the UNANT, the light was triggered by breaking an infra-red light during the jump (approx. 139ms before ground contact).

The deceleration phase of the cross cut was analysed (initial contact to the first propulsive forces). Analysis of Characterising Phases detected differences between the conditions by generating scores from key phases (phases of variance) identified using principal components that captured >99% of the variance in the data[7]. A Repeated Measures ANOVA was performed and Cohen's D (d) was calculated to measure the effect of statistical differences ($\alpha = .05$). Only significant findings of waveforms with a medium ($d > .5$) or large effect size ($d > .8$) are reported.

Results: PRE vs. POST analysis revealed multiple statistical differences without reaching a medium effect size. For the ANT vs. UNANT condition, key phases in knee and hip moments, and pelvic and thoracic angles were found to be significantly different (table 1) with the minimum of a medium effect size ($d>0.5$). A full list of examined key phases is illustrated in figure 1. Multiple significant effects of fatigue (ground reaction force, ankle moments, knee and hip angles and moments, and pelvic and thoracic angles) were observed, supporting previous studies examining the effects of fatigue during cutting movements[8]. However, none of these factors reached a medium effect size suggesting that fatigue has a relatively low effect on the biomechanics of a cross cut.

ANT vs. UNANT findings supported previous studies examining the effect of anticipation on biomechanics during cutting[8,9]. However, within the present study these had a small effect size (knee flexion, abduction and rotation angle, hip flexion and rotation angles). Anticipation had the greatest effect on proximal biomechanics with medium effect sizes at the knee and hip moments and pelvic angles and large effects sizes at the thoracic abduction angle supporting the association between trunk kinematics and ACL injury risk[10]. This has important implications for future studies on unanticipated cutting and ACL injury prevention programmes.

Figure:



Caption: Figure 1: Key phases examined.

Conclusion: The current study demonstrate that fatigue and anticipation alter the biomechanics of a cross cut. The effects of anticipation have a much greater influence on proximal biomechanics in particular.

Table:

Variable	Key Phase	P value	Cohens D
Knee Abduction Moment	20-23 & 29-33	<.001	-.57-.55

BIPEDAL LOCOMOTION OF THE JAPANESE MACAQUE: INTERACTIONS BETWEEN TRUNK, LEGS AND SELF-STABILITY.

Emanuel Andrada [1,*] Yefta Sutedja [2] Eishi Hirasaki [3] Reinhardt Blickhan [2] Naomichi Ogihara [4]

[1]Institute of Systematic Zoology and Evolutionary Biology, [2]Science of Motion, Friedrich-Schiller-University, Jena, Germany, [3]PRI, Kyoto University, Inuyama, [4]Department of Mechanical Engineering, Keio University, Yokohama, Japan

Introduction and Objectives: The adoption of bipedalism as preferred mode of terrestrial locomotion is a fundamental step in evolution of many species. Bipedalism evolved first about 230 million years ago in archosaurs, a group that includes both crocodilians and dinosaurs, being the most recent ancestors of modern bird species. A second evolution towards bipedalism occurred ca. 7 millon years ago in Africa, and marked the start of the divergence of the human lineage from that of other African apes. Interestingly, while the lineage of Theropoda leading to modern birds kept the pronograde (almost horizontal) body posture inherited from quadruped ancestors, early and actual humans adopted an erected trunk posture during bipedal locomotion. Despite trunk orientation, bipedal locomotion needs hip moments to balance the trunk. Controlling hip torque in a way that the ground reaction force points towards a point above the center of mass (CoM) termed Virtual Pivot Point (VPP) can help to stabilize the trunk [1-3]. Our recent investigations show that the balance of the trunk at a certain orientation influences the function of the effective leg (segment hip-foot contact; [3]). In small birds the effective leg, which works asymmetric like a parallel spring –damper, has an effect on balancing the trunk at one hand and stabilizes pronograde locomotion on the other hand. Interestingly, for pronograde posture the majority of the self-stable solutions are grounded running (a running gait without aerial phases, [3]). In the present study, we investigated the dynamics of the interaction between trunk and legs during the bipedal locomotion of a non-human quadrupedal primate, Japanese macaques (*Macaca fuscata*), as their facultative bipedalism may represent an intermediate state between the bird and human bipedal locomotion [4].

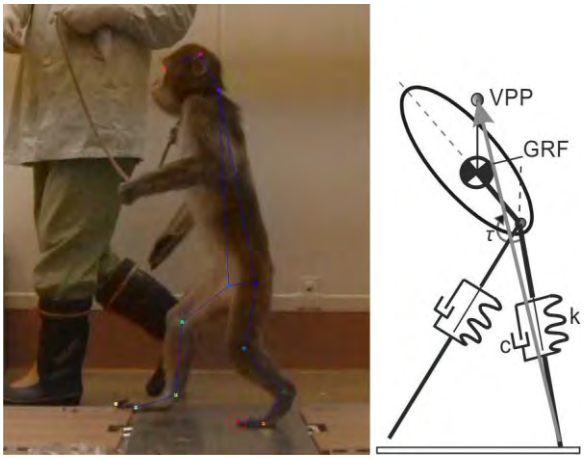
Methods: Two adult trained macaques locomoted bipedally on an instrumented walking track at self-chosen speed. The gait-lab setup in the Primate Research Institute at Inuyama (Japan) consisted of a 3D-forceplate (strain gage based; Kyowa Dengyo, EFP-S-1.5KNSA2), a wooden track to match floor height, and two video cameras (Canon, iVIS HF S21; res. 1920 X 1080 pxls, 60 half-frames/s; shutter: 1/200 s). The videos were stored as half frame .avi's and digitized manually using Winanalyse (Mikromac, Germany). The resulting data were further processed using custom Matlab® software. We computed VPP height, axial leg function, leg stiffness (k), leg damping (c), leg length at TD (l_0), and % of Congruity as shown in [3]. We simulated macaque locomotion with the bio-inspired Pronograde VPP model [3]. Model parameters were obtained from the experimental results and literature [5].

Results: Macaques locomoted bipedally with an erected trunk at speed ranging from 0.7 m/s to 1.1 m/s without aerial phases. They exhibited a left-skewed ground reaction force (GRF) profile, which is similar to those observed in bird grounded running. Accordingly, the values of the % of congruity were higher than 50, indicating bouncing-like mechanics (grounded running) during macaque locomotion. Intersections of GRF in a VPP point were not always as clear as observed for humans and birds. The calculated VPP height was in mean 0.28 m above the CoM. Similar to birds, the

effective leg function was asymmetric (leg length is longer than at touch-down than at toe-off, and protraction angle at TD was larger than retraction angle at TO). Thus a parallel spring-damper leg model was used to fit leg force. The results of the non-linear fit yielded to following mean values: leg stiffness k= 600 Nm^{-1}; leg damping c=20 Nsm^{-1}. When computing only leg stiffness from maximal force and mean leg contraction, the value was k_{sym}= 1500 Nm^{-1}.

In simulations, the PVPP model did not find stable solutions for trunk inclinations ranging from 5° to 50°. Still the model is able to balance the trunk and to locomote for more than 100 steps, but locomotion speed continuously increased even for larger damping values. Interestingly, with vertical trunk and spring-like legs, we found stable walking at speeds ranging from 0.7 to 0.8 ms^{-1}.

Figure:



Caption: Bipedal locomotion of the japaneese macaque and the PVPP model

Conclusion: Contrary to the results obtained for pronograde locomotion, grounded running is not self-stable for vertical or close to vertical trunk orientation. We conclude that rather than the upright locomotion per se, the important locomotion innovation characterizing the human lineage is likely to be the development of a less 'compliant' and more symmetric effective leg function, which enabled the exploration of self-stable walking domains.

WHEN ESTIMATING BONE POSE USING PROCRUSTES SUPERIMPOSITION, ONLY THE RIGID COMPONENT OF THE SOFT TISSUE ARTIFACT IMPACTS ON END RESULTS

Tecla Bonci [1 2 3 4 5,*] Valentina Camomilla [4 5] Raphaël Dumas [1 2 3 5] Laurence Chèze [1 2 3 5] Aurelio Cappozzo [4 5]

[1]Université Lyon 1, Lyon, [2]Université Claude Bernard Lyon 1, Villeurbanne, [3]LBMC UMR_T9406, Laboratoire de Biomécanique et Mécanique des Chocs, IFSTTAR, Bron, France, [4]Department of Movement, Human and Health Sciences, [5]Interuniversity Centre of Bioengineering of the Human Neuromusculoskeletal System, Università degli Studi di Roma ''Foro Italico'', Rome, Italy

Introduction and Objectives: To reconstruct the pose of a bone in the 3D space, stereophotogrammetry and a skin-marker cluster are used. The movement between skin-markers and the underlying bone is regarded as an artefact (soft tissue artefact, STA) having devastating effects on end results. This STA can be described at marker-cluster level by a series of geometrical transformations, such as rotations and translations (cluster rigid motion: CRM), homotheties and stretches (cluster non-rigid motion: CNRM). Recent studies quantified these STA components [1]–[4], showing that CRM is normally predominant with respect to CNRM. Based on this observation, it is concluded, either explicitly or implicitly, that CNRM has a limited impact on bone pose estimation (BPE) and that STA compensation should concentrate on CRM. This study disputes the message carried by this statement and demonstrates that CNRM does not have a limited effect on BPE accuracy, but, rather, it has no effect whatsoever and that this is the case independently from its magnitude relative to CRM. For this reason, the only STA component to be compensated for is CRM.

Methods: The data obtained in [5] and relative to the trajectories of both skin and pin thigh markers recorded during 5 trials of each of 3 running subjects (S1, S2, S3) were used. For each trial and subject, a bone anatomical frame (AF) was defined, based on the pin markers, and the movement of four skin-markers reconstructed in the AF. Relevant displacement vectors were represented, in each k-th sample, as an STA vector field $\mathbf{V}(k)$, ($k=1:n$) [6]. This field was decomposed into modes, by projecting it onto an orthogonal base of unit vectors chosen so that the first six modes represent rotations and translations (CRM), and the further six homotheties and stretches (CNRM) [6]: $\mathbf{V}(k)=\Sigma_{l=1\ldots12}\, a^l(k)\mathbf{\Phi}^l$. The energies associated with CRM and CNRM were calculated as $E_{CRM}=\Sigma_{l=1\ldots6}(1/n\,\Sigma_{k=1\ldots n}\,(a^l(k))^2)$ and $E_{CNRM}=\Sigma_{l=7\ldots12}(1/n\,\Sigma_{k=1\ldots n}\,(a^l(k))^2)$, respectively. The ratio between the former and the latter energy (R) was determined.

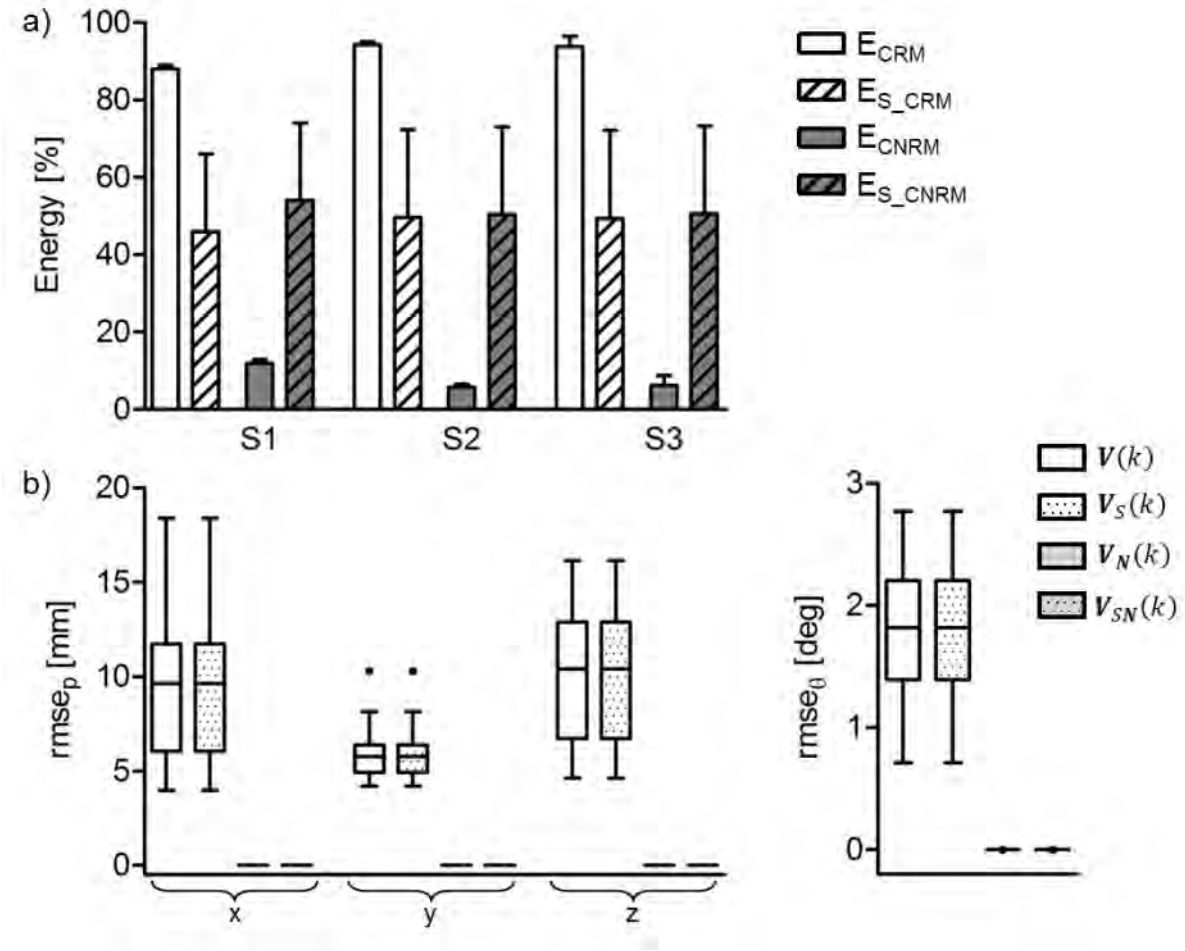
To assess the impact that CNRM has on BPE, a Monte Carlo Simulation was used to generate a set of one thousand STA fields that have the same CRM and amplified CNRMs: $\mathbf{V_S}(k)=\Sigma_{l=1\ldots6}\, a^l(k)\mathbf{\Phi}^l + r\,\Sigma_{l=7\ldots12}\, a^l(k)\mathbf{\Phi}^l$. The amplification factor r was randomly generated in the range from 1 to $2(R)^{½}$ so that the mean CNRM energy of this set was equal the CRM counterpart. Then, the CRM components were removed from both the measured and the amplified STA fields, generating STA fields affected only by the real, $\mathbf{V_N}(k)=\mathbf{V}(k)-\Sigma_{l=1\ldots6}\, a^l(k)\mathbf{\Phi}^l$, and simulated CNRM, $\mathbf{V_{SN}}(k)=\mathbf{V_S}(k)-\Sigma_{l=1\ldots6}\, a^l(k)\mathbf{\Phi}^l$.

Skin-marker trajectories were generated from the reference AF pose and the STA fields available ($\mathbf{V}(k)$, $\mathbf{V_S}(k)$, $\mathbf{V_N}(k)$, $\mathbf{V_{SN}}(k)$) and used to estimate the artefact-affected pose of the AF in the global reference frame with a Procrustes Superimposition (PS) approach. The root mean square difference between the artefact-affected and reference AF pose

was calculated and considered as an error ($rmse_\theta$ for orientation (attitude angle) and $rmse_{px}$, $rmse_{py}$, $rmse_{pz}$, for position components).

Results: The median (inter-quartile range) values of the *R* factors were 7(1), 18(4), and 14(15), for S1, S2 and S3, respectively. Obviously, the CNRM amplification caused an increase in the energy percentage of this component with respect to the total energy: mean (±standard deviation) values went from 8±3% ($\mathbf{V}(k)$) to 52±22% ($\mathbf{V_S}(k)$) (Fig. a). Before and after the amplification of CNRM, errors in pose estimation were exactly the same (although the total STA energy increased) (Fig. b). In all cases, after removing CRM, not altered throughout the simulation, the error was null.

Figure:



Caption: a) Mean values of the CRM and CNRM energy in percentage of the total energy, for the measured (ECRM and ECNRM) and simulated STA (ES_CRM and ES_CNRM). Statistics performed over all trials and subjects (S1, S2, S3). b) Box-plots (minimum, lower quartile, median, upper quartile, and maximum) of the BPE errors, for position and orientation, relative to all the STA fields available.

Conclusion: The results empirically showed that, using a PS approach, only CRM has an impact on the accuracy of the BPE, independently of the amplitude of CNRM. Moreover, after removing CRM, the real BPE was obtained. It must be acknowledged that a reference pose obtained with pin markers was used to compute the modes and to remove CRM from skin-marker trajectories. In the present context, this choice does not constitute a limitation, but does simply show that the

CNRM has no effect on BPE. Results suggest that, in a STA compensation perspective, future work should be focused on modelling and removing only CRM.

ACETABULAR STRESS IN PERSONS WITH AND WITHOUT CAM FEMOROACETABULAR IMPINGEMENT: THE INFLUENCE OF HIP KINEMATICS AND BONY MORPHOLOGY DURING A MAXIMUM DEPTH SQUAT

Jennifer Bagwell [1,*] Christopher Powers [1]

[1] Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, United States

Introduction and Objectives: Cam femoroacetabular impingement (FAI) has been reported to be a cause of hip chondral damage, acetabular labral tears, and osteoarthritis [1]. Cam FAI is defined by abnormal bony morphology (decreased offset at the femoral head-neck junction). Previous finite element modeling studies have demonstrated that as severity of this bony deformity increases, the bony contact shifts from the acetabular cup with the femoral head to the anterosuperior acetabular rim with the femoral head-neck junction [2]. This "impingement" results in a significant increase in acetabular cartilage stress. To date, little is known about the kinematic contributions to cam FAI. More specifically, it is not clear if cam FAI is more a result of abnormal hip kinematics (ie. increased hip internal rotation) or altered bony morphology. The purpose of the current study was to compare kinematics between persons with and without cam FAI during a maximum depth squat task. We also evaluated the contact location and magnitude of acetabular cartilage stress using finite element (FE) models that incorporated respective group kinematics and bony morphological profiles.

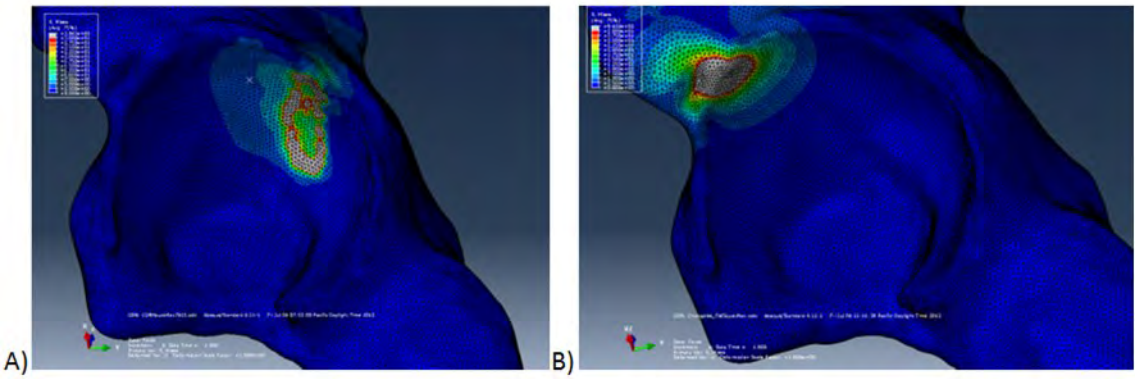
Methods: Fifteen persons with cam FAI (9 female, 6 male) and 15 age and gender matched controls participated. 3D kinematics were obtained during maximum depth squatting using a motion capture system (Qualisys, Inc., Gothenburg, Sweden). To create the FE models, 3T magnetic resonance imaging (GE scanner, General Electric Healthcare, Milwaukee, WI) was performed using a 3D high resolution, fat-suppressed, fast spoiled gradient recall echo sequence on one asymptomatic person who did not have FAI morphology or hip dysplasia. Images were manually segmented in Sliceomatic (Tomovision, Montreal, Quebec) and the femur and hemipelvis meshes were created in Hypermesh (Altair Engineering Inc., Troy, MI). The femur was modeled as a rigid body and the acetabulum was modeled using homogenous, isotropic, tetrahedral elements with an elastic modulus of 17.0 MPa and a Poisson ratio of 0.30. Nodes were manually added to the model at the femoral head neck junction (1:30 position) and the mesh was recreated. This resulted in one model without FAI morphology (control) and one model with moderate cam morphology (alpha angle 66°). The mean kinematics at the time of peak hip flexion during the maximum depth squat task were compared between groups using independent t-tests (α=0.05). Additionally, the control group kinematics were utilized in the control group FE model and the cam group kinematics were utilized in the cam FE model. Simulations were run in Abaqus (SIMULIA, Providence, RI) using a hard contact algorithm, with a surface-to-surface, small sliding contact with a surface coefficient of friction of 0.02. The forces used for both models were identical and were derived from peak hip forces from a previous instrumented hip prosthesis study [3]. The modeling variables of interest were location of contact and the peak acetabular von Misses stres.s.

Results: Peak hip flexion was greater in the control group compared to the cam group (113.0 $\pm$ 6.7° vs. 105.8 $\pm$ 14.7°, respectively; p=0.048). Peak hip internal rotation also was greater in the control group than in the cam group (105.8 $\pm$

14.7° vs. 9.5 ± 8.0°; p=0.043). There was no statistically significant difference in peak hip abduction between groups (12.0 ± 6.8° vs. 11.6 ± 6.0°; p=0.864).

The contact location in the control FE model was within the acetabular cup, whereas the contact location in the cam FE model was at the anterosuperior acetabular rim (Figure 1). The corresponding acetabular peak stresses for the control and cam group FE models were 289 MPa and 673 MPa, respectively.

Figure:



Caption: Figure 1. Acetabular stress profiles with the femur removed for A) the control group kinematics applied to control FE model and B) the cam group kinematics applied to cam FE model.

Conclusion: Despite lower mean hip flexion and internal rotation angles during a maximum depth squat task in the cam FAI group, the cam FE model demonstrated contact locations corresponding to impingement (abutment of the femoral head-neck junction with the anterosuperior acetabular rim). In contrast, the control FE model resulted in a normal contact location (femoral head with the acetabular cup). These results indicate that bony morphology is likely a more important contributing factor in cam FAI during this task.

A RELIABLE PROTOCOL FOR THE ASSESSMENT OF STEP COUNT ACCURACY OF PHYSICAL ACTIVITY MONITORS IN MULTIPLE SCLEROSIS

Fabio A. Storm [1 2,*] Sivaraman Nair [3] Alison Clarke [4] Jill Van der Meulen [4] Shanmuganathan Periyasamy [5] Claudia Mazzà [1 2]

[1]Department of Mechanical Engineering, [2]INSIGNEO Institute for in Silico Medicine, The University of Sheffield, [3]Department of Neurology, [4]The Gait Laboratory, Sheffield Teaching Hospitals NHS Foundation Trust, [5]Sheffield Institute of Translational Neuroscience, Sheffield, United Kingdom

Introduction and Objectives: Physical activity intervention and monitoring are becoming prominent in a number of patient populations and accelerometry is currently the most exploited technology in this context [1]. One of the essential features in activity monitoring is step counting, the accuracy of which is typically limited by the fact that signals are recorded from patients with altered walking patterns and reduced walking speed. Only little evidence is available on the validity and reliability of step counts, and the effect of these errors on the estimation of the final physical activity is unclear.

The aim of this study is to propose a method for the reliable assessment of patient-specific inaccuracies when using a physical activity monitor (PAM) for step detection in patients with multiple sclerosis. The relationship between step count accuracy and walking speed will also be investigated as an indicator of the suitability of a given monitor for those patients with highly restricted walking ability.

Methods: Seventeen participants (8 males, age range 39-75) with diagnosis of multiple sclerosis were recruited for the study. Written informed consent and ethical approval were obtained. The participants were asked to walk four times along a predefined straight walkway while two light-gates recorded their walking speed (WS). Then, they were asked to freely walk for 1 minute in a 100 m^2 empty space. The number of walked steps (N_{PAM}) was recorded during both experiments using a PAM (DynaPort Movemonitor™, Mc Roberts). Two inertial sensors (N_{REF}, OPAL™, ADPM Inc.) placed on the shanks of the participants were used as reference [2]. The same protocol was repeated after seven days to assess its reliability. Between the two lab sessions, the PAM was given to the participants for continuous physical activity recording for one week. Differences between sessions and walking conditions (straight versus free walking) were assessed for N_{PAM} and N_{REF} using repeated measures ANOVA. Bland-Altman plots were used to assess the agreement between N_{PAM} and N_{REF} and the mean absolute percentage error (MPE) between them was also calculated. The reliability of the error estimate was assessed using the Intraclass Correlation Coefficient (ICC(3,1)) [3]. Since walking speed is a commonly used primary outcome measure in clinical studies on physical activity, the relationship between WS and MPE was also investigated using power regression analysis.

Results: Five out of seventeen participants reached the low-active lifestyle threshold of 5000 steps per day.

The difference between N_{PAM} and N_{REF} was not statistically significant ($p=0.065$). No statistically significant differences between visits or walking conditions were found for step count ($p=0.60$ and $p=0.98$) and for MPE ($p=0.42$ and $p=0.27$). The mean (±SD) underestimation in the PAM was equal to 16±20 steps for straight walking and 14±28 steps for free walking.

The power regression trendline used to best fit the data showed a Pearson's r=0.74 for straight walking and r=0.61 for free walking. Two groups of patients where clearly identifiable from the MPE-WS plots (Figure 1), the first one having a high error in step detection (MPE>40%) and a slow walking speed (MWS<0.5 m/s), the second having a lower error (MPE<20%) and a higher WS. Test-retest relative reliability for MPE was high for both straight walking (ICC=0.80) and free walking (ICC=0.89).

Conclusion: The method presented in this study allowed to reliably assess step detection error (MPE) in indoor straight and free walking in a group of patients with multiple sclerosis. When using the same PAM adopted in the study or an equivalently performing one, a walking speed of 0.5 m/s or higher is needed to ensure an error in step detection lower than 20%. The consequences of inaccurate step count from a PAM can be estimated by projecting the error calculated in the lab over the seven days period of observation: the average number of potentially not detected steps per day was 513 (±712), equal to 10% of the low-active daily lifestyle threshold. This method could be used to assess any available PAM and the reference step calculation might be obtained with any alternative system. Reported results suggest that extreme care should be used when interpreting physical activity monitors data obtained in patients walking at significantly reduced speed.

BALLET DANCERS OF DIFFERENT BACKGROUNDS PERFORM SAUTÉ JUMPS WITH DIFFERENT HIP ROTATION

Debora Cantergi [1,*] Andreja Picon [2] Carolina Rodes [2] Jefferson Loss [1] Isabel Sacco [2]

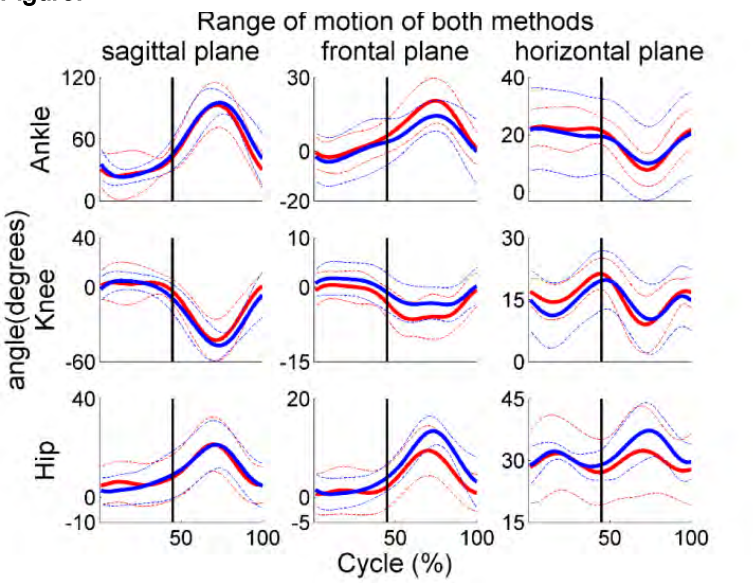
[1]Federal University of Rio Grande do Sul, Porto Alegre, [2]University of São Paulo, São Paulo, Brazil

Introduction and Objectives: The sauté is one of the first jumps a child learns in ballet class and the basis for other jumps in ballet. The sauté jump takes off and lands on both feet, and may be performed in all five ballet positions [1], which require the dancer to laterally rotate the lower limbs (turnout) [2]. While this is common in all ballet methods, the methodology used for teaching the sauté depends on the teachers' background [3]. Most ballet methods are empirical. At least one method, the Royal Academy of Dance (RAD), has developed a pedagogical progression in the study of ballet. This study aimed to evaluate the 3D kinematic characteristics of the ankle, knee and hip joints during the performance of sauté movement in first position by ballet dancers trained in empirical and RAD methods.

Methods: Eighteen elite ballerinas (9 from RAD and 9 from empirical method) performed 2 series of 8 sauté movements with classical music and the 6 central movements were analyzed. 3D kinematic data of hip, knee and ankle joint of the left lower limb were acquired by 6 IR cameras (OptiTrack FLEX: V100, Natural Point). An AMTI force plate was used to identify the contact and aerial phases of sauté. Kinematic trajectories were processed by low-pass 4th order Butterworth filter, cut-off frequency of 6 Hz (Visual 3D, CMotion). A sauté starts when the dancer leaves the force plate until the end of the next aerial phase (aerial phase + landing + full bending of the knees + push off until take off). Maximum and minimum joint angles and the range of motion (ROM) of all joints in 3 planes of motion were compared between groups using t-tests ($p<0.05$).

Results: Difference was found between hip ROM on the transversal plane (rotation), where the RAD group presented a greater ROM than the empirical group. No differences were found between RAD and empirical methods in ROM and maximum and minimum joint angles in all other planes (table 1, figure 1). Shippen showed that the lateral rotation of each joint is not constant while maintaining the same summed turnout in the whole lower limb during the performance of the demi-plié [4]. In a qualitative analysis of the time series of our results, we observed a similar kinematic pattern in the transverse plane during both contact (demi-plié) and aerial phases of the sauté. This qualitative analysis in addition to the observed difference between the methods in the hip ROM in the transverse plane, suggests that the perceived change in the lateral rotation happens in both movement phases in sauté. When the dancer is in contact with the floor, she can use the contact forces to manage her turnout, but in the aerial phase, it was expected that only the hip would perform lateral rotation, what did not happened. The RAD group had a significantly higher ROM than the empirical group, mainly when the dancers were in contact with the floor. It is possible that the RAD dancers had used the contact forces in order to enhance their natural lateral rotation.

Figure:



Caption: Mean range of motion of all dancers in empirical (red) and RAD (blue) groups. Positive values represent ankle and hip flexion, knee extension, ankle, knee and hip abduction and ankle, knee and hip lateral rotation. The contact phase goes from 45 to 100%.

Conclusion: Dancers trained in the RAD method perform the sauté with higher hip ROM in the transverse plane compared to dancers trained in empiric methods, suggesting that the use of a pedagogical method for teaching ballet may influence the turnout position when performing the sauté movement.

LOWER LIMB MUSCLE FASCICLE FUNCTION DURING GAIT IN CHILDREN WITH CEREBRAL PALSY

Lee Barber [1,*] Chris Carty [2 3] Luca Modenese [3] John Walsh [2] Roslyn Boyd [1] Glen Lichtwark [4]

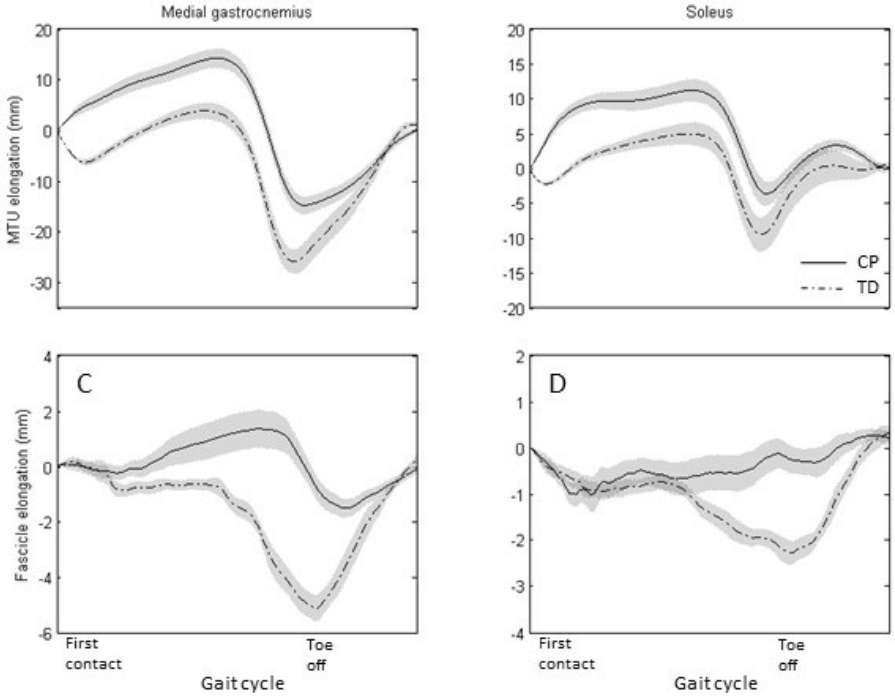
[1]Queensland Cerebral Palsy and Rehabilitation Research Centre, School of Medicine, The University of Queensland, [2]Queensland Children's Gait Laboratory, Queensland Health, Brisbane, [3]Centre for Musculoskeletal Research, Griffith Health Institute, Griffith University, Gold Coast, [4]Centre for Sensorimotor Neuroscience, School of Human Movement Studies, The University of Queensland, Brisbane, Australia

Introduction and Objectives: During gait in typically developed (TD) individuals, the muscles of the calf contract at levels that maintain a relatively constant muscle fibre length while the more compliant Achilles tendon acts like a spring to absorb and return energy during each step[1]. However the calf muscles of individuals with Cerebral Palsy (CP) adapt in response to spasticity to become smaller, weaker, more resistant to stretch, have increased antagonist co-contraction and the Achilles tendon becomes longer[2,3]. These neuromuscular adaptations of the calf in CP could reduce muscular force generation capacity and contribute to altered gait kinematics, however it is difficult to know what impact these spasticity driven adaptations will have on fascicle or tendon behaviour. The primary aim of this study was to investigate the function of medial gastrocnemius and soleus muscle-tendon unit (MG_{mtu}, SOL_{mtu}) and fascicles (MG_{fas}, SOL_{fas}) in children with CP compared to TD children.

Methods: 14 children with CP, age 9 years 10 months (2 years 9 months), 9 males, 5 female, 8 hemiplegia, 6 diplegia, GMFCS I=10, GMFCS II=4, and 10 TD, age 9 years 11 months (2 years 3 months), 6 males, 4 females, participated in the study. Participants performed 10 walking trials at a self-selected speed, barefoot, over a level walkway approximately 10m in length with force platforms embedded in the centre of the walkway. Trajectories of reflective markers attached to the trunk, pelvis, and upper and lower limbs were recorded and 3D gait kinematics and kinetics were computed. The vertical ground reaction force data was used to determine the step and stride times. During walking B-mode ultrasound images of the MG_{fas} and SOL_{fas} were also acquired. Fascicle lengths were analysed using a semi-automated tracking algorithm and MG_{mtu} and SOL_{mtu} were determined using OpenSim. Primary outcome measures were changes in MG_{mtu} and MG_{fas} length during mid- and terminal-phase of stance. An independent t-test ($p<0.05$) was used to compare differences between groups.

Results: In mid-stance the MG_{mtu} increased length similarly in both groups (CP = 5.5(3.8)mm; TD = 5.6(3.9)mm, p=0.96), however fascicles underwent significantly different lengthening between groups (p=0.02) with CP = 1.6(1.9)mm and TD = 0.1(0.8)mm. During late-stance the MG_{mtu} and SOL_{mtu} shortened similarly in both groups (CP = 21.0(6.8)mm, 7.7(2.4)mm; TD = 19.9(6.9)mm,7.4(4.9)), while the MG_{fas} shortened less (p=0.04) in the CP group (CP = 1.9(1.4)mm; TD = 3.4(1.9)mm). The SOL_{fas} underwent significantly different length changes between groups (p=0.04) with CP SOL_{fas} lengthening 0.6(1.7)mm and TD shortening by 0.7(0.8)mm).

Figure:



Caption: Medial gastrocnemius and soleus muscle tendon unit (MTU) and fascicle length change during one gait cycle in CP and TD. Data are mean ± SEM.

Conclusion: During walking, while the MG_{mtu} lengthens comparably between the groups, the MG_{fas} in the CP group lengthens through mid-stance while they remain relatively isometric in TD individuals. The eccentric action of the CP muscle fascicles during walking is consistent with the greater passive stiffness and perhaps greater reliance on passive rather than active muscle force. During the "push-off" phase the CP group had less MG_{fas} and SOL_{fas} shortening indicating that active muscle contraction contributed less to forward propulsion during walking. The altered behaviour is thought to result from structural and functional neuromuscular adaptations, however, conclusions about the contribution of the lengthening fascicles to passive force generation within the MTU cannot yet be established without further investigation. This is the first description of altered in vivo lower limb muscle fascicle and MTU behaviour during walking in children with CP. These novel findings raise clinical questions about the effects of repeated eccentric contractions on muscle function and recovery as eccentric contractions cause muscle damage, muscle soreness and delayed recovery in TD muscles. Furthermore, investigations of the impact of walking speed and gradient, and most importantly, treatments on fascicle, tendon and MTU behaviour are required to inform therapists, paediatric specialists and orthopaedic surgeons and guide conservative, pharmacological and surgical management.

PARTIAL DIRECTED COHERENCE APPLIED IN LOWER LIMB KINEMATIC DATA DURING RUNNING

Theresa H. Nakagawa [1,*] Ana F. Santos [1] Giovana Y. Nakashima [2] Fábio V. Serrão [1] Carlos D. Maciel [3]

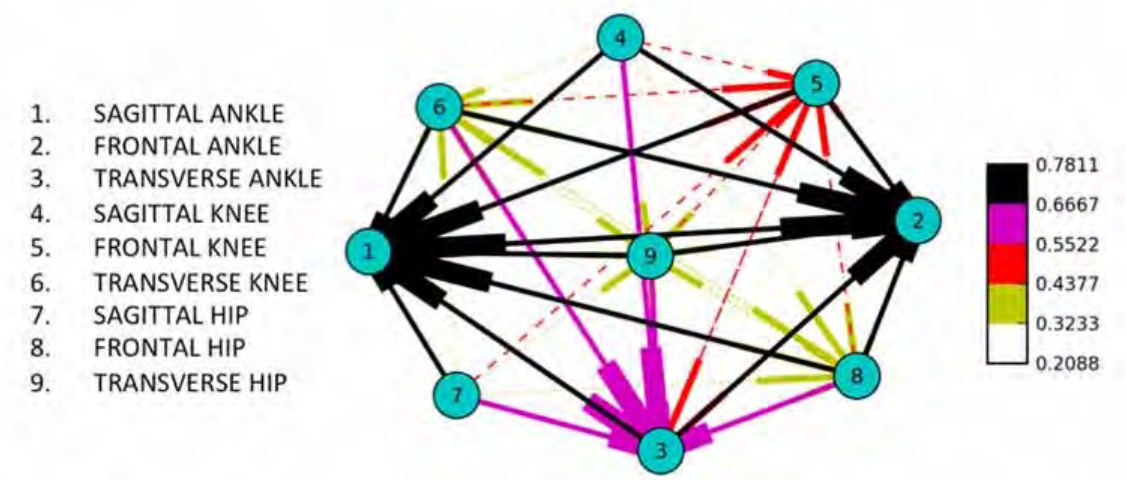
[1]Physical Therapy Department, Federal University of São Carlos, São Carlos, [2]Federal Institute of Education, Science and Technology of São Paulo, Salto, [3]Eletrical Engineering Department, University of São Paulo, São Carlos, Brazil

Introduction and Objectives: Despite the increasing number of runners and the health benefits related to running, this sport presents a potential risk to musculoskeletal injuries. Knee injuries are highly prevalent in runners. Although there is evidence supporting the dynamic coupling between lower limb joints, the causal interaction and the direction of this coupling is inconclusive [1]. In this sense, the *Partial Directed Coherence* (PDC), an approach of Granger causal inference analysis, has the potential to fill this gap of knowledge [2] clarifying if the hip, knee and ankle interjoint couplings occur in the distal to proximal or in the proximal to distal direction. Therefore, the purpose of this study was to analyze the causal directed interaction pattern of the hip, knee and ankle kinematics during running in healthy runners.

Methods: Thirty-one recreational runners (age: 27.7 ± 5.4 years; mass: 72.1 ± 13.6 kg; height: 23.7 ± 2.9 m; average running distance: 35.7 ± 18.3 km/wk; running experience: 4.1 ± 4.0 years) participated in this study. The participants were between 18 and 35 years of age and met the following criteria: they were rearfoot strikers (RFS), familiar with treadmill running and ran a minimum of 20 km/wk at least 3 months prior to study enrollment. After a 5-minute warm-up, the three-dimensional (3D) hip, knee and ankle kinematic data of the dominant lower limb (5 left, 26 right) were recorded at 240 Hz during treadmill running with a six-camera Qualisys motion analysis system (Qualisys Inc., Gothenburg, Sweden). The running trial was performed for 1-minute and 30-s samplings of data were collected. The Cardan angles were calculated using the Visual 3D software (C-Motion Inc, Rockville, MD). To compute PDC, the best Bayesian Information Criterion (BIC) order was used to estimate auto-regressive model. Taken in pairs, all channels PDC values were calculated and the average of their highest value was used in the results. All routines were developed in Python 2.7.4 (Python Software Foundation, USA). Paired samples t-tests were used to compare the distal-proximal or proximal-distal causal influence of the ankle-knee and hip-knee kinematics. The alpha level was set at .05.

Results: For the ankle-knee pair, the PDC value in the proximal-distal direction was significantly higher compared with the distal-proximal direction in the sagittal, frontal and tranverse plane (Table 1 and Figure 1). The PDC was also higher in the proximal-distal direction for the knee-hip pair in the frontal plane. There were no differences in the sagittal and transverse plane for the knee-hip kinematic pair. Granger causality concept has been used to determine causal influences among multivariate time series [3]. Its formulation is based on a simple idea: a causal interaction from a process Y to a process X is suggested if there is a reduction of prediction error of X when including the past of Y. PDC is a different approach of Granger causality applied in frequency-domain [1]. To the best of the author's knowledge, this was the first study to apply PDC analysis in the kinematic data in healthy runners. The causal influence of the ankle-knee and hip-knee pairs showed a predominant proximal-distal influence, meaning that the movement of the proximal joints of the lower limb have greater influence on the movements generate in the distal joints.

Figure:



Caption: Causal influence in kinematic data during running. Nodes 1 to 9 are the 3D kinematic joints, labeled at left. Each edge represents the maximum PDC computed between the joints, where thicker stubs represent “arrows”. Right label shows the ranges of maximum PDC values with different colors, where the first one is black (higher) and the last one is white (lower, invisible due to the white background).

Conclusion: The causal directed influence of the hip, knee and ankle movements during running occurred predominantly in the proximal-distal direction. The understanding of the pattern of causal directed influence may enhance the knowledge about the human movement, allowing a better diagnostic of the movement disturbances and improving the prevention and treatment programs for musculoskeletal injuries related to running.

Table: Mean (SD) of the joint pairs PDC values.

Joint Pairs	**PDC value**			
Sagittal Plane	**Distal-proximal**	**Proximal-distal**	***P-value***	**Direction Result**
Ankle-Knee	0.24 (0.14)	0.71 (0.13)	0.000*	Proximal-distal
Knee-Hip	0.24 (0.12)	0.26 (0.13)	0.51	~
Frontal Plane				
Ankle-Knee	0.45 (0.17)	0.75 (0.15)	0.000*	Proximal-distal
Knee-Hip	0.35 (0.11)	0.48 (0.18)	0.002*	Proximal-distal
Transverse Plane				
Ankle-Knee	0.41 (0.13)	0.58 (0.15)	0.001*	Proximal-distal
Knee-Hip	0.36 (0.14)	0.41 (0.13)	0.11	~

ACHILLES TENDON SHEAR WAVE SPEEDS SHOW NON-UNIFORM AGING EFFECTS

Laura C. Slane [1,*] Jack Martin [2] Ryan DeWall [1] Darryl Thelen [3] Ken Lee [1]

[1]Radiology, [2]Materials Science Program, [3]Mechanical Engineering, University of Wisconsin-Madison, Madison, United States

Introduction and Objectives: Tendon injuries and disease increase in incidence during aging. This susceptibility may result from age-related changes in tendon tissue properties, including reduced compliance of the interfascicular matrix [1] and an increase in collagen cross-linking [2]. However, it remains unclear how these microstructural changes affect macro-scale tendon compliance. Further, recent reports suggest that tendons are mechanically heterogeneous, with significant variations in material properties both within regions of the same tendon [3], and between different types of tendons [4]. Thus, it is also important to consider whether age-related changes progress uniformly throughout the tendon structure. Shear Wave Elastography is an ultrasound-based approach capable of noninvasively measuring localized shear wave speed (SWS) in soft tissues [5]. In transversely isotropic materials, such as tendon, SWS is believed to primarily depend on the shear elastic modulus [6], thus reflecting an important tissue mechanical characteristic. We have recently shown that SWS varies spatially throughout the Achilles tendon and increases with passive stretch [3], with middle-aged adults showing evidence of increased compliance in the proximal Achilles tendon (i.e. the gastrocnemius aponeurosis) [7]. The purpose of this study was to test the hypothesis that older adults would exhibit even greater declines in proximal Achilles SWS, and that evidence of the reduced compliance would extend into the more distal aspects of the Achilles tendon.

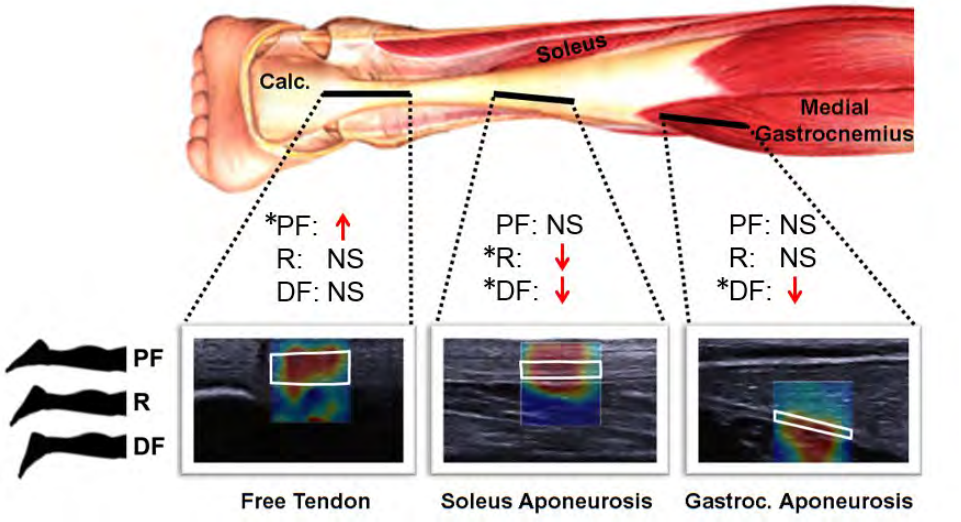
Methods: Thirty-five healthy adults (aged 21-71, mean: 46±19 yrs) were recruited for this study. Subjects provided written consent and were positioned prone on an exam table with their leg extended. SWS data were collected from the Achilles free tendon, the soleus aponeurosis and the medial gastrocnemius aponeurosis of the right limb. Data were collected from three different ankle postures in a random order: resting (R), dorsiflexed (R-15 deg) and plantarflexed (R+15 deg). SWS data were evaluated post-hoc at regions of interest defined within tendon boundaries. Regression analyses of SWS and age were performed for each tendon region and ankle posture, with significance evaluated at $p < 0.05$.

Results: SWS varied significantly with age in all tendon regions. Similar to aging effects observed previously in middle-aged adults [7], we found SWS in the dorsiflexed gastrocnemius aponeurosis to correlate negatively with age ($p<0.001$). With the inclusion of older adults (aged 61+) in this study, we also saw evidence of increased compliance in the soleus aponeurosis when the tendon was in a stretched position ($p<0.001$). This result suggests that not only does an age-related change in tendon compliance progress in severity with increased age, but that the location of these aging effects also progresses from the proximal region of the Achilles (i.e. the gastrocnemius aponeurosis) to more distal regions (i.e. the soleus aponeurosis). To our knowledge, only a few studies have evaluated non-uniform progression of aging effects in tendon, but of these, a similar progression was observed in a study of mouse tibalis anterior tendon stiffness [8].

In contrast to the other regions of the tendon, in the Achilles free tendon we found a significant aging effect only when the ankle was plantarflexed, and in this posture we found aging to correlate with increased SWS ($p=0.005$). In this posture, the Achilles tendon is close to its slack length [9], and is almost entirely unstretched. Thus, we hypothesize that this

decrease in compliance arises from age-related changes in tendon composition that have previously been observed (e.g. reduced compliance of the interfascicular matrix [1]).

Figure:



Caption: SWS data were collected from the Achilles tendon in plantarflexed (PF), resting (R) and dorsiflexed (DF) postures. Regions of interest (represented in white) were defined within the tendon boundaries. Significant SWS trends with aging are shown in red. *p<0.05, NS: Not significant, Calc: Calcaneus

Conclusion: Achilles tendon SWS is highly dependent on age, tendon stretch (i.e. ankle posture), and tendon region. These results suggest that aging-related changes in tendon progress non-uniformly with age, with different regions of the tendon showing contrasting effects of aging on compliance. Future studies will consider how spatially varying material properties affect localized tendon tissue strains, which is important for understanding the increased susceptibility for tendon tissue damage seen with aging.

AS-0154

IMPACT OF COMPETITION ON STRIDE RATE IN DISTANCE RUNNING

Michelle Norris [1,*] Ross Anderson [1] Ian Kenny [1]

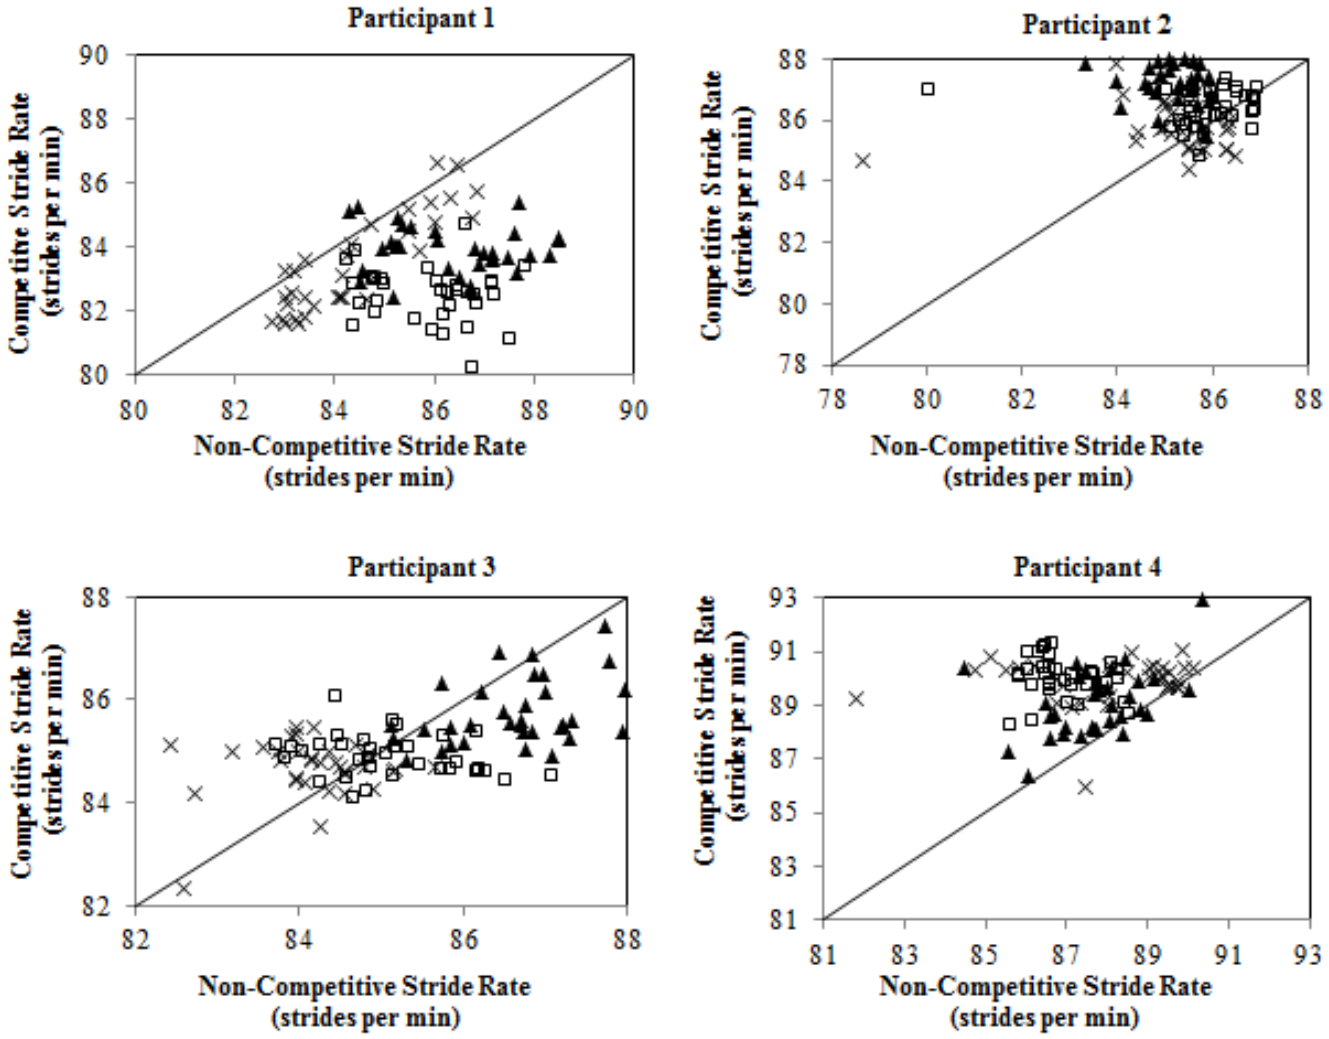
[1] Physical Education and Sport Sciences, University of Limerick, Limerick, Ireland

Introduction and Objectives: Stride rate (SR) has been identified as a major contributing factor to running economy and run completion time (Hunter and Smith 2007). However, much of the research investigating stride rate has focused around elite athletes. Whilst recent research surrounding recreational runners has investigated step width alterations (Brindle *et al.* 2014) there is no data pertaining to stride rate over a longitudinal period within this population. Objectives were to investigate how the stride rate of recreational runners during training compared to their stride rate during a competitive distance running event and its relationship with event outcome i.e. time.

Methods: To investigate stride rate changes accelerometer data from four recreational runners training for, and completing, a half marathon was collected. Participants were required to attach a tri-axial accelerometer (SHIMMER, Dublin, Ireland) to their anterio-medial distal tibia bi-laterally for each training run and the half marathon event. Data were sampled at 204.8 Hz (range = ±6 g, sensitivity = 200 mV/g). Participants' half-marathon race data were analysed as a competitive race (114 ± 13 minutes), whilst their longest recorded training run was analysed as a non-competitive comparison (106.5 ± 23 minutes). Data processing was performed using a custom built LabView™ programme (National Instruments, Berkshire, UK) with subsequent analysis in Excel. Running stride time data was extracted with any stride above 1s eliminated as this was designated to be a walking step (Rowe *et al.* 2011). Run time was then broken into 1% epochs and stride rate (strides per minute) was calculated for each epoch. Predicted half marathon time was calculated via the McMillan Running Calculator (McMillan 2014).

Results: Modal stride rate for the 1% epochs illustrated that competitive stride rate varied compared to non-competitive. Participant 1 chose a lower stride rate during the competitive run compared to their non- competitive run (83 vs 86 strides per minute). In contrast participant 4 ran at a higher stride rate than ran in their non-competitive run (90 vs 87 strides per minute). When investigating half marathon completion time participants 1 and 3 completed in less time than predicted (-10 and -2.5 minutes), whereas participants 2 and 4 completed in greater time than predicted (+5 and +6 minutes) (Table 1). Participant 1 and participant 4's data (Figure 1) are comparable to their modal stride rate. Participant 1 ran at a lower stride rate in all but 6 of the 1% epochs, while participant 4 ran at a higher stride rate in all but 5 of the 1% epochs. In contrast participant 2's stride rates indicate that for the majority of the competitive run they ran at a higher stride rate than the non-competitive run, whilst their modal stride rates were the same. Participant 3's data also illustrates variation to both to a higher and lower stride rate, with clear differences for the beginning and end of the runs. Both participant 2 and participant 4 completed the half marathon outside of their predicted completion time whilst also running at a higher stride rate for the majority of the run than in their non-competitive run.

Figure:



Caption: Figure 1. Comparison of 1% epoch stride rates for competitive and non-competitive runs. Diagonal line inserted representing no change in stride rate between competitive and non-competitive runs at that % epoch

Conclusion: Recreational runners' stride rates are variable both within a competitive running event and when compared to non-competitive runs. Results here indicate that variable and lower stride rate than previously utilised may be a better strategy to completing a running event. Participants who ran at higher stride rates then had previously been performed (participants 2 and 4) resulted in a decline in predicted performance outcome. Whilst participant 3 and participant 4 saw identical increases (0.07 m/s) in speed from non-competitive to competitive runs participant 3 may have adopted more efficient stride rates throughout the race resulting in a preferred race outcome. As increased stride rate is associated with numerous biomechanical alterations linked to injury and efficiency, such as impact shock and decreased centre of mass vertical excursion (Schubert *et al.* 2014), perhaps more emphasis should be placed upon stride rate than previously thought.

Table:

	Participant 1	Participant 2	Participant 3	Participant 4
Non-Competitive Average Speed (m/s)	2.96	2.47	3.48	3.04
Competitive Average Speed (m/s)	3.06	2.71	3.55	3.11
Non-Competitive Modal Stride Frequency (strides per minute)	86	86	85	87
Competitive Modal Stride Frequency (strides per minute)	83	86	85	90
Predicted Marathon Time (minutes)	125	125	102.5	107
Half Marathon Completion Time (minutes)	115	130	99	113

LEG LENGTH DISCREPANCY AFFECTS THE SAGITTAL PLANE BIOMECHANICS OF THE LOWER LIMBS DURING THE STANCE PHASE OF WALKING

Renan Alves Resende [1,*] Kevin Deluzio [2] Renata Noce Kirkwood [3] Renato Guilherme Trede Filho [1] Carolina Carvalho Martins [1] Sérgio Teixeira Fonseca [4]

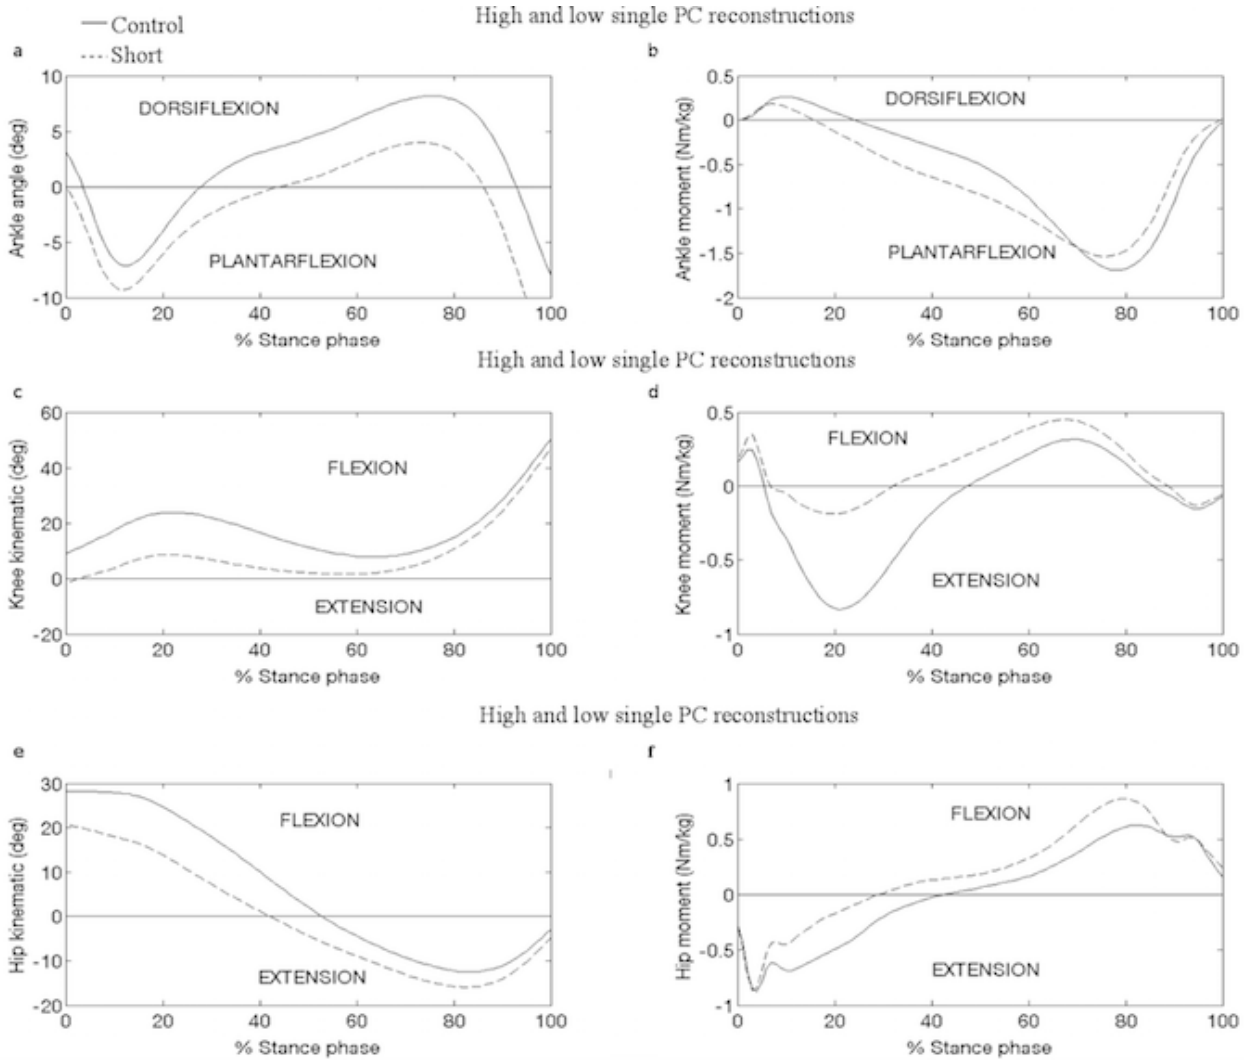
[1]Physical Therapy, Universidade Federal dos Vales do Jequitinhonha e Mucuri, Diamantina, Brazil, [2]Mechanical and Materials Engineering, Queen's University , Kingston, [3]Kinesiology and Physical Education, Wilfrid Laurier University, Waterloo, Canada, [4]Physical Therapy, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

Introduction and Objectives: Leg length discrepancy (LLD) occurs in up to 70% of the population[1]. LLD has been related to the occurrence of different lower limb injuries, such as trochanteric bursitis[2], patello-femoral pain[3] and posterior tibial tendon dysfunction[4]. Although it has already been demonstrated that LLD greater than 2 cm affects the biomechanics of lower limbs during gait, there is no consensus regarding the effects of having LLD smaller than 2 cm. Therefore, the purpose of the present study was to investigate the effects of small LLD on the angular displacement and moments of force of the ankle, knee and hip in the sagittal plane during the stance phase of gait. These findings may improve understanding of the relationship between LLD and the occurrence of lower limb injuries, since most people have LLD smaller than 2 cm.

Methods: Kinematic and kinetic data of 19 participants were collected while they walked wearing flat thick and flat thin sandals (1.45 cm of thickness difference between sandals). Individuals with true or functional LLD were excluded. Two conditions were investigated: (1) control condition - the participant walked wearing flat thick sandals; (2) short limb condition – thin flat sandal on the right foot and thick flat sandal on the left foot. The right lower limb biomechanics were analyzed for both conditions. Ankle, knee and hip angular displacement and internal moments of force during the stance phase were measured with a motion capture system and force platforms. Principal component analysis was used to compare differences between conditions[5]. The scores of the principal components retained for analysis were compared between conditions using Student's t-test.

Results: Table 1 presents the results of this study. Gait waveforms represented by high (+ 1 standard deviation) and low (- 1 standard deviation) principal component scores for each significant principal component are shown in Figure 1.

Figure:



Caption: Control and short limb condition differences demonstrated by the Student's t-test. Shown in the figures are the waveforms that represent high and low principal component (PC) scores for the indicated measure and PC. In all cases, the waveform that represents the PC score (i.e. high or low PC score) that characterizes the short limb condition is shown as a dashed line; the solid line is the waveform that represents the control condition PC score. The ankle dorsiflexion angle PC1 (a); ankle dorsiflexion moment PC1 (b); knee flexion angle PC1 (c); knee flexion moment PC1 (d); hip flexion angle PC1 (e); hip flexion moment PC1 (f).

Conclusion: The increased ankle plantarflexion and knee extension and reduced hip flexion angles may be the strategies implemented by the participants in order to increase functional lower limb length during the short limb condition. The increased ankle plantarflexion moment may help to explain the relationship between LLD and the posterior tibial tendon dysfunction[4]. In addition, the increased knee extension angle and reduced knee extension moment during early stance may indicate reduced quadriceps action on the short lower limb, which may help to explain the association between patella-femoral pain and LLD[3]. Therefore, the results of this study suggest that LLD smaller than 2 cm should not be overlooked in clinical settings.

Table:

Measure	PC	Variance explained (%)	*p-value*	Effect size	Interpretation based on the effects of the short limb condition
Ankle dorsiflexion angle	1	53.7	<0.001	0.85	Had greater ankle plantarflexion throughout stance.
Ankle dorsiflexion moment	1	60.3	<0.001	0.92	Had greater ankle plantarflexion moment in early stance and smaller plantarflexion moment in late stance.
Knee flexion angle	1	73.2	0.018	0.52	Had greater knee extension in early stance.
Knee flexion moment	1	76.2	0.002	0.64	Had smaller knee extension moment in early stance.
Hip flexion angle	1	78.8	<0.001	0.90	Had smaller hip flexion during the first half of the stance phase.
Hip flexion moment	1	50.4	<0.001	0.84	Had smaller hip extension moment in early stance and greater hip flexion moment in late stance.

Caption: Principal components (PCs) that demonstrated differences between short limb and control conditions. Percentage of variance explained and an interpretation of each PC are also provided.

THE MECHANICAL FUNCTION OF THE TIBIALIS POSTERIOR MUSCLE AND ITS TENDON DURING WALKING

Jayishni Maharaj [1,*] Andrew Cresswell [1] Glen Lichtwark [1]

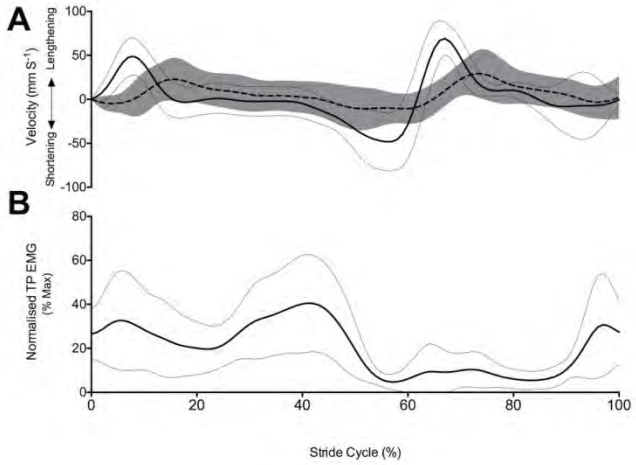
[1]School of Human Movement and Nutrition Sciences, The University of Queensland, Brisbane, Australia

Introduction and Objectives: During walking, the tibialis posterior (TP) muscle is active during initial contact, to resist subtalar joint (STJ) pronation and presumably to absorb mechanical energy. The TP muscle is also active during mid- to late-stance to enable STJ supination and generate mechanical energy in the frontal plane. The ability of a muscle to store and release energy is highly dependent on the interaction of its muscle fascicles and series elastic element (SEE), consisting of the tendon and aponeurosis. Compliant tissues are able to decouple the length changes of muscle fibres from the whole muscle-tendon unit (MTU) during cyclic activities such as gait [1]. Therefore, distinguishing the roles of the contractile and SEE is fundamental in understanding the mechanics and energetics of the whole MTU during locomotion. Based on the architectural properties of the TP, which has short fibres and a long SEE, we hypothesised the TP tendon might be sufficiently compliant to store and release energy during walking, particularly to buffer stretch in early stance. We speculated a lengthening in the TP MTU during early stance with little or no stretching of its muscle fascicles.

Methods: We directly measured TP length and activation in healthy subjects (n=8, 6 male, age 19-35yrs, height 1.60-1.87m, mass 54-100kg) at a preferred speed. Muscle electrical activity was recorded using bipolar fine-wire electrodes inserted in the TP under ultrasound guidance. MTU strain and joint moments were modelled in Opensim [2] in a custom, scaled model driven through an inverse kinematics and dynamics approach. Muscle fascicles were imaged in the sagittal plane using dynamic ultrasound imaging (80 Hz) and fascicle length changes were tracked with a semi-automated optic flow algorithm [3]. Length changes of the MTU and fascicles were calculated relative to mean fascicle length at foot contact for each participant and mean values were calculated for complete stride cycles across all subject.

Results: As illustrated in Figure 1A, TP fascicles followed a different strain pattern than that of the MTU over the stride cycle. At contact, the MTU rapidly lengthened, indicated by a peak positive velocity during early stance, whilst its activation increased (Figure 1B). The TP muscle was actively generating a supinatory moment during this time to decelerate the rapid STJ pronation. Active MTU lengthening with isometric fascicles (Figure 1A) indicates stretch and absorption of energy in the SEE. Muscle fascicles did lengthen after the MTU ceased stretching, indicating some absorption of energy by the fascicles, however the magnitude of the fascicle lengthening velocity was significantly less than the MTU ($P \leq 0.05$). During late stance, most of the shortening observed in the muscles fascicles occurred during muscle deactivation (Figure 1B) when the elastic tissues were also rapidly recoiling. Energy stored in the SEE was likely released during late stance to power supination of the STJ.

Figure:



Caption: Figure 1: Group mean and standard deviation of (A) velocity of tibialis posterior (TP) muscle fascicles (dotted line) and MTU (solid line) and (B) TP muscle activity (rectified and filtered) during a stride cycle at preferred walking speed. Initial contact occurs at 0% of the stride cycle.

Conclusion: The results of this study illustrate two important findings. First, decoupling of muscle fascicle strain from MTU strain was enabled by the compliant SEE of TP. This finding is consistent with results from other distal lower limb muscles (e.g. medial gastrocnemius) during gait [4], however this is the first demonstration in a lower limb muscle that acts predominately in the frontal plane.

Second, we showed that immediately following contact, TP fascicles remained relatively isometric whilst its MTU lengthened, suggesting stretch of the SEE. Energy absorbed in the SEE during this period was a result of a rapid supinatory moment at the STJ with excessive STJ pronation (negative STJ power) in the braking phase of walking. It is apparent that TP tendon compliance can mechanically buffer excessive strain and high velocities in the muscle fascicles, potentially protecting its fascicles from eccentric muscle damage. The role of the SEE in dissipating energy has mainly been illustrated in the distal tendons of wild turkeys and cats [5], [6]. This study, presents a similar role for the human TP muscle during walking. Excessive strain of the SEE during early stance may, however, predispose some individuals to overuse tendon pathologies. Further investigations into how extrinsic factors and foot dynamics influence TP tendon strain is required.

THE EFFECT OF A RIGID ANKLE BRACE ON JOINT KINETICS DURING MAXIMAL CYCLING

Paul R. Barratt [1,*] Thomas Korff [1]

[1]Centre for Sports Medicine and Human Performance, Brunel University, Uxbridge, United Kingdom

Introduction and Objectives: Maximal cycling power is predominantly produced by hip extensor, knee extensor, knee flexor and plantarflexor power. Hip extensor power is absorbed by the plantarflexors and transferred to the crank [1,2]. For this mechanism to work effectively, the plantarflexors need to contract quasi-isometrically to stiffen the ankle joint, which requires strong plantarflexor muscles.

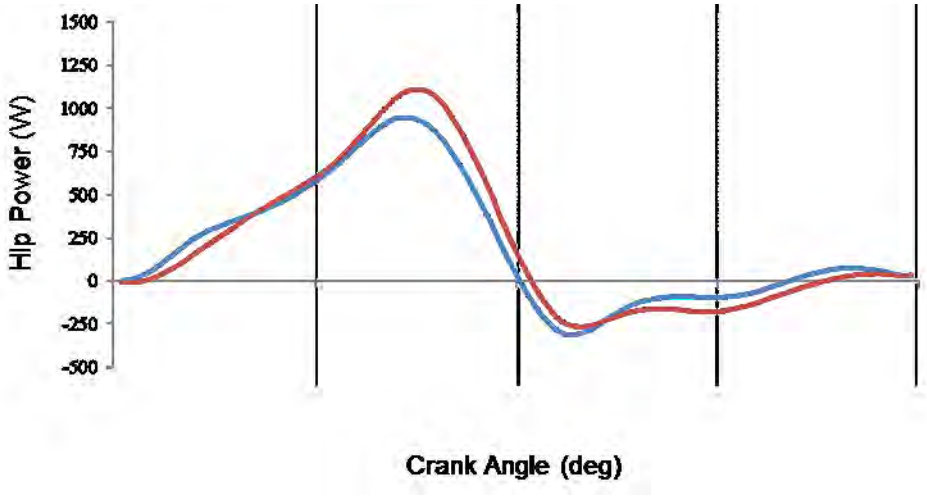
It has previously been demonstrated that the plantarflexors are maximally recruited during maximal cycling [3], and that ankle extension strength differentiates between more and less powerful sprint cyclists [4]. Interestingly, it has also been reported that the hip extensors are not maximally recruited during maximal cycling [3] , and that hip extension strength does not differ between more and less powerful sprint cyclists [4]. Taken together, these findings suggest that the amount of usable hip extension power may be limited by the plantarflexor's ability to stiffen the ankle joint sufficiently. If this was the case, a stiffer ankle joint could allow the hip extensors to operate closer to its maximal capacity, which would in turn result in higher overall maximum power.

In this study, we used an ankle brace to probe this mechanism. We hypothesized that the increased joint stiffness imposed by a rigid brace that fixed the ankle in place would allow the hip extensors to generate more power during maximal cycling.

Methods: Eight male cyclists (31 ± 5 years old, 79.2 ± 6.1 kg), performed a short (4 s) isokinetic maximal cycling bout at 90 rpm with braces that held the ankle joints in a fixed-position. For the control condition, the participants performed the same protocol with weights of equivalent mass to the braces (1.16 kg per leg) attached to each leg. Joint powers were determined by means of sagittal plane inverse dynamics. Kinetic data were acquired by instrumented force cranks, and kinematic data were acquired by means of high speed motion analysis. A paired t-test was used to test the hypothesis that mean hip extension power would be greater when using the ankle braces compared to the ankle weights.

Results: In conformity with our hypothesis, cyclists produced greater hip extension power when cycling with the rigid ankle braces compared to the ankle weights (Braces; 567 ± 112 W vs. Weights; 501 ± 74 W, $p = 0.028$). The magnitude of this effect was moderate (effect size; 0.73). Figure 1 illustrates that the ankle brace (red) and ankle weights (blue) hip power curves tend to diverge at the point of peak power production during the pedal cycle (approximately 135 degrees).

Figure:



Caption: Figure 1. Hip power during maximal sprint cycling when using ankle braces (red) and ankle weights (blue).

Conclusion: These results demonstrate that the ability to stiffen the ankle joint limits hip extension power during maximal cycling. They thereby explain previous findings as to why the hip extensors are not maximally activated during maximal cycling.

Confirmation of this mechanism gives significant insights into the mechanisms underlying power production during maximal multi-joint movements. In particular, these results highlight the importance of all power producing muscle groups during maximal cycling. Previous research focussed predominantly on the dominant power producing actions of knee extension and hip extension during maximal cycling. Our results add to this body of knowledge that the plantarflexors are an important muscle group to consider not only for their power producing capability but also for their ability to enable muscular power to be transferred from the proximal muscles to the pedal.

From an applied perspective, these findings give insights into the potential benefits of training interventions targeting ankle joint strength for sprint cycling performance. They suggest that strengthening the plantarflexors could result in improved sprint cycling performance.

BIOMECHANICAL ANALYSIS OF THE UPPER BODY IN THE PEN-HOLD GRIP AND THE HAND-SHAKE GRIP IN TABLE TENNIS

Tianjiao Dai [1]Graham Arnold [1]Walter Williamson [1]Rami Abboud [1]Weijie Wang [1,*]

[1]University of Dundee, Dundee, United Kingdom

Introduction and Objectives: There are two ways of griping the table tennis bat, pen-hold grip and hand-shake grip. Argument about which grip is better is endless where one group belief suggests that the pen-hold grip provides a faster speed but may more easily result in wrist injury; whereas others think that the hand-shake grip can get a larger range of motion. Although there were some previous studies comparing the two grips, their research methods were limited to video observation or literature review. The aim of this study was to investigate the movements and muscle activities in the upper limbs, back, and waist during the hitting ball in both pen-hold grip and hand-shake grip and to compare the differences between these two hand grips biomechanically.

Methods: Seventeen male subjects aged from 21 to 31 were recruited in this study. They were required to play the hitting ball using four ways, pen-hold forehand, pen-hold backhand, hand-shake forehand, and hand-shake backhand. A set of markers on their body were collected using Vicon® motion capture system, and the electromyography (EMG) in the brachioradialis, pronator teres, biceps brachii, triceps brachii, deltoid, trapezius and erector spinae were synchronically measured using wireless Delsys® system. An in-house made model was deigned to calculate the joint movements in the shoulder, elbow and wrist.

Results: Significant differences were found in the shoulder, elbow and wrist joint angles and seven muscles EMGs between the pen-hold and hand-shake grips. Four ways of holding bat produce different ranges of motion in the shoulder, e.g. in Table 1. In general, the pen-hold backhand needs the largest movement of the three joints, followed by the hand-shake forehand, the pen-hold forehand and the hand-shake backhand as the least. As whole, the pen-hold grip requires larger movements in joints than hand-shake grip in a swing motion. Regarding to EMG, it is readily identified that the pen-hold grip relies on the forearm, back and waist muscles much more than the hand-shake grip. Although the hand-shake grip employs more upper arm muscles than the pen-hold one, the assessing scores from both grips are very similar. Therefore, the pen-hold grip needs to active more muscles to achieve a swing motion than the hand-shake one.

Conclusion: Evidence of this study suggests the hand-shake grip is appropriately recommended for the table tennis beginners, recreational players and amateurs, while the pen-hold grip is more suitable for the more skilful players. The pen-hold grip generally needs a larger range of motion, especially in the elbow flexion, and involves more muscle activities, especially in the forearm, back, and waist than the hand-shake grip. This may result in a higher risk in the injury of wrist, elbow, and waist for using the pen-hold grip.

Table:

Hand-grips	Mean (Degree)	Std. Error	p
Pen-hold Forehand	90.15	1.18	-
Pen-hold Backhand	85.88	1.07	0.008
Hand-shank Forehand	84.82	1.15	0.001
Hand-shank Backhand	84.70	1.22	0.001

Caption: Table 1. Range of motions in the shoulder flexion and extension from 4 holding ways (p values against the pen-hold forehand)

SPRINT ACCELERATION MECHANICS: THE ROLE OF HAMSTRING MUSCLES IN HORIZONTAL GROUND REACTION FORCE PRODUCTION

Jean-Benoit Morin [1,*] Pascal Edouard [2] Philippe Gimenez [3] Pierrick Arnal [2] Pedro Jimenez-Reyes [4] Pierre Samozino [5] Jurdan Mendiguchia [6] Matt Brughelli [7]

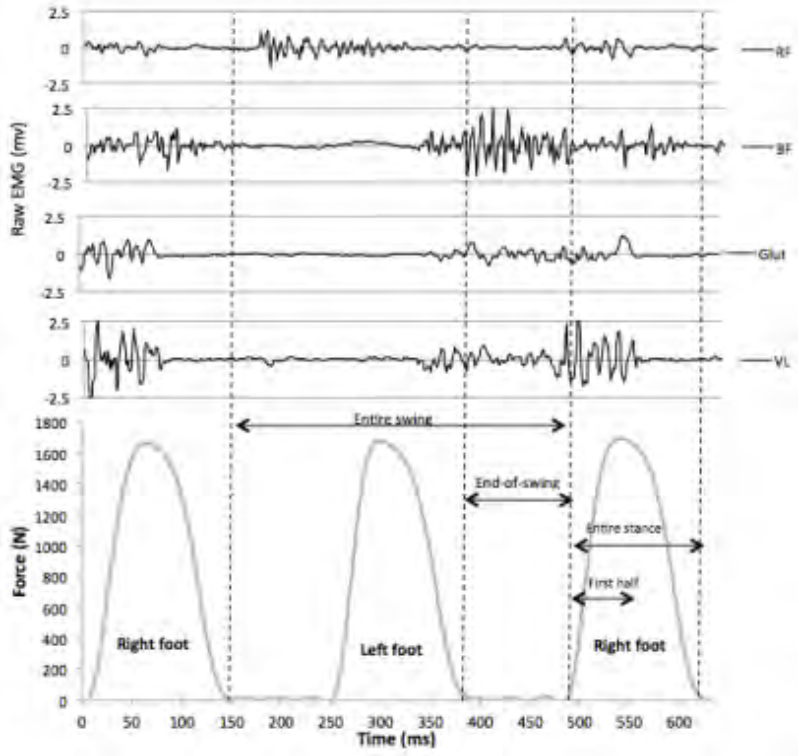
[1]University of Nice Sophia Antipolis, Nice, [2]University of Saint-Etienne, Saint-Etienne, France, [3]University of Montreal, Montreal, Canada, [4]Catholic University of San Antonio, Murcia, Spain, [5]University of Savoy, Chambéry, France, [6]Zentrum Rehab and Performance Center, Barañain, Spain, [7]Auckland University of Technology, Auckland, New Zealand

Introduction and Objectives: Recent literature has clearly shown the importance of horizontal ground reaction force (GRF) production in sprint acceleration performance, with direct applications in numerous sports such as soccer, rugby or athletics [1,2]. Furthermore, an increasing number of modeling and clinical studies have shown that hip extensors, hamstring muscles in particular, are (i) very likely contributors of sprint acceleration performance [3] and (ii) some of the most frequently injured and re-injured muscles in all sports that involve sprinting [4,5]. However, no study has approached the problem using synchronous experimental measurements of GRF and muscle activity during accelerated (i.e. non-constant speed) runs. In this context, the ability to develop high amounts of horizontal GRF during sprint acceleration, notably at high velocity and/or in an upright body posture, could be related to a higher contribution of hip extensors. Our aim was therefore to experimentally test the role of the main hip extensor muscles (hamstring and gluteus) in producing horizontal GRF during short, maximal sprints.

Methods: The torque capability of knee and hip extensors and flexors were tested concentrically and eccentrically with an isokinetic dynamometer in 14 males familiar with sprint running (team sports and athletics). Then, subjects performed 6-s sprints from a crouched still start on a motorized instrumented sprint treadmill. EMG activity of Vastus Lateralis, Rectus Femoris, Biceps Femoris and Gluteus Maximus muscles of the right leg was synchronized (1000 Hz) with horizontal and vertical GRF measurements. For each muscle, EMG activity was expressed relative to the activity measured during a maximal voluntary isometric contraction in a standardized position. EMG and GRF data were averaged for all the steps from the second step to the end of the 6-s. EMG data were also averaged over the first half of stance, entire stance, entire swing and end-of-swing phases.

Results: None of the isokinetic variables were significantly correlated with horizontal GRF. Only a tendency ($P = 0.074$) was found between EMG activity of the BF at the end of the swing and horizontal GRF. However, multiple linear regression analysis showed a significant relationship ($P = 0.024$) between horizontal GRF and the combination of both BF EMG during the end of the swing and peak torque during eccentric knee flexion. Finally, gluteus force and EMG activity were not related to horizontal GRF production. We found similar results when sub-dividing the analysis into an early acceleration phase (first 3 seconds), and a late acceleration phase (last 3 seconds).

Figure:



Caption: Synchronized raw EMG data and vertical GRF signals during a typical sprint stride (7th stride of a maximal 6-s acceleration). The following phases for EMG analysis were determined from vertical GRF data (30 N threshold): entire swing, end-of-swing, entire stance and first half of the stance.

Conclusion: The greatest amount of horizontal GRF production during sprint acceleration was found in subjects who were both able to highly activate their hamstring muscles just before ground contact and had the greatest capacity to produce eccentric hamstring torque. In other words, hamstring EMG activity during the swing and end-of-the-swing phases and eccentric knee flexor peak torque is related to the amount of horizontal GRF produced during sprinting, likely because of the backward “pawing” action of the leg just before contact. This relationship, observed here experimentally for the first time, makes even more sense when accounting for the electromechanical delay between EMG activity and force production by the muscles.

UNEXPECTED CHANGES IN FRICTION ON CLAY COURT SURFACES ARE ASSOCIATED WITH ANKLE INVERSION INJURY RISKS IN TENNIS PLAYERS

Chelsea Starbuck [1,*]Victoria Stiles [2]Daniel Ura [3]Matt Carre [3]Sharon Dixon [2]

[1]Sport and Health Sciences, University of St Mark and St John, Plymouth, [2]Sport and Health Sciences, University of Exeter, Exeter, [3]Sports Engineering Research Group, The University of Sheffield, Sheffield, United Kingdom

Introduction and Objectives: Ankle inversion injuries are the most commonly reported injuries in tennis [1]. Although lower friction clay surfaces have been associated with reduced injury risks [2, 3], lower limb injuries are still reported on clay [4]. During match play friction properties across the surface may change due to player interaction with the court. Therefore there may be areas of expected and unexpected friction levels to which players must respond and attempt to maintain balance in order to successfully execute a tennis stroke. The current study aims to examine players' response to expected and unexpected changes in friction and the implications biomechanical factors associated with injury risk.

Methods: Sixteen university tennis players (19.93 ± 0.96 years, 1.74 ± 0.10 m and 66.75 ± 10.36 kg) volunteered for the current study approved by the Institutional Ethics Committee. On a synthetic clay surface participants performed an 180^{o} turning movement (running approach speed 3.9 ± 0.20 m.s^{-1}). To adjust friction levels the volume of sand above the force plate was altered (kg per m^2 surface area). Five testing conditions consisted of a baseline condition (12 kg/m^2), two expected conditions (16 kg/m^2 and 20 kg/m^2) and two unexpected conditions (16 kg/m^2 and 20 kg/m^2). The order of the five testing conditions were randomly assigned. Ten trials of each condition were collected with any unsuccessful trials omitted and repeated. Participants were told which condition (12/ 16/ 20 kg/m^2) they would receive for the expected trials. However, for the unexpected trials the were told they would experience the baseline condition. Prior to each test trial participants performed a baseline condition to allow them to make comparisons with the baseline condition. Ankle kinematics (Peak Performance Technologies, 120 Hz), in-shoe pressure data (Pedar, 100 Hz) and onset time of tibialis anterior muscle activity (Delsy trigo wireless system, 4000 Hz) were collected. Ankle frontal plane moments were calculated using inverse dynamics from synchronised force (AMTI, 960 Hz) and kinematic data. A mixed model ANOVA was conducted to examine the influence of expectation and friction level on players' biomechanical response.

Results: The expected friction conditions resulted in lower ankle inversion angles at ground contact (-.33 ± 3.82^{o}) compared to the unexpected conditions (-7.73 ± 3.24^{o}; ES = .595, P =.001). For the lowest friction condition, the tibialis anterior activated earlier during the expected conditions (.031 ± .014 s) compared to the unexpected changes in friction (.016 ± .021 s; ES = .343, P =.013). Significantly (P <.05) greater pressures were produced in the medial regions of the foot (forefoot, midfoot and heel) for the expected conditions compared to the unexpected conditions. The expected 16 kg/m^2 condition resulted in greater everter moments (-158.43 ± 99.39 N.m) compared to the unexpected 16 kg/m^2 condition (-150.56 ± 95.04 N.m; ES = .330, P =.04). However, no differences in everter moments were observed between the expected and unexpected conditions with 20 kg/m^2 of infill.

Conclusion: Results indicated differences in biomechanical measurements associated with greater risk of ankle inversion injuries during unexpected conditions on a clay court surface. Later onset of muscle activity of the tibialis anterior, which

eccentrically controls ankle inversion during ground contact, is consistent with greater initial inversion angles during the unexpected conditions. Previous reports have suggested larger initial inversion angles to increase risk of the occurrence of an ankle inversion injury [5]. Thus, when clay court friction is unexpectedly reduced players are at greater risk of sustaining an ankle inversion injury. During the expected conditions players increased their control of sliding through greater pressures in the medial regions of the foot. Additionally, players had greater everter moments during the expected conditions and therefore were able to control the subtalar joint during sliding. Greater control of sliding and of the subtalar joint suggest reduced player risk of ankle inversion injuries during the expected conditions when compared to the unexpected conditions. Unexpected changes in clay court friction may occur during match play as a result of players' interaction with the surface, which could have implications on biomechanical aspects related to injury. Therefore maintenance of the clay court surfaces during match play in addition to appropriate conditioning training of the lower limb musculature controlling the subtalar joint is important in preventing ankle inversion injuries on clay court surfaces.

SPATIOTEMPORAL VARIABLES OF ABLE-BODIED AND AMPUTEE SPRINTERS IN MEN'S 200-M SPRINT

Hiroaki Hobara [1,*] Yoko Sano [1] Yoshiyuki Kobayashi [1] Thijs Heldoorn [1] Masaaki Mochimaru [1]

[1] Digital Human Research Center, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan

Introduction and Objectives: Time difference of world records between able-bodied sprinters and amputee sprinters using running-specific prostheses (RSPs) in the men's 200-m sprint is still about 1.5 seconds (as of 12 December 2014). Theoretically, forward velocity in a 200-m sprint is the product of step frequency and step length. According to a previous study, the differences in 100-m sprint performance between able-bodied (ABS) and amputee sprinters (bilateral and unilateral transtibial amputees using RSPs) groups would be due to a shorter step length rather than lower step frequency [1]. However, it remains unclear if the step length deterioration in amputee sprinters exists or changes at other sprint events. Therefore, the goal of this study was to examine the hypothesis that the difference in the 200-m sprint performance of ABS and amputee sprinters is due to a shorter step length rather than a lower step frequency.

Methods: 16 ABS, 13 sprinters in the T44 class (defined as any athlete with lower limb impairment/s that meets the minimum disability criteria for lower limb deficiency, impaired lower limb passive range of motion, impaired lower limb muscle power, or leg length difference) and 5 sprinters in the T43 class (defined as double below-knee amputees and other athletes with impairments that are comparable to a double below-knee amputation) competing in men's 200-m races were analyzed from publicly available internet broadcasts. These races included several Olympics and Paralympics (2008 and 2012) competitions, the International Association of Athletics Federations (IAAF) World Championships in athletics (2009, 2011, and 2013), the International Paralympic Committee (IPC) Athletics World Championships (2011 and 2013), and the IPC Athletics European Championship (2014).

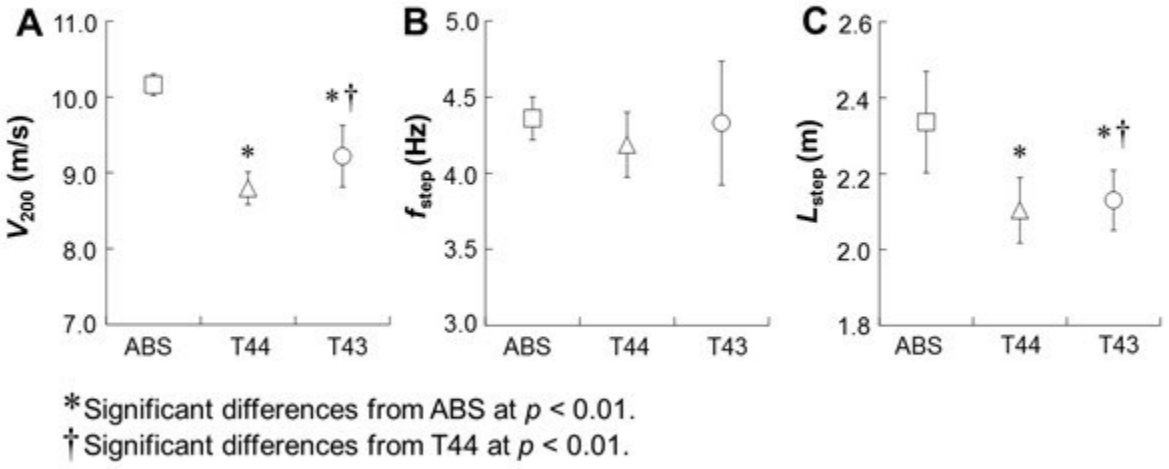
Data were collected only from the finals in each competition. In the present study, individual races were excluded from the analysis if the athlete did not complete the race or the athlete's body was not visible throughout the entire race. In the case of the T44 and T42 athletes, sprinters who did not use RSPs were also excluded from the analysis.

According to a previous study [1], we determined the mean forward velocity in the 200-m sprint (V_{200}) of each individual by dividing the race distance (200 m) by the official race times, which were obtained from each competition's official website. In the present study, we calculated the average step frequency (f_{step}) by dividing the number of steps by the official race time. Finally, average step frequency (L_{step}) was computed by dividing race distance (200-m) by the number of steps. One-way analyses of variance (ANOVA) were performed for V_{200}, f_{step}, and L_{step} to determine whether there were significant differences among the four groups (ABS, T44 and T43). Bonferroni post-hoc multiple comparison tests were performed if a significant main effect was observed. Statistical significance was set to be $p < .05$.

Results: As shown in Figure 1-A, we found that the V_{200} of ABS was faster than that of the T44, T43 and T42 groups. Furthermore, although there were no significant differences in f_{step} among the three groups, the L_{step} of the ABS was significantly longer than in the T44 and T43 groups (Figure 2-B and C). The results of the present study suggest that the differences in 200-m sprint performance between ABS and amputee sprinters can indeed be attributed to a shorter L_{step} rather than a lower f_{step}. A shorter L_{step} in amputee sprinters may be the result of lower force generation in their RSPs

compared with the legs of ABS [2-5]. Additionally, in 200-m sprint events, races are performed in a counterclockwise direction, beginning on the curve and ending on the home straight. Amputee sprinters have to compensate for higher rotational forces by using remaining joints when running in the bend track, leading to a relatively shorter step length.

Figure:



Caption: Comparison of average forward velocity (A), step frequency (B), and step length (C) for the four groups.

Conclusion: In conclusion, the results of the present study support our initial hypothesis that the difference in the 200-m sprint performance of ABS and amputee sprinters is due to a shorter step length rather than a lower step frequency. A shorter step length in amputee sprinters may be the result of lower force generation in their RSPs compared with the legs of ABS, or compensatory strategies for running on a curved track.

FATIGUE LEADS TO MORE CHANGES IN TRUNK AND HIP KINEMATICS IN NOVICE VERSUS COMPETITIVE RUNNERS

Ellen Maas [1,*] Jorien de Bie [1] Riet Vanfleteren [1] Wouter Hoogkamer [1] Benedicte Vanwanseele [1]

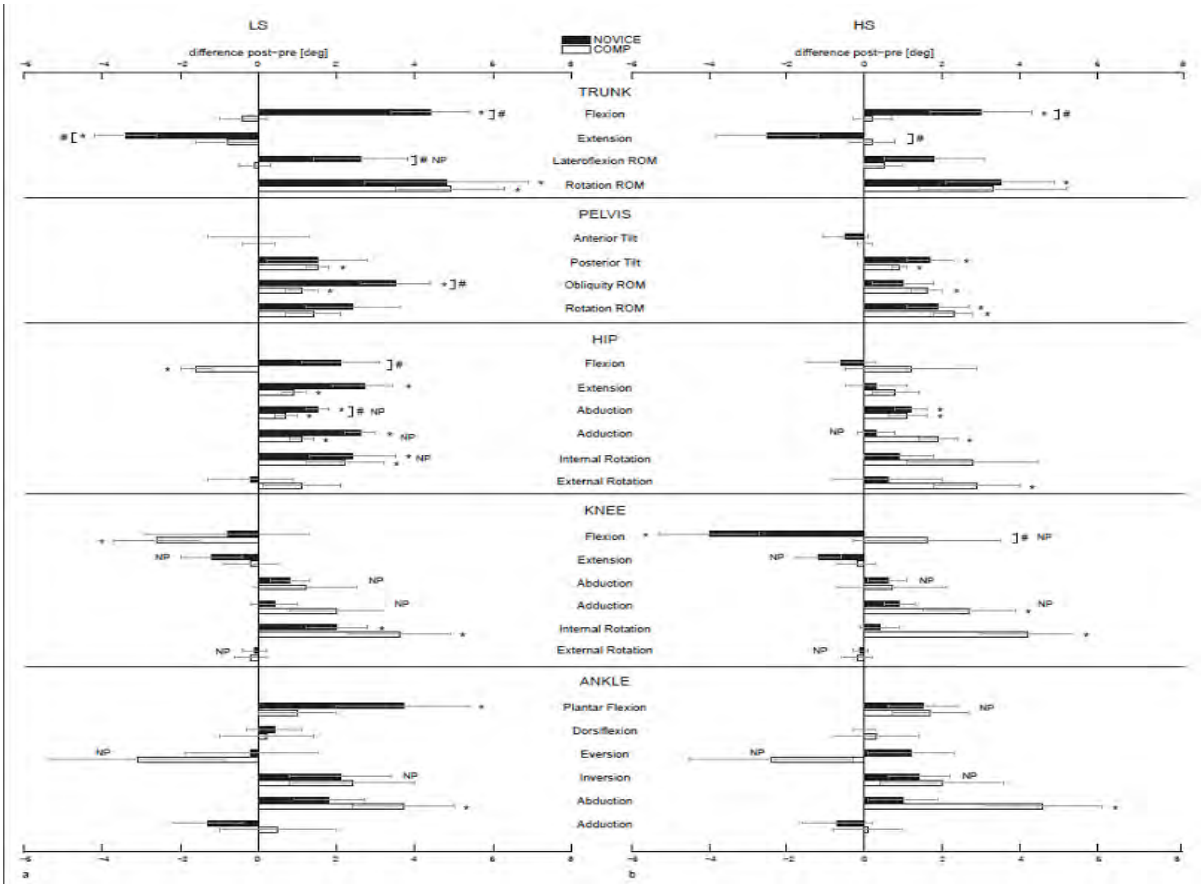
[1] department of kinesiology, KU Leuven, Leuven, Belgium

Introduction and Objectives: The development of overuse injuries has been associated with kinematic variables of all lower limb joints such as increased hip internal rotation[1,2], hip adduction[3,4], knee adduction, knee internal rotation[3,4] and ankle pronation[5]. Some of these variables have been found to be influenced by fatigue, developed over the course of a run. Fatigue, and subsequently altered kinematics, can magnify risk factors for developing overuse injury. The influence of fatigue on kinematics is likely to be related to training status, since well-trained runners are more resistant to muscular fatigue and are trained to maintain their running technique and posture even when fatigued. Therefore, the aim of the present study was to compare kinematic changes during a run to exhaustion in novice versus competitive runners.

Methods: 15 novice (training distance <10 km/week) and 15 competitive long distance runners (training distance >50 km/week for females and >70 km/week for males) performed a treadmill run till voluntary exhaustion at their average 3200m time-trial pace. Joint angles of the lower limb, as well as absolute trunk and pelvis angles were recorded before and after the fatiguing run using a 3D motion analysis system (Vicon, Oxford, UK) on an instrumented treadmill (Forcelink, Culemborg, the Netherlands).

Results: Some significant differences in peak joint angle between both groups in the non-fatigued state were found in the trunk, hip and knee. Interaction effects of group and fatigue, indicating a different adaptation to fatigue between groups, were the main findings of interest from this study. At the level of the trunk, significant interaction effects were found for peak global trunk flexion at both LS and HS, peak global trunk extension at both LS and HS and lateroflexion ROM at LS (figure 1). All these effects indicated more trunk flexion and more lateroflexion in the novice group as a result of fatigue. At the level of the pelvis, a larger change in obliquity ROM at LS with fatigue was found in the novice group. At the hip level, a significant interaction effect was found at LS for peak hip flexion, occurring at the end of the swing phase, which increased in the novice group and decreased in the competive group. Peak hip abduction (during swing phase) increased more due to fatigue in the novice group. Finally, peak knee flexion during swing phase at HS increased in the competitive group and decreased in the novice group.

Figure:



Caption: Figure 1a: differences in joint angles between pre and post fatigue for both groups for low speed (LS). Black bars represent data for novice runners (NOVICE), white bars represent data for competitive runners (COMP). Error bars indicate standard deviation. Figure 1b: differences in joint angles between pre and post fatigue for both groups for high speed (HS).

Conclusion: Fatigue had an effect on the kinematics of the lower limb and trunk in both novice and competitive runners. These effects were largest at the level of the trunk and hip. Kinematic changes were more pronounced in the novice runners, indicating that less experienced runners alter their running style more when fatigued. This may increase injury risk in novice runners. The difference in kinematic changes between both groups can be explained by better trunk and hip muscle strength and endurance in the competitive group. Upon post-hoc questioning, the competitive runners indeed spent more time training core and hip strength. This could indicate a negative relationship between core strength training and kinematic changes with fatigue during running, demonstrating the importance of core strength training for injury prevention.

ACCURACY OF ULTRASOUND MEASUREMENTS OF HUMAN MEDIAL GASTROCNEMIUS MUSCLE ARCHITECTURE

Bart Bolsterlee [1,*] DirkJan (HEJ) Veeger [2] [3] Frans CT van der Helm [2] Simon C Gandevia [1] Robert D Herbert [1]

[1]Neuroscience Research Australia, Sydney, Australia, [2]Dept. of Biomechatronics & Biorobotics, Delft University of Technology, Delft, [3]Research Institute MOVE, Vrije Universiteit Amsterdam, Amsterdam, Netherlands

Introduction and Objectives: When muscle architecture is measured from ultrasound (US) images, as is frequently done, it is assumed that fascicles are oriented in the image plane and that the image plane is perpendicular to the aponeurosis at the intersection of fascicle and aponeurosis. This study presents an *in vivo* validation of those assumptions by comparing US image plane orientation to 3D reconstructions of muscle fascicles and aponeuroses obtained with diffusion tensor imaging (DTI) and anatomical MRI scans of the human medial gastrocnemius (MG). The consequences for fascicle length and pennation angles measurements are also reported.

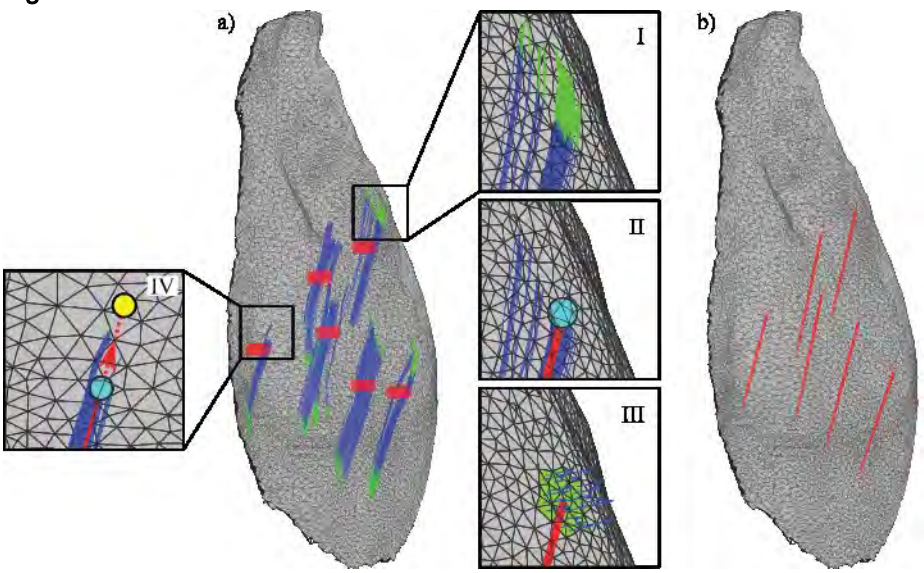
Methods: All measurements were conducted under static, passive conditions with the subjects lying supine, the knee slightly flexed and the ankle in a dorsiflexed position. Fascicle orientations, fascicle lengths and pennation angles were obtained at 16 locations in the left MG on a group of 8 healthy subjects by two methods, one based on US and the other based on DTI and MRI data. Two linear-array US transducers (Esaote MyLab 25) casted into a single unit (image size: 111×40mm with an 18mm gap) were positioned over each of the 16 sites in the MG while recording the 3D orientation of the transducers and leg with a motion capture system. For each of the images, both of the intersections of a clearly visible fascicle and its proximal and distal aponeuroses were identified. The distance between these intersections is the US fascicle length and the mean of the angles between fascicle and aponeuroses at their respective intersections is the US pennation angle. From each subject, 75 axial MRI and DTI images of the left lower leg were obtained with a 3 Tesla MRI scanner. The DTI scans were obtained twice. Muscle boundaries of the MG were outlined on the anatomical scans and a 3D surface mesh was created. DTI data were denoised, and the diffusion tensor was calculated for each voxel. MRI and US coordinate systems were aligned by using MRI-visible markers whose locations could also be identified in US coordinates. DSI studio was used to obtain 100 tracts which passed through a seed region of 9 voxels near the midpoint of an US fascicle, as well as through the deep and superficial aponeuroses (Figure 1). After trimming the ends of tracts that intersected the surface mesh, a line connecting the median location of the endpoints was extended until the muscle surface was intersected. The distance between the intersections of the fascicle with the proximal and distal aponeuroses is the DTI fascicle length and the mean of the two angles between the tangent plane to the surface mesh at the points of intersection and the line connecting the two endpoints is the DTI pennation angle.

To quantify US measurement errors, the angle ϕ between the DTI fascicle and the US image plane was calculated, as were the differences between US and DTI fascicle lengths and between US and DTI pennation angles.

Results: On average, fascicles reconstructed with DTI made an angle ϕ of 1.1 ± 6.7° with the US image plane. This small mean value indicates there was little or no systematic error in the alignment of the US transducers. The mean *absolute* angle, $|\phi|$, which quantifies the average misalignment of the US transducer in individual measurements was 5.5 ± 4.1°

(90th percentile 10.8°). Fascicles reconstructed with US were slightly longer (mean length 54.6mm) than those reconstructed with DTI (52.8mm and 51.5mm). Although *mean* measurements of fascicle length made using US and DTI differed only slightly (1.2 and 2.9mm), the individual pairs of US and DTI measurements differed on average by about 10mm. Pennation angles measured with US were significantly smaller than pennation angles measured from the DTI scans (-5.4° and -6.0°).

Figure:



Caption: Fig. 1 a) To reconstruct a muscle fascicle, DTI fibre tracts (blue lines) were trimmed to the muscle surface (I), the median endpoint location (II) was extended to the surface (IV) and the pennation angle was calculated (III). b) Example of 6 fascicles (red lines).

Conclusion: On average, DTI measured muscle fascicles lay very close to the US image plane, but for individual measurements there was substantial misalignment of DTI muscle fascicles with the plane of the US image. On average, US yielded similar measurements of fascicle lengths to DTI (mean difference <3mm), suggesting that the measurements were unbiased. However the mean absolute difference in length between any pair of measurements made with US and DTI was substantial (10mm or 20% of the mean), indicating US measurements were imprecise. The significantly smaller pennation angle measured with US (mean difference 6°) was apparent only at the superficial insertion of the muscle fascicles, and was probably due to pressure on the skin applied by the US probes. It is concluded that US measurements of deep pennation angles and fascicle lengths in the medial gastrocnemius are unbiased but have a low precision and that superficial pennation angles are underestimated by approximately 10°.

AS-0164

ACTIVE MUSCLE FORCE IS INFLUENCED BY MUSCLE COMPRESSION

Tobias Siebert [1,*] Norman Stutzig [1] Olaf Till [2] Reinhard Blickhan [2]

[1]Sport and Motion Science, University of Stuttgart, Stuttgart, [2]Motion Science, Friedrich-Schiller University, Jena, Germany

Introduction and Objectives: External forces compress skeletal muscles during daily activities such as sitting, carrying loads or wearing orthoses. Surrounding muscles, connective tissue, and bones also transfer external forces that compress the muscle. In a recent study [1] we transversally applied external forces to the line of pull in the middle of the muscle belly. Corresponding to the mean pressure at the body-seat interface during sitting, a transversal muscle load of 1.3 N/cm^2 revealed a reduction in maximum force (F_{im}) and rate of force development of approximately 5 and 25 %, respectively. Comparatively higher muscle compressions are, however, expected for e.g. car drivers during accidents or athletes involved in contact sports (e.g. boxing and wrestling). Thus, the aim of the present study was to examine the influence of increasing transversal muscle loading on contraction dynamics.

Methods: We performed isometric experiments on isolated rat *M. gastrocnemius medialis* (n=9) without and with five different transversal loads corresponding to increasing pressures of 1.3 N/cm^2, 2.3 N/cm^2, 3.3 N/cm^2, 4.3 N/cm^2 and 5.3 N/cm^2 at the contact area between muscle and load. Muscle loading was induced by a custom-made plunger which was able to move in transversal direction. During supramaximal muscle stimulation, the isometric force was measured at the distal tendon and the movement of the plunger was captured with a high-speed camera.

Results: Increasing transversal muscle loading (1.3 till 5.3 N/cm^2) resulted in an almost linear decrease in muscle force from 4.8 ± 1.8 % to 12.8 ± 2 % F_{im}. Compared to an unloaded isometric contraction, rate of force development decreased from 20.2 ± 4.0 % at 1.3 N/cm^2 muscle loading to 33.9 ± 4.4 % at 4.3 N/cm^2. Further increase of compression up to 5.3 N/cm^2 had no significant impact on the rate of force development. Lifting height of the plunger decreased from 1.69 ± 0.24 mm at the lowest transversal load to 0.61 ± 0.18 mm at the maximum load applied. Lifting work performed to lift the load increases significantly from 1.06 ± 0.14 Nmm at 65 g muscle loading to 1.50 ± 0.19 Nmm at 115 g. Further increase of transversal loads did not result in significant differences in lifting work.

Conclusion: Transversal muscle loading influences contraction dynamics and should be considered in musculo-skeletal models simulating the interaction of muscles with transversal forces, e.g. in impact biomechanics. Experimental observation of the impact of transversal muscle loading on contraction dynamics may help to better understand muscle tissue properties and to describe more precisely compression of the human body in rehabilitation studies. Moreover, applying transversal loads to muscles opens a window to analyse three-dimensional muscle force generation. Data presented in this study may be important to develop and validate muscle models which enable simulation of muscle contractions under compression and enlighten the mechanisms behind.

ESTIMATION OF ELASTIC AND DYNAMIC PROPERTIES OF A FINGER ATTRIBUTED TO MUSCLE-TENDON COMPLEX BY MEASURING JOINT ANGLES

Satoshi Makita [1,*] Momoko Maeda [2] Yuki Kawafuchi [3] Ryota Nawata [4]

[1]Control Engineering, [2]Advanced Course of Information Technology, Sasebo College, National Institute of Technology, Sasebo, [3]Yaskawa Electric Corporation, Kitakyushu, [4]General Education, Sasebo College, National Institute of Technology, Sasebo, Japan

Introduction and Objectives: The objective of the paper is to estimate elastic and dynamic properties of a finger easily by measuring joint angles. We show some measurement results of the properties: the relationship along joint angles, resultant fingertip forces and angular velocities of the finger.

Muscle-tendon complex (MTC) exerts tension and accumulates elastic energy during stretching, and converts the energy into kinetic energy to move bones with high velocity during shortening. As to ball games such as volleyball, the actions of hands are key issue to perform dynamic and flexible contacts with a ball.

Two typical methods to analyze viscoelastic property of MTC are measuring isolated MTC mechanically [1] and observing MTC by using a ultrasonography [2]. These methods are, however, difficult to observe the behavior of MTC in sports activities including quick movements of upper limbs because of its lack of portability.

Another approach to analyze human-body movement is to use motion capture, which is generally expensive to introduce. It is, however, difficult to track both fingers and whole body in same time.

Our proposed method is to measure joint angles of fingers, which can be easily measured by data gloves. It aims to estimate elasticity of fingers attributed to the MTC immediately for evaluation of performances in sports.

Methods: We introduce a hypothesis that MTC of a finger composed of flexor digitorum muscle and its tendon can stretch during dorsiflexion by pushing the fingertip with external forces. The MTC stretches and exerts resultant force according to increasing the angle of MP joint, and then we can estimate fingertip force by measuring the angle of the joint.

Moreover we can also estimate the resultant angular velocity of the joint after the applied external force is removed because the movement of finger is induced by the MTC shortening with energy transduction.

For the above estimations, we before have to obtain the relationship between them. First, we fix a hand of a subject person on the measurement equipment. Since MTC is few stretched by its own tension of muscle, the subject can lift up his/fer index finger at a certain angle. We define the angle as "initial angle". Next, we push his/her fingertip to lift it up. Then the MP joint angle and the applied force can be measured by a goniometer and a force sensing resister respectively. When the limitation angle that the finger cannot move no longer occurs, the measurement is suspended. This process from the initial to the limitation angle is called as "loading". After the limitation angle, we bring the finger down and similarly measure the two parameters until the initial angle. The downward process is "unloading".

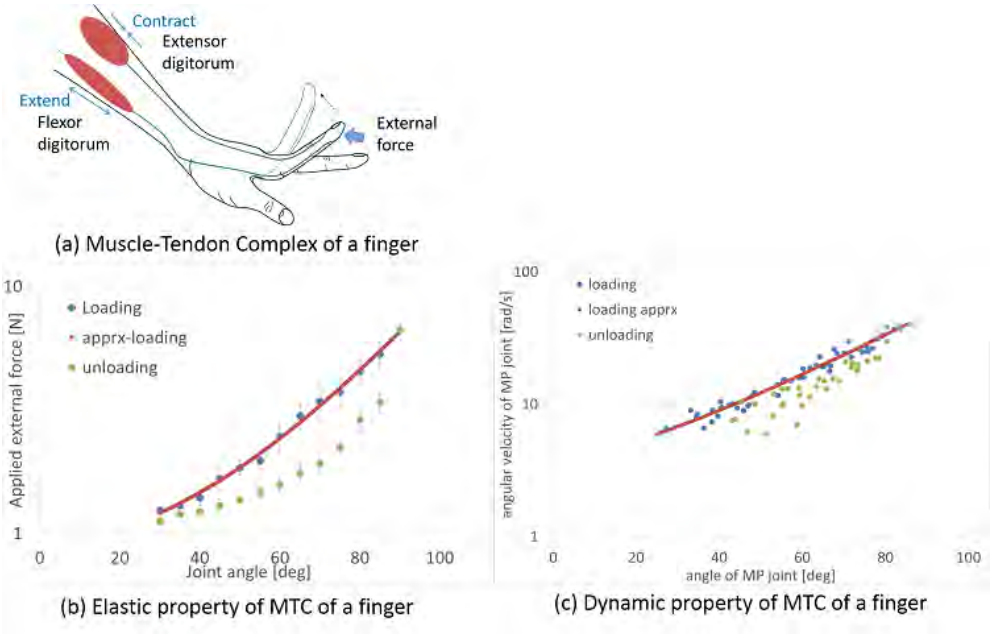
As to measuring angular velocity, we use the same equipment to load and unload an external force to a fingertip. We lift the finger up to a certain angle, and remove the load supporting it instantly to release it. The angular velocity can be

estimated from several images captured by a high-speed camera. In unloading process, we lift the finger up to the limitation angle once and bring it down to a certain angle, and release it.

Results: The relationship between angles of MP joint and the applied external forces, which are equal to the resultant forces exerted by the fingertip, in a loading process can be approximated by an exponential function. This trend is similar to a relationship between tension and length of an isolated tendon reported in previous works [1, 3]. The relationship in a unloading process has, however, larger hysteresis with sudden reduction of exerted force than that of the isolated tendon. The loss of the force may be caused by any loss of muscular strength, although the factor has not yet been proved.

On the other hand, the relationship between the angle of MP and the angular velocity of the finger can be expressed by an approximation derived from the energy transduction. Note that it also has large hysteresis in its trend, which is probably caused by the loss of elastic energy mentioned above.

Figure:



Caption: Estimating elastic property of muscle-tendon complex of a finger

Conclusion: This paper presented a method of estimating elastic and dynamic properties of muscle-tendon complex of a finger easily by measuring joint angles. Based on the hypothesis that the MTC can stretch during dorsiflexion with pushing the fingertip with an external force, we obtained the relationship between the joint angle and the exerted force as an approximation of relationship between tension and length of MTC. The obtained relationship derived an expression of estimating angular velocity of the finger induced by removing the applied force, from formulas of energy transduction. Consequently, the measured angular velocities can fit to the approximation.

A PATIENT-SPECIFIC MUSCULOSKELETAL MODELLING PIPELINE APPLIED TO PHALANGEAL LOADING CONDITIONS IN GAIT.

Joe A. I. Prinold [1 2] Claudia Mazzà [1 2,*] Stefan Wesarg [3] Roberto Di Marco [4] Pieter van Dijkhuizen [5] Laura Tanturri De Horatio [6] Clara Malattia [5] Marco Viceconti [1 2] and MD-PAEDIGREE Consortium

[1]Mechanical Engineering, [2]Insigneo Institute for in silico medicine, The University of Sheffield, Sheffield, United Kingdom, [3]Visual Healthcare Technologies, Fraunhofer IGD, Darmstadt, Germany, [4]Department of Mechanical and Aerospace Engineering, Sapienza University of Rome, Rome, [5]UOC Pediatria II - Reumatologia, Istituto Giannina Gaslini, Genova, [6]Ricerca Sanitaria, Ospedale Pediatrico Bambino Gesù, Rome, Italy

Introduction and Objectives: Juvenile Idiopathic Arthritis (JIA) is the leading cause of childhood disability from a musculoskeletal disorder (affects 0.16-4 in 1000; [1]). Distal joints, like the ankle, are often affected first [1]. JIA is an auto-immune disease of unknown aetiology. It is hypothesized that altered joint loading (JRF), due to pain and inflammatory processes, influences disease progression. Musculoskeletal modelling predicts patients' JRF. Standard modelling practice involves scaling a generic model to a patient [2]. However, JRF is sensitive to muscle moment arms [3] and patient-specific moment arms can differ significantly from a scaled generic model [4] – particularly in a pathological juvenile population.

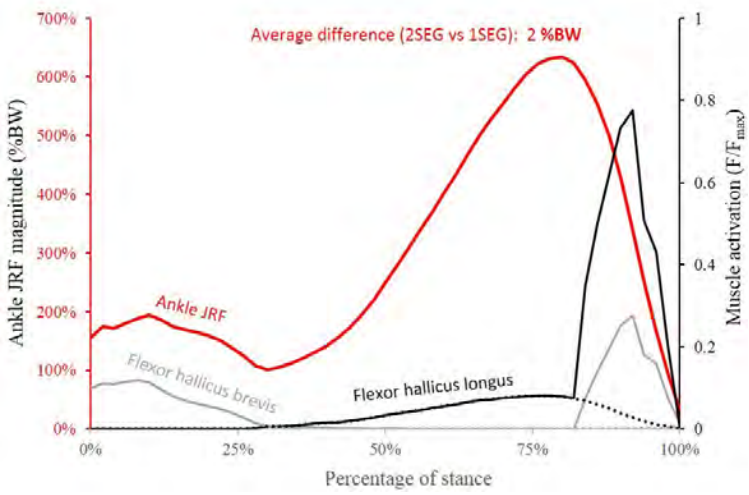
Musculoskeletal models usually idealise the foot as one, two or three segments [2,5]. However, the importance of these assumptions to ankle joint loading is unclear. The aim is to develop a pipeline for construction of a lower-limb model with a patient-specific foot. The resulting model simulations will analyse sensitivity of ankle JRF to foot segment idealisations.

Methods: An MRI scan of the foot and the distal shank was segmented to give a patient-specific foot geometry. Landmarks were virtually palpated and used to register the hindfoot (10 landmarks), metatarsal (15), and toe (17) segments of two generic models [2,5] onto the virtually palpated landmarks on the patient-specific foot geometry. The muscle attachments and via points were transformed according to the same registration. The registered muscle points were then adjusted to fit the muscles seen in the patient's MRI data. The joint coordinate systems and joint centres were defined from the patient-specific foot geometry [2] and the modified Oxford Foot Model [6]. A cylinder fitted to the talus defined the ankle joint centre. This gave a three segment, 7 degree of freedom foot model. 3 proximal segments of the generic model were scaled homogeneously (femur, shank and patella) and 1 non-homogeneously (pelvis). These segments were fitted to the patient-specific distal tibia via a rigid registration. The resulting model was exported as an OpenSim model. This processing was completed with the open-source NMS Builder software. Gait analysis markers [6] were included in the MRI scan of the foot. These markers were fixed to the relevant segments of the musculoskeletal model. Thus, gait analysis markers drove the model's motion via OpenSim's Inverse Kinematics routine. Static Optimization (minimising the sum of the squared muscle activations) and Joint Reaction Analysis was then used to compute the ankle joint forces. In the Static Optimisation the fore/hindfoot rotations and the int/external hindfoot rotation were locked, and thus not required to reach static equilibrium.

Two models of JIA patients (ages: 12 & 15 years) were simulated, according to the described pipeline (five trials per patient). Sensitivity to segment idealisation was tested by analysing two cases of possible ground reaction force (GRF) application. In the one segment assumption (1SEG) the GRF was applied to the hindfoot segment throughout the trial, thus underestimating the toe loading. In the two segment assumption (2SEG) the GRF was applied to the hindfoot segment until the centre of pressure crossed the metatarsophalangeal joint's flexion/extension axis. At this point the GRF was applied to the toe segment, thus overestimating the toe loading (the metatarsal heads share some of the load).

Results: A large effect of the 1SEG and 2SEG assumptions on the toe flexor muscles is observed (Figure 1). The mean difference between the segment assumptions (|1SEG – 2SEG|) is 2% body weight (BW): 1.3% higher ankle JRF in the 2SEG assumption than in the 1SEG assumption. So, even with the large differences in muscle activations, there is a negligible effect on the magnitude of the ankle JRF.

Figure:



Caption: Figure 1: Mean ankle joint reaction force (thicker red line, left axis) and mean flexor muscle activations (black and grey lines, right axis) during the stance phase of gait, with the 1SEG (dashed lines) and 2SEG (solid lines) assumptions. The black lines represent the flexor hallicus longus and the grey lines the flexor hallicus brevis. Abbreviations: JRF (joint reaction force), %BW (percentage of body weight), Fmax (maximum isometric muscle force).

Conclusion: A novel pipeline for the construction of a lower-limb model with a patient specific foot has been presented. This modelling process has been applied to predict the ankle JRF in JIA patients during gait. Finally, the effect of a one or two segment foot has been shown to be small through a comparison of two GRF applications that underestimate (1SEG) and overestimate (2SEG) the toe loading.

MUSCULAR ARCHITECTURE DIFFERENCES BETWEEN MALE AND FEMALE AMATEUR SOCCER PLAYERS

Maher A. Hamzeh [1,*] Marit Undheim [1] Adam Taylor [1]

[1]Life Sciences, University of Roehampton, London, United Kingdom

Introduction and Objectives: It has been well documented that adult males have significantly greater absolute strength compared to adult females. The mechanisms resulting in sex differences in muscle performance are not well understood (Chow et al., 2000)[1]. When considering what affects muscle performance, muscle architecture has shown to greatly affect the muscle's force-production capacity. Muscle architecture changes during contraction and data measured when the muscle is relaxed might not represent the accurate sex differences in muscle architecture. Therefore, the purpose of the study was to investigate the sex differences in muscle thickness of the rectus femoris (RF) and pennation angles of the vastus lateralis (VL) when the knee extensor muscles were at rest and while performing isometric knee extensions at 25%, 50%, 75%, and 100% maximal voluntary contraction (MVC).

Methods: Fifteen male amateur soccer players (age 22.6 ±2.3 years; body mass 78.1± 9.2 kg; height 1.81 ±0.07 m; mean ±s) and 15 female amateur soccer players (age 27.2±2 years; body mass 65.7 ±12.6 kg; height 1.68 ±0.08 m) volunteered to participate in the present study. Participants performed a 5 minute warm- up. Prior to testing, the sites at which the ultrasound measurements were taken were located on the participants' dominant legs. Participants were then seated in the isokinetic dynamometer (Cybex, Norm, USA) in an upright position with their hips at 85^0 of flexion and their dominant knee at 70^0 of flexion. The muscle thickness and pennation angles were recorded twice when the muscles were at rest and at 100%, 75%, 50% and 25% of their MVC using a real-time ultrasound scanner (Sonosite, M-Turbo, USA). Independent t-test was run for each measurement and the significant value was set at $P<0.05$.

Results: The results in Table 1 show that males had statistically significantly ($p<0.05$) greater muscle thickness in the RF compared to females at rest, 50% MVC, 75% MVC and 100% MVC, but not at 25%. There was no statistical significant difference ($P>0.05$) between males and females in pennation angle of the VL muscle (Table 1). Significant differences ($P<0.05$ were found in the muscular strength between male and female participants.

The results of muscle thickness are similar to those found by Chow et al. (2000)[1] and Kubo et al. (2003)[2] who reported that young males had significantly greater muscle thickness and pennation angles compared with young females for three different muscles (VL, medial gastrocnemius and long head triceps brachii). However, the present study did not find any significant differences in pennation angle between males and females. Ichinose et al. (1998)[3] reported that male soccer players had significantly greater muscle thickness of the triceps branchii compared to female soccer players, but not for pennation angles which confirmed the findings of the present study.

Conclusion: The results suggest that muscle thickness contributes more towards sex differences in muscle performance compared to pennation angle. However, further research needs to be done on various muscle groups and at various measurement locations.

Table:

Contraction	Muscle thickness (mm)		Pennation angle (^{0})	
	Males	Females	Males	Females
100% MVC	35.09±3.90	31.52*±3.58	16.77±1.68	17.75±3.05
75% MVC	34.69±3.60	31.79*±3.77	16.37±1.79	17.52±2.46
50% MVC	34.73±3.50	31.87*±3.29	15.50±1.83	16.79±2.34
25% MVC	33.96±3.99	32.13±2.87	14.31±1.74	15.85±2.50
0% MVC	29.99±3.36	27.45*±2.75	13.57±1.49	14.82±2.04

*Significant lower ($P<0.05$) than male participants

CHANGES IN PEAK VERTICAL FORCE AND LOADING RATES AT THE BEGINNING AND END OF LOADED WALKING

Jennifer Neugebauer [1,*] Angela Boynton [1]

[1]Dismounted Warrior Branch, U.S. Army Research Laboratory, Aberdeen Proving Ground, United States

Introduction and Objectives: As military loads carried by Soldiers increase, walking kinetics increase as well, specifically vertical ground reaction forces (Fz) and loading rates (LRz) [1,3]. To date, little is known about the effect of distance walked on the differences in peak Fz and LRz at the beginning and end of a loaded walk. Increased Fz and/or LRz over the course of a loaded walk may result in decrements in Soldier performance or injury [2]. The objective of this study was to determine if peak Fz and LRz during the stance phase of gait differ between the first and last minute of walking for a light, short walk (1.45 km with 27.6 kg) and for a heavy, long walk (5.63 km with 38.5 kg).

Methods: For the light, short walk, 12 active duty Soldiers (86.9 ± 10.9 kg, 1.77 ± 0.07 m) carried a 27.6 kg military load (weighted rucksack, body armor, dummy weapon) for a 1.45 km walk (20 minutes on a treadmill at 1.25 m/s). For the heavy, long walk, 12 active duty Soldiers (78.0 ± 14.6 kg, 1.72 ± 0.06 m) carried a 38.5 kg military load (weighted rucksack, body armor, dummy weapon, helmet) for a 5.63 km walk (5 minutes on a treadmill at 1.25 m/s before and after a 4.83 km walk outdoors through uneven terrain). Ground reaction forces (GRFs) were collected using a force plate instrumented treadmill. Data were collected for 20 seconds during first and last minute of walking. Peak Fz (N) and LRz (N/sec) were determined during the stance phase of gait for the left leg while walking. Fz and LRz were normalized to both body weight (BW) and loaded BW (LBW), defined here as BW plus carried load weight. The first and last minute of walking were compared within each load using paired t-test ($p < 0.05$). If no differences were found, average peak Fz and LRz were compared between the two walking conditions using a t-test ($p < 0.05$).

Results: Peak Fz was significantly greater during the last minute compared to the first minute of the long, heavy walk. LRz did not differ ($p > 0.17$) between the first and last minute of walking for either the short, light walk or the heavy, long walk (Table 1). Additionally, when normalized to LBW, peak Fz at each time point did not differ between load conditions ($p > 0.10$) while when normalized to BW, peak Fz was greater in the long, heavy load compared to the short, light load (short, light: first minute 1.50 ± 0.09 BW, last minute 1.49 ± 0.11 BW; long, heavy: first minute 1.66 ± 0.14 BW, last minute 1.68 ± 0.15 BW). LRz was greater for the long, heavy walk compared to the light, short walk at both the first and last minute of walking regardless of the normalization method used.

Conclusion: Over the course of a long, heavy load walk, peak Fz increased while LRz did not differ. During a short, light load walk, no differences in peak Fz or LRz at the beginning and end of the walk were observed. Generally, higher forces suggest greater loads on the body and may be indicative of muscle fatigue which may affect Soldier performance. Further investigations are needed to determine if the load or the distance resulted in increased Fz at the end of the long, heavy walk. When normalized to LBW even though peak Fz did not differ between load conditions LRz was greater for the heavy load. Increased loading rates are considered unfavorable [2,4] and may lead to injury after prolonged exposure. It should be noted that the two conditions compared involved treadmill walking and treadmill walking combined with outdoor

walking. Although all data were collected while the subjects walked on the treadmill, walking on different terrain may have affected the findings. Future studies should vary the loads and distance walked on similar terrain (either all outdoors or all treadmill walking). Additionally, further comparisons of medial-lateral and/or braking-propulsive GRFs may illustrate kinetic changes with increasing carried loads for longer distances.

Table: Walking kinetics for the short, light walk and the long, heavy walk normalized to LBW. Peak Fz was greater in the last minute compared to the first (*). LRz was greater in the long, heavy load compared to the short, light load (#) at each time. Average ± standard deviation is presented for data collected during the final 20 seconds of the first and last minute of walking.

Condition	Distance (km)	Load Carried (kg)	Peak Vertical Force (LBW)		Vertical Loading Rate (LBW)	
			First minute	Last minute	First minute	Last minute
Short, light	1.45	27.6	1.13 ± 0.05	1.12 ± 0.06	6.12 ± 0.57	6.05 ± 0.61
Long, heavy	5.63	38.5	1.10 ± 0.05	1.11 ± 0.06*	8.41 ± 0.99#	8.36 ± 0.92#

FLEXIBLE FOOT LONGITUDINAL ARCHES ARE LOWERED MORE IN PASSIVE LOADING AND LIFTED MORE DURING SINGLE-LEG STANCE COMPARED TO RIGID ARCHES ALTHOUGH MUSCLE ACTIVATIONS ARE SIMILAR

K. Michael Rowley [1,*] Toshiyuki Kurihara [2] Stephen Reischl [1] Lucinda Baker [1] Kornelia Kulig [1]

[1]Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, United States, [2]Graduate School of Sport and Health Science, Ritsumeikan University, Shiga, Japan

Introduction and Objectives: Passive loading of the lower leg has been used to investigate behavior of the longitudinal arch of the foot and the muscles controlling it. From recent research into the function of intrinsic foot musculature, it has been suggested that intrinsic muscles can produce enough force to aid in postural stabilization by shifting center of pressure location [1], support for the concept of the foot core [2]. It is known that arch flexibility varies greatly in an asymptomatic population, but it is largely unknown how intrinsic and extrinsic foot muscle activity differs with flexibility and whether all feet respond similarly to loads applied passively or actively. The objective of the current study was to investigate the change in height and muscle activity of the longitudinal arch of the foot in response to passive loading and single-leg stance (SLS) conditions in feet with rigid and flexible arches.

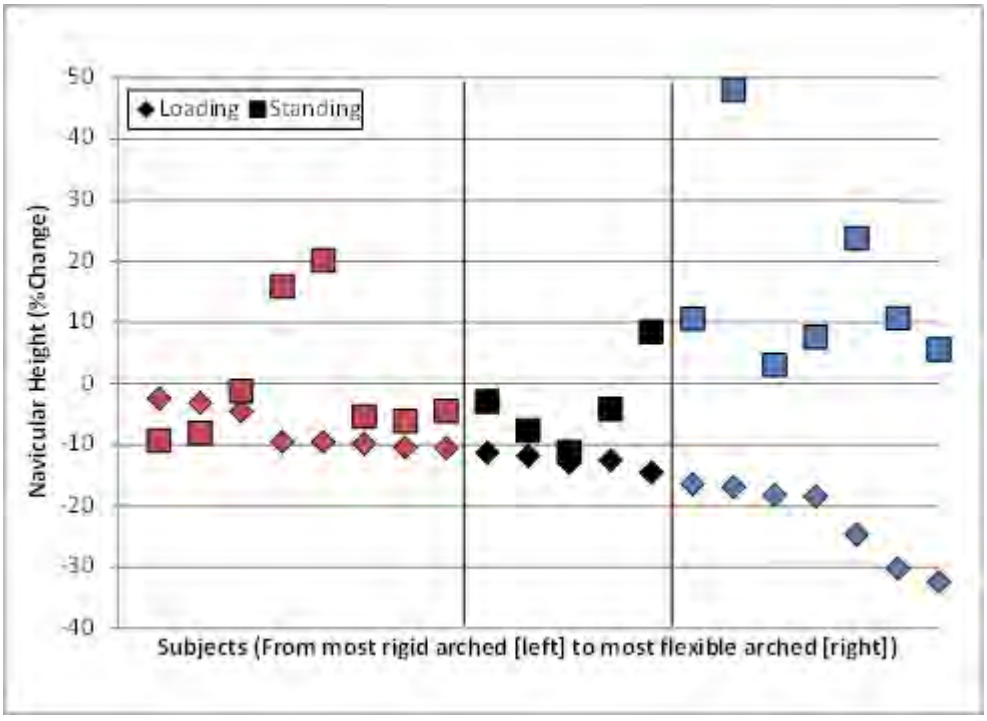
Methods: Healthy young adults were screened for inclusion in the study. The foot contralateral to the preferred kicking foot was examined to include participants with a range of foot arch flexibility. Arch deformation, measured by percent change in navicular height, comparing the unloaded arch and the arch loaded at 100% of body weight ranged from 2.4% to 32.4%. Cutoffs of < 11% and > 15% deformation were chosen to define rigid and flexible arches, respectively. Eight participants had rigid arches (4 male) and seven participants had flexible arches (all female). Fine-wire intramuscular electrodes were inserted into the abductor hallucis (AH), flexor hallucis longus (FL), flexor hallucis brevis (FB), and tibialis posterior (TP) muscles in the supporting foot of each participant. Surface electromyography (EMG) was collected from peroneus longus (PL) and tibialis anterior (TA). Three-dimensional kinematic data were obtained using an 11-camera motion capture system. Ground reaction force (GRF) data were collected using a force plate.

Each participant was tested in two conditions. Incremental loads up to 100% of body weight measured by vertical GRF under the instrumented foot were applied to the distal aspect of thigh using a custom built rig. The participant was asked to refrain from any voluntarily elevation of the knee or foot, hold arms across chest, and sit up straight. Each participant then stood in SLS for 5s. This was repeated three times and results were averaged. Data were analyzed using paired t-tests to compare within-subjects between conditions and using independent sample t-tests to compare means between arch flexibility groups. Significance levels were set at α=.05.

Results: In both rigid and flexible arch groups, muscle activation amplitudes of all muscles instrumented were significantly greater during SLS than during passive loading even though both loads were 100% body weight ($p<.05$) (Table 1). During passive loading, a trend was observed showing greater activation in all muscles in flexible arches. This difference was greatest in the intrinsic foot muscles, but only reached significance in the AH ($p=.003$). There were no significant differences in activation amplitude between groups during SLS. Arch deformation during passive loading of body weight deformed rigid arches by 7.5 ± 3.5% and was significantly less than deformation of flexible arches by 22.4 ± 6.7%

(p<.001) (Figure 1). During SLS most subjects lifted the arch where the average lift in the rigid arch group was 0.19 ± 11.3% and was significantly less than the average lift in the flexible arch group, 15.6 ± 15.7% (p=.046).

Figure:



Caption: Navicular height change during passive loading and single-leg stance.

Conclusion: For all arch types, both intrinsic and extrinsic foot muscles controlling the longitudinal arch were more active during SLS compared to passive loading of 100% body weight. Flexible arches were both lowered more in passive loading and lifted more during SLS, even though muscle activation was not different between groups. Passive loading was not sufficient to elicit muscle activations and arch lift seen during SLS indicating that muscle activation plays a role in postural stabilization and is not merely a response to loading. Control of arch stiffness may be necessary to use the foot as a lever to aid in balance. Despite the fact that all subjects tested were asymptomatic and free of injury or pathology, there are clear differences in behavior and control of the longitudinal arch. This wide range of asymptomatic arch behavior calls into question the homogeneity of healthy control groups used in foot and lower extremity research.

Table:

	TP	FL	FB	AH	TA	PL
	Rigid N=8					
Load	4.0*	3.2*	3.0*	2.7*†	7.1*	3.1*
Stance	67.7*	21.5*	65.4*	70.0*	28.2*	40.5*
	Flexible N=7					
Load	8.7*	3.6	13.0*	20.2*†	7.7*	4.0*

Stance	63.3*	30.8	66.5*	75.8*	34.2*	50.6*

THE AMPLITUDE OF H-REFLEX AS AN OUTCOME FOR TO INVESTIGATE MUSCLE INHIBITION IN PEOPLE WITH PATELLOFEMORAL PAIN SYNDROME

Nathalie C. S. Faria [1,*]Fernando Magalhães [2]Deisi Ferrari [3]Danilo Silva [1]Marcella Pazzinatto [1]Neri Alves [3]Fábio Azevedo [1]

[1]Physiotherapy, Universidade Estadual Paulista- UNESP, Presidente Prudente, [2]Universidade de São Paulo-USP, São Paulo, [3]Universidade de São Paulo-USP, São Carlos, Brazil

Introduction and Objectives: The Patellofemoral Pain Syndrome (PFPS) is characterized by presence of anterior knee pain on retropatellar region[1] and it is a common found in actives adults[2].The pain commonly appears during some functional or physical activities [3], demonstrating intermittent characteristic. Although the PFPS has a high incidence until this moment its etiology is unclear [4,5]. The traditional therapeutic exercise many times demonstrate not very good prognostic with little increase at the strength and little decrease of pain level. [6,7]. The disinhibitory interventions are suggested for to improve clinical outcomes by changing the neuromuscular function [6,7]. Since the presence of muscle inhibition has been suggested to prevent the total recuperation of function of the person after injury [6]. The H-reflex is a confident measure for analyzes the inhibition and activation muscle [8]. We hypothesize that many times people with PFPS can be free of the pain but the muscle inhibition process continues installed and this favors the recurrence of pain and the characterization of the PFPS with intermittent pain. Our objective is to compare the amplitude of the vastus medialis H-reflex in asymptomatic and PFPS women and to investigate if this measure can be an outcome for to examine the muscle inhibition before and after treatments.

Methods: Twenty women participated of this study (10 asymptomatic and 10 with PFPS) with average age 23.05(3.53) years, the peak to peak maximum H-reflex amplitude (Hmax) and the peak to peak maximum M-wave magnitude (Mmax) of vastus medialis were assessed of all participants. The Mmax was used as a normalization factor. For to record the Hmax and Mmax the participants were at supine position, the femoral nerve was stimulated in the inguinal region and the electromyography signal was captured at the vastus medialis. The femoral nerve was stimulated using 1 ms pulses until the H wave reaches its maximum and thus the same was done to Mmax. Ten signals of each wave were recorded.

Results: The test T for independent sample was performed at the SPSS Statistical Package. The mean and standard deviation of normalized Hmax for the group with PFPS and asymptomatic were 0.09(0.06) and 0.19(0.10) respectively. We found statistical differences at the normalized Hmax between the groups with a p-value of 0.023 and a F-value of 1.25 at the Levene's test. Our results showed that the women with PFPS have smaller amplitude than asymptomatic. This achieved support that the presence of intermittent pain is accompanied by muscle inhibition. This inhibition is an important alteration that needs to be broken [7]to obtain good results after treatments.

Conclusion: The amplitude of Hmax is smaller in women with PFPS than asymptomatic women and the measure of the H-reflex is a confident diagnostic for the muscle inhibition. Therefore the measure of H-reflex can be a technic useful for to investigate the changes in the neuromuscular function after treatments.

IMPROVING EMG DATA CLASSIFICATION ACCURACY BY SUPPORT VECTOR MACHINE SPACES

Stefan Hoerzer [1,*] Vinzenz von Tscharner [1] Erica Buckeridge [1] Benno Nigg [1]

[1] Human Performance Lab, University of Calgary, Calgary, Canada

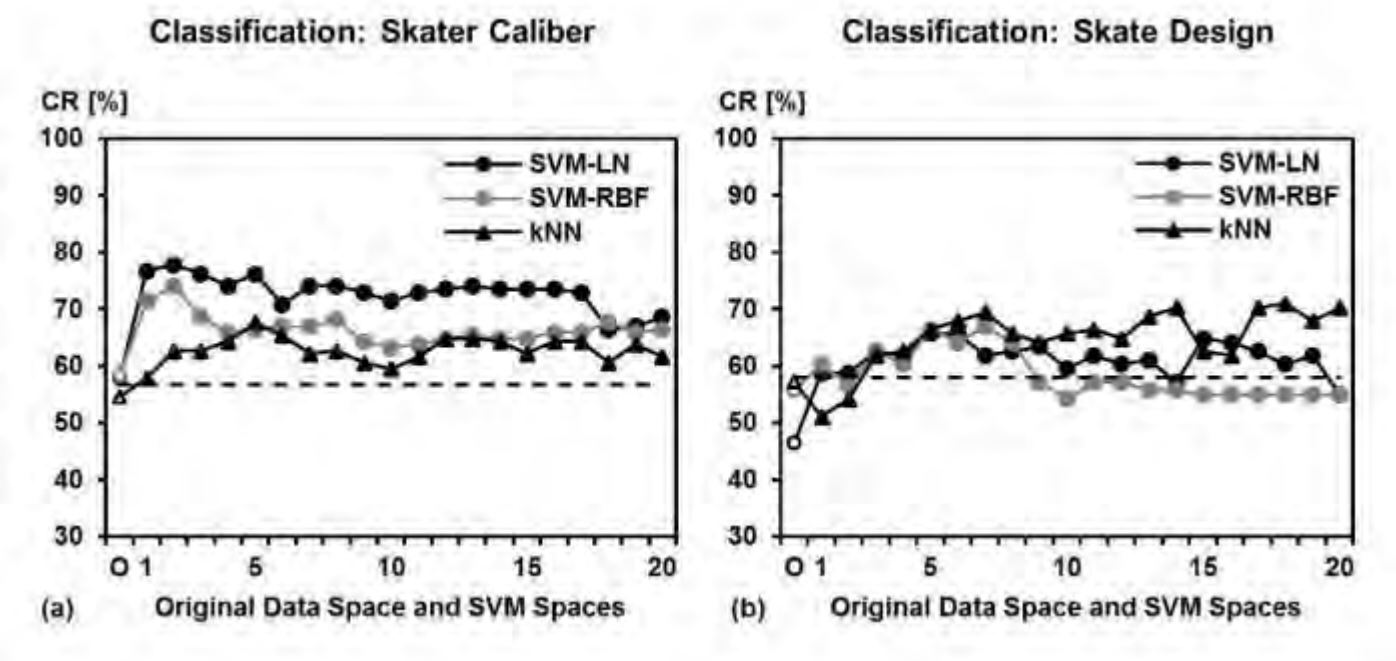
Introduction and Objectives: The classification and interpretation of EMG signals is important in sports research for a functional understanding of group differences caused by, for example, different skillsets or sports-equipment [1,2]. EMG data classification has also significant clinical applications, such as assessing neuromuscular diseases [3] or providing input information for robotic prostheses [4]. Especially in such clinical settings, high data classification accuracy is crucial. EMG signals can demonstrate high inter-subject variability and the signal-to-noise ratio is often unfavourable. Thus, EMG data classification accuracy might be often low, especially when the EMG signals were recorded during highly dynamic movements (e.g. running; ice skating) or when the expected group differences are small (e.g. at the onset of a disease; when comparing sports-equipment). Recently, Support Vector Machines (SVM) were used to extract all the discriminating information between groups in a given data set and isolate them in a new data/vector space (SVM space) [5]. It is hypothesized that classifying EMG data in a SVM space would enhance classification accuracy. Thus, the study objective was to investigate if EMG data classification accuracy could be improved by the utilization of a SVM space.

Methods: Sixteen healthy male subjects (31.4±6.8yrs) performed 15 maximum effort forward skating trials. Using this setup, the following groups were established: *skater caliber* (low vs. high skillset) and *skate design* (low vs. high quality sports-equipment). During each trial muscle activation was measured using bipolar surface EMG electrodes on the vastus lateralis, tibialis anterior and medial gastrocnemius. The ice contact phases of two specific skating strides (i.e. accelerative and steady state stride) were used for the analysis. EMG data were processed with a non-linear wavelet transform. The resulting time-frequency patterns of each muscle and trial were used as input data for the data classification task. This task included classifying skater caliber and skate design. To this purpose, three frequently used data classification algorithms were utilized: SVM-Linear kernel (SVM-LN), SVM-Gaussian Radial Basis Function kernel (SVM-RBF), and k-Nearest Neighbor classification (kNN). First, all algorithms were used in the original data space. The classification accuracy was determined by calculating classification rates (CR) using a leave-one-out cross validation approach. Second, the original data space was decomposed by an iterative application of the SVM-LN into 20 orthogonal discriminants. Afterwards, 20 SVM spaces were created spanned by 1 to 20 discriminants. All classification algorithms were then applied to each of the 20 SVM spaces and the corresponding CRs were obtained. A binominal test (α=0.05) was used to determine if the calculated classification rates were significant and indicated statistically significant group differences.

Results: When classifying skater caliber, the SVM space allowed maximally improving the CR by 20.0% (SVM-LN), 15.7% (SVM-RBF), or 13.0% (kNN) (Fig. 1a). Considering only the maximum CR showed that each algorithm achieved a significant classification in the SVM space. Classifying skate design revealed that the SVM spaces maximally improved

the CR by 19.1% (SVM-LN), 11.5% (SVM-RBF), or 13.7% (kNN) (Fig. 1b). None of the CRs obtained in the original space were significant. However, the SVM space allowed each algorithm to reach a significant classification.

Figure:



Caption: Classification rates (CR) between ice skater calibers and skate designs. The first hollow data point of each data series represents the CR in the original data space (O) and the following points indicate CRs based on SVM spaces formed by 1-20 discriminants. Three classification algorithms were used: SVM-Linear kernel (SVM-LN), SVM-Gaussian Radial Basis Function kernel (SVM-RBF), k-Nearest Neighbor classification (kNN). The dotted black horizontal line indicates the lowest statistically significant CR.

Conclusion: Classifying different skillsets and sports-equipment based on surface EMG signals provided a low accuracy. Using SVM spaces to filter out non-discriminating information provided a significant improvement in classification accuracy, independent of the algorithm used. In some cases statistically significant and, therefore, meaningful differences could only be detected in the SVM space. Thus, it is expected that the SVM space classification will lead to higher EMG data classification accuracy in both clinical and sports-related applications. In the future, reconstructing data in the SVM space will allow to visually assess the group differences, therefore, providing potential for functional interpretations.

SHAPE AND MAGNITUDE OF LOWER EXTREMITY KINETICS CHANGED STEPS BEFORE GAIT TRANSITION DURING INCREASING SPEED INDUCED WALK-TO-RUN TRANSITION

Jiahao Pan [1,*] Li Li [1]

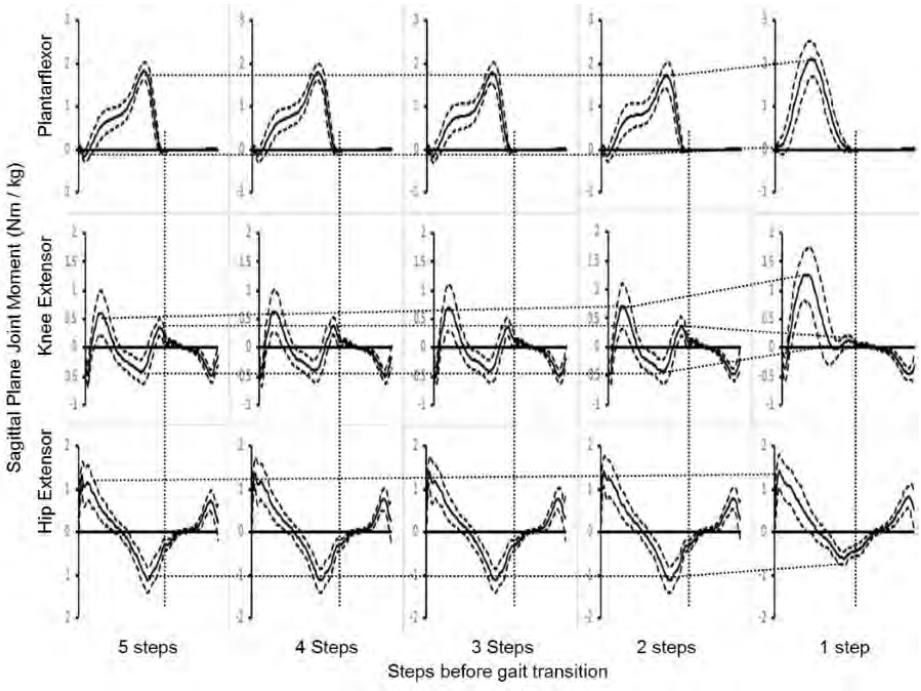
[1]Kinesiology, Shanghai University of Sport, Shanghai, China

Introduction and Objectives: Walking and running represents two different steady states in human locomotion. Study walk-to-run gait transition helps us to understand how human movement changes from one steady state to another. The purpose of this study was to investigate lower extremity joint moments and power patterns during gait transitions with continuously increased walking speeds.

Methods: Walk-to-run gait transitions were tested with thirteen college aged participants. The gait transitions were induced by increase treadmill speed. Full body reflective markers were captured using eight digital cameras while the participants walked on a force plate embedded treadmill. Inverse dynamics was employed to estimate sagittal plane ankle, knee, and hip joint moments / power for the last five steps before walk to run gait transition.

Results: Ensemble curves of joint moments data presented in Figure 1. Horizontal axes represent 100% of a gait cycle. Vertical dotted lines indicate the end of stance phase and the beginning of swing phase. We have used horizontal (or slightly slopped) dotted lines to represent changes of a particular parameter across the five steps before walk-to-run gait transition. Ankle joint moments can be seen at the upper panel of Figure 1, where plantarflesor moments are presented as positive. The most observable changes occurred at the last step before walk-to-run gait transition, where 1) the peak plantarflexor moment increased and happened earlier during the stance phase, along with 2). the disappearance of the dorsal flexor moments which commonly happens at the beginning of the stance phase. There are three knee joint moment peaks can be observed during the stance in the middle panel: extensor peaks at the beginning and end of the stance phase, as well as the flexor peak between the two. The first extensor peak increased slightly during the first four steps displayed here where the other two remain largely unchanged. The first peak in creased to almost twice as observed in the previous steps, with the other two almost disappeared during last step before gait transition. Hip joint moments (lower panel in Figure 1) remained steady for the first four steps presented here. But hip joint flexor moments reduced significantly during the last step before changed to run. Joint power data will not be presented here with the limited spaces allow for this abstract but they do support the same trends observed with the joint moments.

Figure:



Caption: Figure 1. Sagittal plane ankle (upper), knee (middle) and hip (lower) joint moments ensemble curves five steps before walk to run gait transition (see text for details of the figure).

Conclusion: We have observed transition specific non-linear joint kinetic behavior in this study. Sagittal plane lower extremity joint moments and joint power changed in shape and magnitudes during the five steps approach walk to run transition, especially the last step before transition. These results indicated that, in preparation for transition, joint kinetic changes steps before gait transition along with increased walking speed.

A COMPARATIVE STUDY OF THE MUSCLE SYNERGY PATTERNS IN HEALTHY AND ACL-DEFICIENT SUBJECTS

Gil Serrancolí [1,*] Joan C Monllau [2 3 4] Josep M Font-Llagunes [5]

[1]Department of Mechanical Engineering and Biomedical Engineering Research Centre, Universitat Politècnica de Catalunya, [2]Department of Orthopaedic Surgery, Hospital del Mar, [3]ICATME, Hospital Universitari Quirón-Dexeus, [4]Universitat Autònoma de Barcelona, [5]Department of Mechanical Engineering, Universitat Politècnica de Catalunya, Barcelona, Spain

Introduction and Objectives: It is believed that human gait is controlled by a muscle synergistic pattern [1]. This can be represented by signal factorization of muscle activations or electromyography (EMG) in Neural Commands (NCs) and Synergy Vectors (SVs). NCs are time dependent signals, and SVs represent the weight factors of each muscle to the NCs. As far as the authors know, no muscle synergy analysis has been applied for the study of ACL-deficient subjects. The goal of this study is to investigate whether there are observable differences in NCs and SVs between healthy and ACL-deficient subjects.

Methods: Ten healthy subjects, five men and five women (age 31.5 ± 12.9 years), and eighteen ACL-deficient subjects, twelve men and six women (age 32.3 ± 10.99 years), volunteered as participants in this study. All injured subjects were classified as adapters [2]. They were asked to walk some gait trials over ground. EMG signals of 16 muscles (8 from each leg) were measured (Biometrics, Newport, United Kingdom). The 8 muscles are the main contributors to the human gait (Extensor Digitorus Longus, Tibialis Anterior, Soleus, Gastrocnemius Lateralis, Vastus Lateralis, Rectus Femoris, Semitendinosus and Gluteus Maximus). Ground Reaction Forces (AMTI, Watertown, MA) and trajectories of 2 foot markers (NaturalPoint, Corvallis, OR) were also measured to identify the gait cycle.

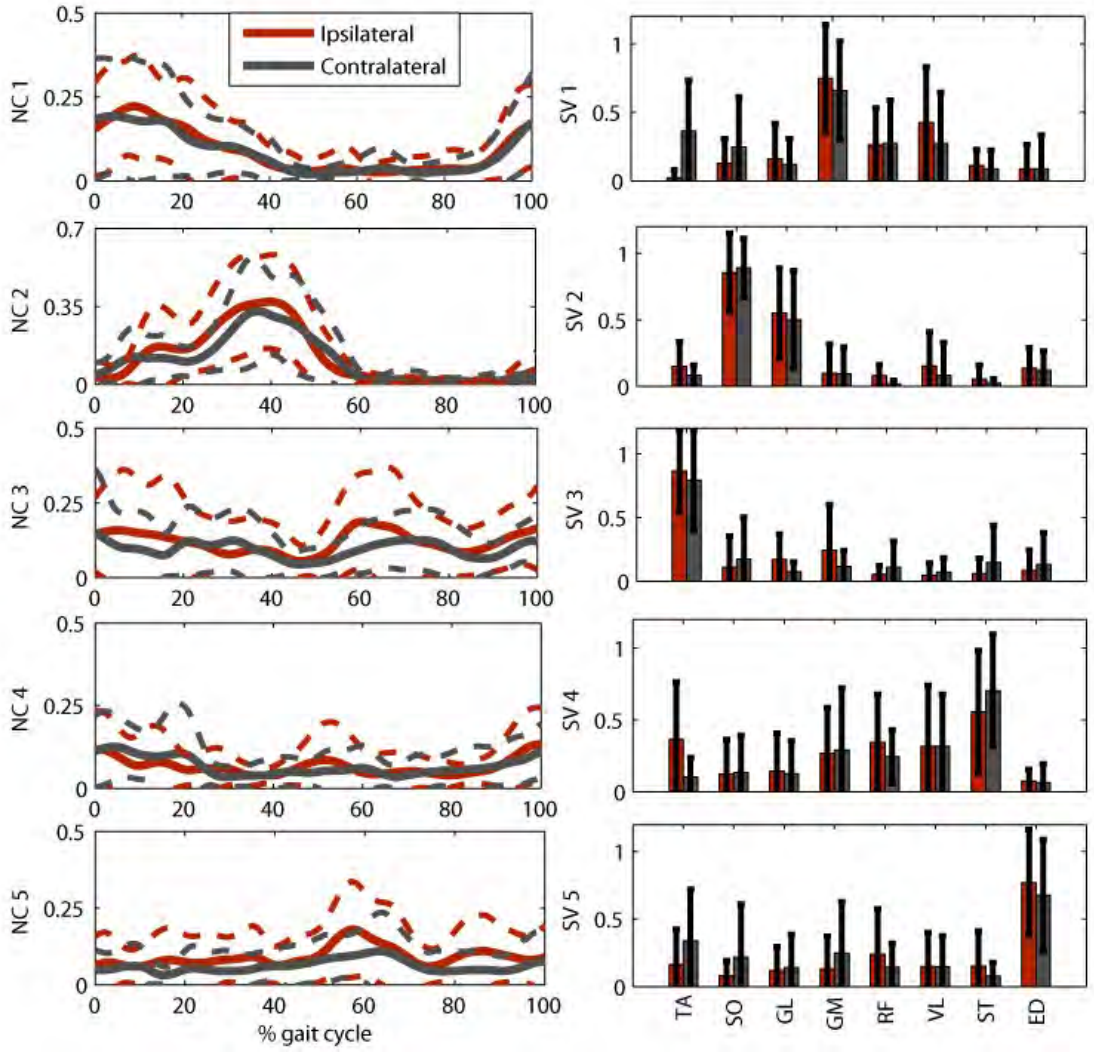
EMG data were filtered and normalized to maximum values obtained after doing certain MVC exercises. The processed EMG signals were factorized by means of a Non-Negative Matrix Factorization (NNMF) algorithm based on a non-linear least squares algorithm that minimizes the error between the reconstructed and the experimental EMG signals [3]. NCs and SVs were calculated when factorizing data with 1 to 6 modules. For each set of data, VAF (variance accounted for) was calculated for each muscle to evaluate the dimensionality.

The subjects were divided in three groups: Control (healthy subjects), Ipsilateral (injured subjects' injured legs) and Contralateral (injured subjects' non-injured legs). SVs and NCs were compared between groups.

Results: The analysis of dimensionality showed that 5 modules can account for ≥ 90% of the variability for each individual EMG signal. There were no significant differences regarding the dimensionality among groups, therefore, muscle synergy components of all three groups were compared using 5 modules.

The correlations among NCs and SVs from two modules of different groups were calculated (Table 1). The obtained patterns showed similar tendencies (Figure 1), but some differences were observed. The most representative ones are that the Ipsilateral NC of module 2 has two peaks, whereas the same NC of the Control group shows only one peak; and that modules 3 and 4 have higher Ipsilateral's NC values compared with the ones obtained for the Control group.

Figure:



Caption: Figure 1. NCs (left) and SVs (right) of Control and Ipsilateral groups. Both cases show the mean value (solid line and bar) and the standard deviations (dashed line and error bar).

Conclusion:

NCs and SVs were in general comparable with other published studies [4-5]. The fact that there were no significant differences in the dimensionality of the signal factorization means that the pattern of all groups has the same complexity.

The observed differences in NCs and SVs among groups can be associated with the changes in the strategy that the Central Nervous System uses to activate the muscles in ACL-Deficient subjects. The higher values of NCs that contain basically activations of ankle plantar flexors and dorsiflexors (modules 2 and 3) during the stance phase, suggest that there is a transfer of the leg control away from the injured knee joint.

This study on muscle synergy analysis can be useful at two levels. In a clinical field, to evaluate the progress during the rehabilitation treatment of ACL-deficient subjects; and, in a computational dynamic analysis, to reduce the indeterminacy in the muscle force calculation of ACL-deficient subjects.

DOES A HIGH FREQUENT ROTATION IN INDUSTRIAL TASKS POSITIVELY AFFECTS MUSCLE FATIGUE AND PERCEIVED DISCOMFORT?

Tessy Luger [1 2 3,*] Marco Hoozemans [1] Tim Bosch [2 3] Dirkjan Veeger [1] Michiel de Looze [2 3]

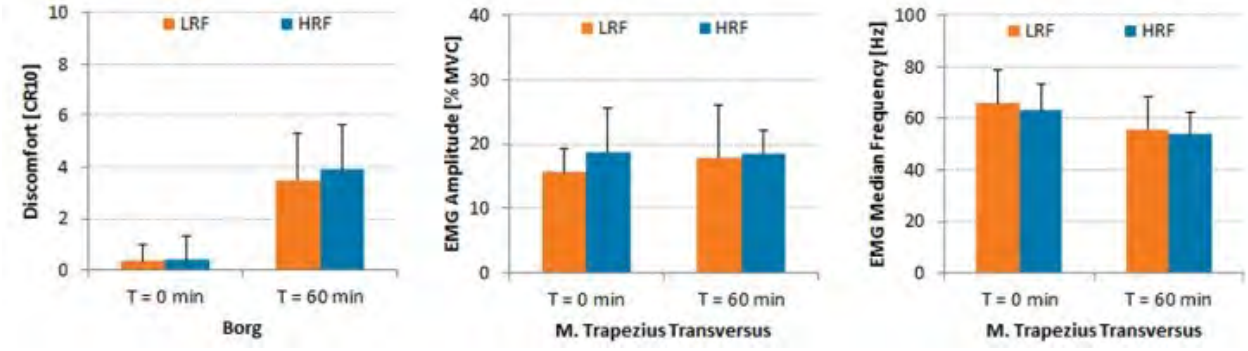
[1]MOVE Research Institute, Faculty of Human Movement Sciences - VU University Amstserdam, [2]Body @ Work, Research Centre of Physical Activity, Work and Health, Amsterdam, [3]TNO, Leiden, Netherlands

Introduction and Objectives: Upper extremity musculoskeletal disorders are a major problem in occupational work. Task rotation can be used to counteract musculoskeletal disorders because it may attenuate effects of important risk factors including high repetitiveness and monotony. However, a clear evidence based advice as to the effectiveness of task rotation in industry is not available. The aim of this study was to determine the influence of low and high task rotation frequency on muscle fatigue and perceived discomfort during a one-hour simulated industrial work setting including a pick-and-place and box-lifting task.

Methods: 10 healthy subjects performed a pick-and-place and a box-lifting task in 2 one-hour conditions: (1) a low rotation frequency condition, 1 rotation (LRF): 30 minutes pick-and-place work followed by 30 minutes box-lifting work; (2) a high rotation frequency condition, 9 rotations (HRF): 6 minutes pick-and-place work and 6 minutes box-lifting work interchanged 9 times. We recorded muscle activity in the Transversal and Descending part of the M. Trapezius with multichannel surface electromyography; from the recordings we calculated the amplitude and median frequency. Furthermore, subjects rated their locally perceived shoulder discomfort with the CR10 Borg scale. Measurements were recorded at the start and at the end of each condition. The sequence of the conditions was systematically varied between subjects.

Results: At 60 minutes, the amplitude and median frequency of both the Transversal (see Figures) and Descending part of the M. Trapezius did not significantly differ between the two rotation conditions. Furthermore, the discomfort rating at 60 minutes did not show differences between the low and high rotation frequency conditions either.

Figure:



Conclusion: We expected that a high task rotation frequency between the pick-and-place and the box-lifting task would result in (more) opportunities for recovery, and thus less manifestations of muscle fatigue and perceived discomfort at the shoulder, compared to a situation in which both tasks are switched only once. Since the differences we found between the

low and high rotation frequency were relatively small and not significant, the effectiveness of a higher task rotation frequency in the attenuation of musculoskeletal symptoms in the upper extremity can still be debated.
Both muscle fatigue and perceived discomfort at the shoulder are minimally influenced by high rotation frequency of pick-and-place and box-lifting tasks in a simulated industrial work setting.

MODELING AND COMPUTATIONAL COMPARISON OF FOOT ORTHOSES FOR PLANTAR PRESSURE RELIEF

Óscar Libardo Rodríguez-Montaño [1,*] Carlos Julio Cortés-Rodríguez [1 2] Octavio Silva-Caicedo [1 3]

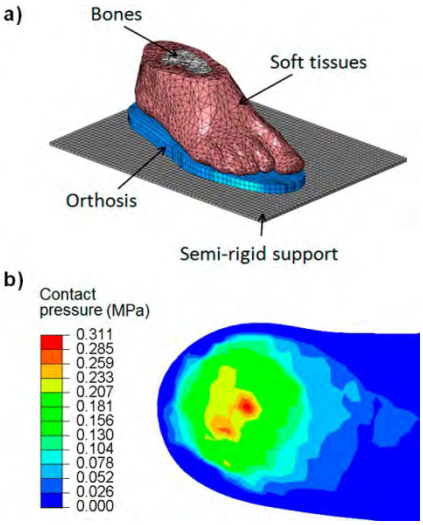
[1]Biomechanics Research Group, [2]Department of Mechanical Engineering and Mechatronics, [3]Faculty of Medicine, Universidad Nacional de Colombia, Bogotá, Colombia

Introduction and Objectives: The high-pressure areas in the plantar foot region are related to the pain and development of injuries, due to mechanical stresses on regions that support the forces owed to both body weight and dynamics of the movement during walking. Pathological conditions such as diabetic foot could increase complication risks of foot injuries produced by high pressures. These injuries could trigger ulcers that eventually can lead to partial or total foot amputation. Such conditions demand the use of prevention strategies like plantar pressure relief with therapeutic orthoses (also called insoles). Besides orthosis material, its effectivity depends on the upper surface topography and specially on the effective contact area provided by this surface. The design and manufacturing of foot orthoses is generally high-dependent on the clinical specialist expertise, who usually employs prefabricated orthotic inserts. This is due to the lack of clear guidelines to design the upper topography or the surface contact between the foot and the orthosis. This work shows the development and implementation of algorithms for the generation of insoles based in geometric and load criteria, and their respective effects on plantar pressure distributions, which were assessed using a dynamic simplified non-linear finite element model of foot during the stance phase.

Methods: Computed tomography (CT) information from a subject with diabetic foot condition was used to obtain 3D foot geometry. The soft tissue was defined by a hyperelastic constitutive model [1]. Bones, tendons and joints were defined as isotropic elastic materials. Muscle and body weight forces were set in their respective application regions.The pressure distributions produced by three upper-orthoses topographies were compared: a plantar shape-based topography; a topography obtained by an own proposed method which implements an algorithm that uses the dynamic average pressure maps (DAPM) in the gait cycle providing by in-shoe plantar pressure analysis system F-Scan® (Tekscan, USA); and a clinical-prescribed custom orthosis topography that was digitized with a 3D laser scanner.The material of foot orthoses was defined as EVA (Ethylene vinyl acetate), which is a foam that was employed to model all orthoses, due to the fact that it is a material commonly used in therapeutic footwear [2]. The EVA's behaviour was described by Ogden's hyperfoam material model. Additional to the gait normal phases in barefoot and custom orthosis employment effects (Figure 1a.), the contact effects on the upper surface of an EVA rectangular block were compared. This scenario allows to assess the response of EVA in plantar pressure relief without the influence of a custom topography. In order to assess the validity of the model, the comparison of center of pressure (COP) trajectories, values and distributions of pressures and force vs. time curves of the model with experimental data obtained from both F-Scan® and force plates in a gait laboratory (BTS-GAITLAB, BTS Bioengineering, Italy), was performed. Other scenarios with higher rate loads than the normal step case were also simulated, in order to observe the plantar pressure relief effects provided by the orthosis in each case (Figure 1b.).

Results: Regardless of the simplifications that were made in the model, the maximum pressure values and COP trajectories for the barefoot simulation are consistent with the experimental data.The contact pressures were notably reduced in all evaluated cases on the simulations, if they are compared with barefoot pressures (Table 1).
The insole model that shows the best results is generally the dynamic DAPM-based topography, followed by the shaped-based form.

Figure:



Caption: Figure 1: a) Mid Stance simulation with clinical-prescribed custom orthosis, b) Contact Pressure distribution on heel provided by plantar shape-based topography during an instant of heel strike.

Conclusion: The obtained results show that the implementation of computational techniques, based on quantitative criteria such as dynamic gait-process pressure maps, could be a useful tool to validate clinical-prescribed insoles and therapeutic footwear, giving the possibility to know the behaviour in dynamic conditions with more certainty in the results than those obtained by employing standard devices or experience-based designs. This is crucial especially in cases where the value of plantar pressures is critical, such as in diabetic subjects.

Table:

Scenario	Support Topography Type			
	EVA Flat Surface	Plantar Shape-Based	DAPM-Based	Clinical-prescribed custom
Heel Strike	50%	67%	67%	43%
Mid-Stance	8%	45%	60%	21%
Initial Push-off	40%	41%	52%	35%
Final Push-off	62%	55%	46%	37%

Caption: Table 1: Reduction percentages in maximum contact pressure, compared to barefoot model.

STRETCHING YOUR ENERGETIC BUDGET: THE EFFECT OF TENDON COMPLIANCE ON THE METABOLIC COST OF RUNNING

Thomas Uchida [1,*] Jennifer Hicks [1] Christopher Dembia [2] Scott Delp [1 2]

[1]Bioengineering, [2]Mechanical Engineering, Stanford University, Stanford, California, United States

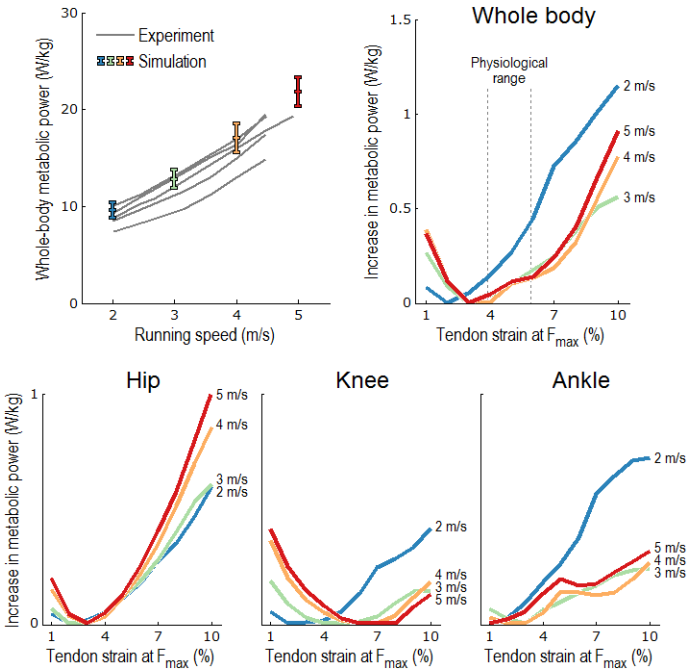
Introduction and Objectives: Humans naturally conserve energy, selecting running stride lengths that are most energetically economical [1], for example. The drive to maximize locomotion efficiency is also evident in the physiology of our musculoskeletal system. The triceps surae muscle group has evolved to allow storage and release of elastic strain energy in the calcaneal tendon [2]. Several studies have investigated the sensitivity of triceps surae efficiency to calcaneal tendon compliance and running speed. Lichtwark and Wilson [3] used a simplified, isolated model of the medial gastrocnemius (MG) musculotendon actuator during running at 2.8 m/s, and found that the simulated calcaneal tendon was most efficient at its physiological compliance. In this work, we investigate the effect of tendon compliance on the metabolic cost of running using a full-body musculoskeletal model with a detailed model of muscle energetics. We perform simulations of running at several speeds and tendon compliances, and predict the resulting whole-body and per-muscle metabolic costs. We explore two hypotheses: (1) whole-body metabolic cost is minimal when tendon compliance is physiological, and (2) the muscles crossing the ankle experience a greater increase in metabolic cost than those crossing the knee or hip as tendon compliance increases.

Methods: Simulations are generated for 10 subjects running at 2, 3, 4, and 5 m/s using the Computed Muscle Control (CMC) tool in OpenSim [4]. We use a 3D musculoskeletal model with 86 lower extremity muscles [5]. The CMC simulation results are used as inputs to a modified version of the muscle energetics model proposed by Umberger et al. [6]. We first simulate several running cycles for each subject at each speed, using the methods reported by Hamner and Delp [5], for physiological tendon compliances. We then repeat each simulation with a range of tendon force–strain curves that produce between 1% strain at maximum isometric force (Fmax) and 10% strain at Fmax. Averages of energy consumed by each muscle are obtained for each subject at each running speed; averages are then computed across the entire cohort.

Results: Our simulations correctly predict that the average power expended by muscle increases as running speed increases when tendon compliance is physiological (see figure). We also find that whole-body metabolic cost is minimal when tendon strain is 2–4% at Fmax, which falls just below the physiological range [7]. Further, muscles crossing the hip are most sensitive to tendon compliance at high running speeds, while muscles crossing the ankle experience a substantial increase in metabolic cost with increasing tendon compliance when running at low speed. These results coincide with the known shift in power generation from the ankle to the hip as running speed increases. The MG musculotendon actuator is the largest contributor to the increase in metabolic cost at the ankle when running at 2 m/s with very compliant tendons. When the tendon is compliant, the MG fiber is operating far from its optimal length during the stance phase, thereby requiring a greater activation signal to generate the necessary plantarflexion moment and

increasing the activation heat rate in the metabolic model. The MG fiber shortening velocity is also greater when the tendon is compliant, which increases the shortening and lengthening heat rate.

Figure:



Caption: Comparison between whole-body metabolic power measured experimentally [8] and predicted by our simulations using physiological tendon force–strain curves (top-left); increase in average metabolic power from the lowest metabolic power at each speed, observed in all lower extremity muscles (top-right) and in muscles crossing each of the lower extremity joints (bottom row) as tendon compliance varies. Averages over 10 subjects are shown. At the hip and knee, less compliant tendons are favored at low running speeds, while more compliant tendons are favored at high speeds. At the ankle, very compliant tendons are particularly detrimental when running at low speed.

Conclusion: Our simulations predict that whole-body metabolic cost is minimal when tendon strain is 2–4% at Fmax, which falls near the physiological range and confirms our first hypothesis. Our second hypothesis—that the muscles crossing the ankle experience a greater increase in metabolic cost than those crossing the knee or hip as tendon compliance increases—is true in our simulations only when running at 2 m/s; at higher running speeds, it is the muscles crossing the hip that are most sensitive to variations in tendon compliance.

RAPID QUANTIFICATION OF BONE ANATOMY FROM MRI

Saikat Pal [1,*] Marc Safran [2] Gary Beaupre [3] Garry Gold [4] Scott Delp [5]

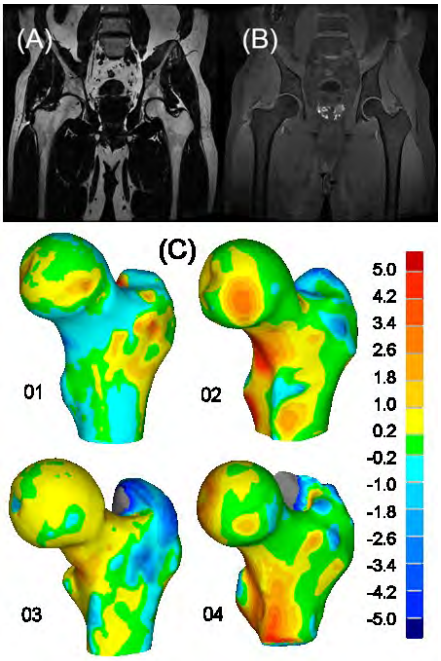
[1]Biomedical Engineering, California Polytechnic State University, San Luis Obispo, [2]Orthopaedic Surgery, Stanford University, Stanford, [3]Veterans Affairs, Palo Alto, [4]Radiology, [5]Bioengineering, Stanford University, Stanford, United States

Introduction and Objectives: Computed tomography (CT) scanning provides large contrast between bone and surrounding soft-tissue structures, enabling rapid segmentation and reconstruction of bone geometry. These 3D reconstructions are routinely used in clinics for diagnosis and treatment of bone geometry abnormalities, such as femoroacetabular impingement (FAI). CT scanning exposes patients to radiation and its side-effects, including cancer [1]. FAI is prevalent in young adults, and subjecting the pelvic region of young adults to multiple CT scans is particularly alarming because their reproductive organs are exposed to radiation. Magnetic resonance imaging (MRI) provides an alternative to CT scanning for evaluation of bone geometry abnormalities in patients with FAI. There is no exposure to radiation from MRI. However, clinical use of MRI scanning remains qualitative, with radiologists relying on visual detection of bone abnormalities. A major limitation in quantitative use of MRI for clinical evaluation of bone abnormalities is the time-intensive process of manual segmentation of bones. The objectives of this study were – 1) to develop a computational method to segment rapidly bone geometry from MRI of patients diagnosed with FAI, and 2) to quantify the errors in bone geometries from our MRI-based method compared to a standard CT-based method.

Methods: We acquired MRI and CT data from four patients (3 males, 1 female; 29.3±3.7 years) with FAI. The images were collected as part of standard clinical practice. The MRI scans were obtained from a GE 3T scanner: coronal IDEAL SPGR, in-plane resolution 0.8 mm, slice thickness 1.5 mm, TR 7.2 ms, TE 3.0 ms, flip angle 45º, ~12 minutes. The CT scans were obtained from a Siemens scanner: axial in-plane resolution 0.8 mm, slice thickness 1 mm, 120 kVp, exposure time 500 ms, and tube current 317 mA. We developed an interactive graphical user interface (GUI) in Matlab (Mathworks Inc., MA) to segment bone geometry from fat- and water-saturated MRI (Figure 1A,B). We used a k-nearest-neighbors algorithm [2] to cluster pixels associated with cancellous and cortical bone, with the remaining pixels binned with background pixels. We used a user-guided iterative bridge-breaker algorithm [3] to break spurious connections between the cancellous bone and background pixels. We used a logical OR operator to combine the cancellous and cortical bone pixels, and repeated the iterative bridge-breaker algorithm until we were left with only the desired bone pixels. We extracted the boundaries of the bone pixels and smoothed the boundaries using a locally weighted smoothing algorithm. The bone boundaries from all slices of an MRI dataset were output as a 3D point cloud. We converted the point cloud data to a 3D surface using Geomagic (3D Systems, NC) [4]. We used a standard threshold-based algorithm to segment the bone geometries from CT data. The bone boundaries from all slices of a CT dataset were output as a 3D point cloud and converted to a 3D surface. We registered the MRI and CT geometries spatially, and quantified the differences in surface morphology by measuring the shortest distance from a point on the CT-based geometry to any point on the MR-based geometry.

Results: We developed an interactive GUI to segment rapidly bone geometry from MRI. It took ~2 minutes and ~15 mouse clicks to create a 3D point cloud of a proximal femur bone using our GUI. In contrast, it takes ~30 minutes and several hundred mouse clicks to create a 3D point cloud of a proximal femur bone using manual segmentation.
For the proximal femur, average difference in surface morphology between the MRI and CT-based methods was 1.0 mm from the four FAI patients (Figure 1C, Table 1). The average difference was 0.7 mm in the femoral head and neck regions, which are the regions of interest in FAI.

Figure:



Caption: Multi-contrast MRI images with (A) fat-saturated and (B) water-saturated sequences. (C) Comparison of proximal femur surface morphologies from MRI and CT from four FAI patients. The contour maps represent the shortest distance between the surfaces in millimeters.

Conclusion: The results of this study demonstrate that our MRI-based method produces bone geometries that closely match geometries obtained from CT imaging, and at a fraction of the time compared to manual segmentation. The average differences in morphology between the MRI and CT-based methods were similar to the in-plane resolution of the images (0.8 mm). Our study has the following clinical applications in diagnosis and treatment of FAI – 1) eliminate the need for CT scanning for surgical planning, 2) minimize radiation dose in young adults, and 3) reduce health care costs.

Table:

Patient	Proximal femur (mm)	Femoral head & neck (mm)
01	0.8	0.7
02	1.0	0.7
03	0.8	0.6
04	1.3	0.9

PREDICTION OF THE SUBJECT-SPECIFIC KNEE PASSIVE MOTION FROM NON-INVASIVE MEASUREMENTS

Nicola Sancisi [1,*] Michele Conconi [1] Vincenzo Parenti-Castelli [1]

[1] DIN - Department of Industrial Engineering, University of Bologna, Bologna, Italy

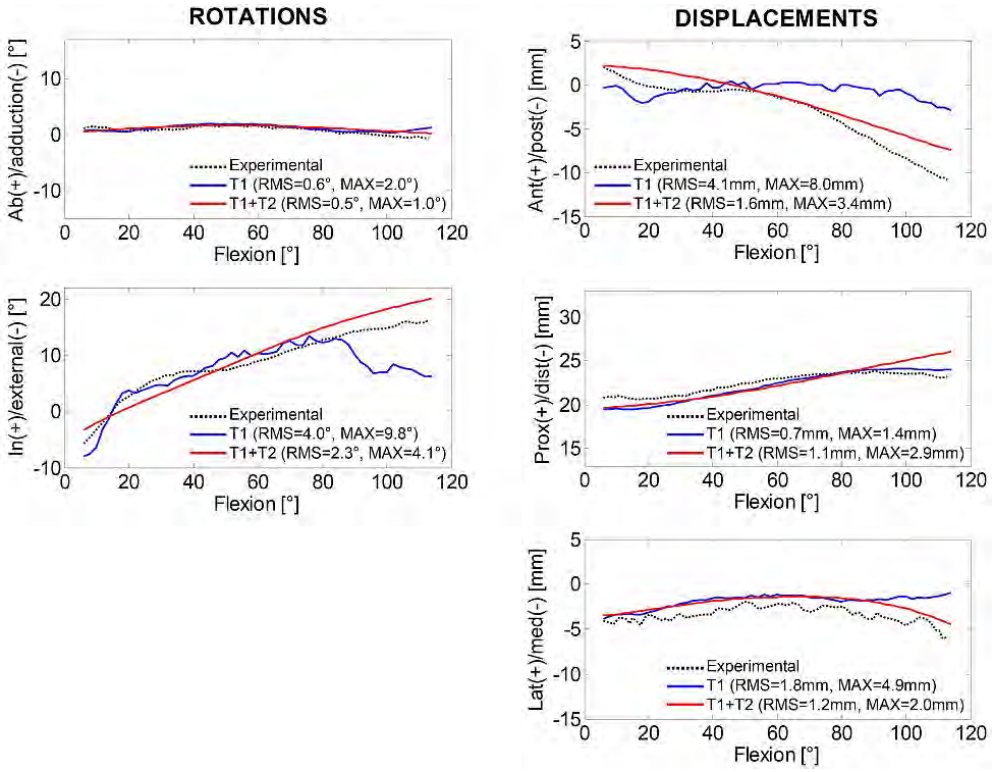
Introduction and Objectives: The passive motion of the knee is the natural motion of the joint in unloaded conditions. It is the joint starting condition when loads are applied, thus affecting the joint behaviour also in loaded conditions. For this reason, the knowledge of this motion is useful in all applications which aim at replicating or restoring the natural behaviour of the knee, such as lower-limb modelling, surgical planning, prosthetic design. Several studies measured the passive motion of the joint and the mean results can be used as a reference [1-3]. However, there is an increasing request of subject-specific results that would allow personalization of model parameters or of prosthesis geometry on a patient. In these cases, the subject motion would be required. An accurate estimation of the joint motion is difficult to obtain in vivo: non-invasive techniques can be inaccurate (skin-markers) or too complicated (fluoroscopy) for standard practice, while more invasive techniques (bone-pins) are not acceptable in several applications. Thus, new techniques are needed to predict the natural joint motion with a good accuracy, starting from non-invasive measurements. Two techniques were proposed for the knee passive motion modelling. Both methods start from the consideration, supported by relevant experimental analyses [2,3], that in passive conditions the knee behaves as a single degree-of-freedom (1DOF) system guided by the passive structures of the joint. The first technique (T1) predicts the passive motion by maximizing the joint congruence at all flexion angles [4]: it only requires the 3D model of articular surfaces with menisci, that can be obtained by MRI. T1 was developed for the ankle joint. At this stage, its application to the knee revealed a good accuracy, but the errors increased at high flexion angles, particularly for some motion components. The second technique (T2) models the knee as a 1DOF spatial mechanism, featuring the two articular contacts and the three isometric fibres of the anterior cruciate, posterior cruciate and medial collateral ligaments [3,5]. T2 was very accurate to replicate the passive motion of specimens over the full flexion arc, but a reference motion is needed to adjust the model parameters and the specimen motion was previously used [3]. The limitations of T1 and T2 are overcome in this paper by combining the two methods. An estimate of the joint motion is obtained by T1. This estimate is used as an input for T2 by which a new motion prediction is defined. The idea is that ligament constraints of T2, starting from the estimate provided by T1, can improve the overall motion prediction over the full flexion arc. The technique is here presented and applied on a specimen.

Methods: Geometrical data were obtained from a knee specimen, free from anatomical defects [3]. Anatomical landmarks, articular surfaces and ligament attachment areas were digitized by a stereo-photogrammetric device. For validation purposes only, several full passive flexion-extension cycles were performed and the same device recorded the tibia-femur relative motion by bone pins. Anatomical reference frames were defined and the relative motion was represented as 6 motion components (i.e., 3 displacements and 3 rotations) [3]. The digitized surfaces were used to apply T1. Flexion angle was imposed and the other 5 motion components were obtained by maximizing joint congruence; the procedure was repeated over the full flexion arc [4]. This T1 motion estimate was used as an input for T2: preliminary mechanism

parameters were obtained from the surface and ligament data, and were then adjusted (maximum difference of 2mm for all parameters) to best-fit the T1 motion [3]. The specimen motion was never used, except for result analysis.

Results: The passive motion was well predicted by T1 if flexion angle was not too high (Fig. 1): T1 began to diverge from the specimen motion at 100° and 80° respectively for ab/adduction and in/external rotation, and at 60° and 90° respectively for ant/posterior and lateral/medial displacements. The mechanism defined by applying T2 after T1 improved the motion estimate (Fig. 1): except for proximal/distal displacement beyond 90°, errors were lower and curve trend was more similar to the specimen motion over the full flexion arc.

Figure:



Caption: Experimental motion components, together with T1 and T1+T2 predictions. RMS and maximum errors are also reported.

Conclusion: The combination of joint congruence maximisation and of equivalent spatial mechanisms allows prediction of the natural subject-specific passive motion of the knee with a good accuracy. The proposed technique does not require invasive measurements and the motion can be obtained by standard MRI.

CORRESPONDENCELESS GROUPWISE REGISTRATION OF ANATOMICAL OBJECTS USING SPHERICAL EXTENT FUNCTIONS

Anton Semechko [1] Anne Agur [2] Jeremy Mogk [3,*]

[1]Institute of Medical Science, [2]Department of Surgery, Division of Anatomy, University of Toronto, [3]Autodesk Research, Autodesk Canada, Co., Toronto, Canada

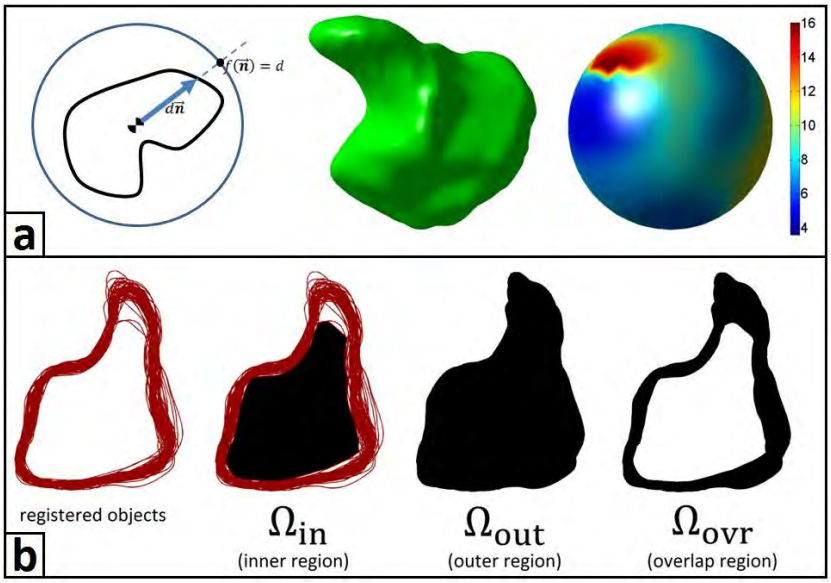
Introduction and Objectives: Aligning anatomical objects to a common frame of reference is a key pre-processing step for many biomedical applications, including analyses of joint kinematics and bone morphology. How to reliably align multiple samples (N≥2) of the same bone remains an open research problem. Common solutions, such as iterative closest point (ICP) algorithms, minimize the distances between corresponding points on multiple surfaces; however, suboptimal correspondences can result, thus reducing the quality of the registration. When N>2, the reference sample selected can bias alignment solutions [1]. We describe a new and robust technique that aligns multiple samples of a bone type to an unbiased frame of reference, without needing to determine surface correspondence. Further, we compare our new method to three other registration techniques using sample bone data.

Methods: Bone data originated from an electronic database containing triangular surface meshes for the 8 carpal bone types (60 wrists) [2]. Prior to aligning each bone type set, we aligned all samples of a common bone type by their centroids, and divided the surface coordinates of each bone sample by the cube-root of its volume to normalize scale. Using the normalized surface meshes, we applied each of four registration techniques to align the 60 samples of each bone type. For our new registration method, we first computed the spherical extent function (SEF) for each bone surface (Fig. 1a). Next, we randomly searched for three SEFs, $\{SEF_A, SEF_B, SEF_C\}$, for which the rotations that optimally aligned them met the following condition: $R_{AB}R_{BC} \approx R_{AC}$, where R_{jk} is the rotation that best aligned the j-th and k-th surfaces by minimizing the total absolute difference between SEFs. After rotating SEF_A and SEF_B to align with SEF_C, these three SEFs were averaged to create a reference SEF, to which we registered the SEFs of the remaining 57 bones. The mean of the registered SEFs became the new reference SEF, and the SEFs of all 60 bones were registered to that new reference. This registration-update cycle ended once the reference SEF changed by <1% (2 to 4 iterations). We parameterized rotations using three Euler angles (ZYZ convention) and optimized using gradient descent, initialized by grid-search (9x9x9 grid). We compared our new registration method to three other techniques. The first involved aligning the principal axes of inertia (PAI) across bone samples. The second used a symmetric ICP algorithm to minimize the sum of squared differences between the bone surfaces. The third, considered state-of-the-art, registered multiple surfaces using rotations that minimized the description length (DL) for each bone set [3]. We evaluated registration quality using V_{ovr}/V_{ave} as our alignment metric, where V_{ovr} is the volume of the overlap region (Ω_{ovr}) enclosed by the registered surfaces (Fig. 1b), and V_{ave} is the average volume of the registered bones. Division by V_{ave} made the metric invariant to global scaling.

Results: Based on registration quality, the SEF approach aligned bone surfaces as closely as the DL method, and greatly improved alignment over ICP and PAI (Table). Specifically, the SEF method aligned bone surfaces to within 3% of the DL

technique (across bone types), and performed 40-50x faster than DL. In comparison to ICP and PAI methods, our SEF registration improved the alignment of bone surfaces by an average of 35% and 53%, respectively.

Figure:



Caption: Process to compute a) the SEF for a sample hamate bone, and b) the metric used to evaluate registration quality. a) The maximal distances from the centroid to the surface are computed in uniformly distributed sample directions and projected onto the enclosing sphere. b) Better aligned surfaces (i.e., higher quality registration) show less difference between the outer (Ωout) and inner (Ωin) regions enclosed by the registered surfaces, and thus have smaller volumetric overlap (Ωovr).

Conclusion: Bone alignment using our new SEF approach closely matched that of the state-of-the-art DL method, and reduced registration time by removing the need to compute surface correspondences. Compared to working with the original surfaces, SEFs create representations that are simpler to work with, yet rich enough to encode the underlying morphology. Thus, the registered SEFs could be used to evaluate morphological differences between populations (e.g., normal vs. diseased, female vs. male) and identify where on the bone variations occur.

Table:

Registration Method	Bone type							
	sca	lun	trq	pis	tpd	tpm	cap	ham
DL	0.903	0.740	0.782	0.827	0.889	0.783	0.829	0.995
SEF	0.933	0.756	0.801	0.860	0.924	0.799	0.858	1.020
ICP	1.742	0.973	1.079	1.144	1.530	1.282	1.622	1.650
PAI	2.745	1.912	1.565	1.626	1.666	1.455	2.038	2.160

Caption: Quality metric values used to quantify groupwise alignment of the 8 carpal bone types, for each of the 4 registration methods. Lower values indicate better alignment.

CALCULATION OF STUMP-SOCKET PRESSURE IN TRANSTIBIAL PROSTHESES DURING DYNAMIC GAIT SIMULATIONS.

Wouter Aerts [1] Friedl De Groote [2,*] Luiza Muraru [1 3] Louis Peeraer [3 4] Ilse Jonkers [5] Jos Vander Sloten [1]

[1]Mechanical Engineering, Biomechanics Section, [2]Mechanical Engineering, PMA, KU Leuven, Leuven, [3]MOBILAB, Thomas More, Geel, [4]Department of Kinesiology, Musculoskeletal Rehabilitation, [5]Department of Kinesiology, Human Movement Biomechanics, KU Leuven, Leuven, Belgium

Introduction and Objectives: One of the major concerns in transtibial amputees is the avoidance of pressure sores. Resulting gait compensations often result in an asymmetrical gait pattern [1]. Identifying the relation between gait pattern and pressure sore formation is of high clinical interest, since it would allow optimizing the socket design and foot-prosthesis alignment.

This cause-effect relationship is currently most often calculated using finite elements for describing the contact in static or quasi-static situations. Nevertheless these fail to incorporate important dynamic effects during gait. . In this study, we introduce a numerical efficient contact model that allows us to calculate the interface pressure between stump and socket during dynamic gait simulations based on 3D Mocap data. The simulated pressures are evaluated through comparison against measured pressures.

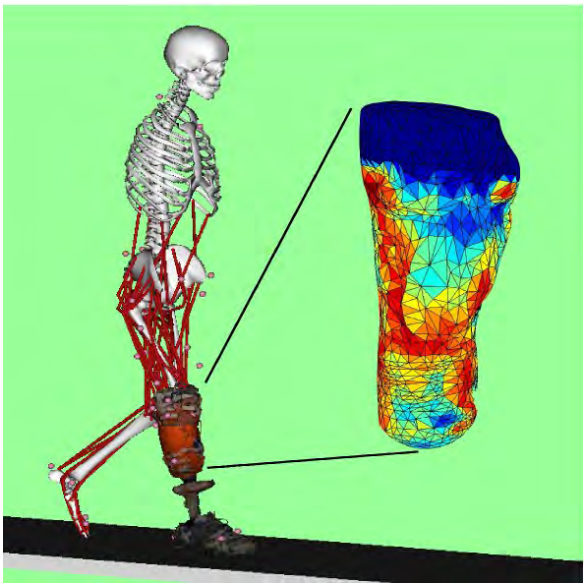
Methods: The gait pattern of one transtibial amputee is simulated using open-source software OpenSim [2] based on integrated 3D motion capture data. This data is collected in the gait laboratory of the research center Mobilab, Belgium, using a four cameras stereophotogrammetric system (Codamotion, Charnwood Dynamics Ltd, UK, 200 Hz) and two force plates (AMTI, Watertown (MA, USA), 200Hz). Simultaneously the pressure between socket and stump is measured with 20 M-flex pressure sensors (Maasbree, the Netherlands, 100 Hz) uniformly distributed over the stump.

A forward simulation is performed based on a dedicated musculoskeletal model representative for a transtibial amputee that integrates a patient-specific description of the contact between socket and stump (figure 1).The socket-stump contact is described using an elastic foundation model [3], which calculates the interaction via spring-damper systems scattered over the stump and inside of the prosthesis socket. Patient-specific contact geometries are obtained from a 3D surface scan of the stump, and from a CT-scan of the inner surface of the socket. The spring-damper systems are placed at each triangle of the triangle mesh representing these contact geometries. Stiffness and damping are estimated based on values for the Young's modulus found in literature [4].

The root mean square errors (RMSE) between the simulated pressures and the corresponding measured pressures for the 22 pressure sensors are calculated.

Results: The range and the median of the RMSE of the 20 sensors are shown in table 1. The median RMSE for all sensors has a low value of 25kPa, with a range of 29kPa, which is low compared to the maximum measured pressure of 184kPa. When grouping the sensors according to their location on the stump, the results show a smaller error for the lateral, anterior and medial aspect compared to the posterior aspect of the stump.

Figure:



Caption: Musculoskeletal model used in the dynamic gait simulation with a zoom out of the simulated pressure on the stump

Conclusion: The stump-socket interaction can be calculated accurately during dynamic gait simulations. This allows us to further investigate the effect of the gait pattern, stump and socket geometries, and prosthesis alignment on contact pressure. Future work aims at further reducing the RMSE by using non-uniform contact model parameters that are related to the local stiffness of the stump.

Table:

Median and range of RMSE of simulated pressure						
	Total		**Posterior**	**Lateral**	**Anterior**	**Medial**
Median RMSE (kPa)	25.16		38.06	22.22	24.95	22.86
Range RMSE (kPa)	29.09		7.10	14.16	20.26	18.28

Caption: Median and range of RMSE between simulated and measured pressure for 20 pressure sensors

OLDER ADULTS SHOW LESS TRICEPS SURAE MUSCLE FASCICLE SHORTENING IN WALKING COMPARED TO YOUNG ADULTS

Lauri Stenroth [1,*] Patricio Pincheira [1] Sarianna Sipilä [2] Neil Cronin [1] Taija Finni [1]

[1]Department of Biology of Physical Activity, [2]Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland

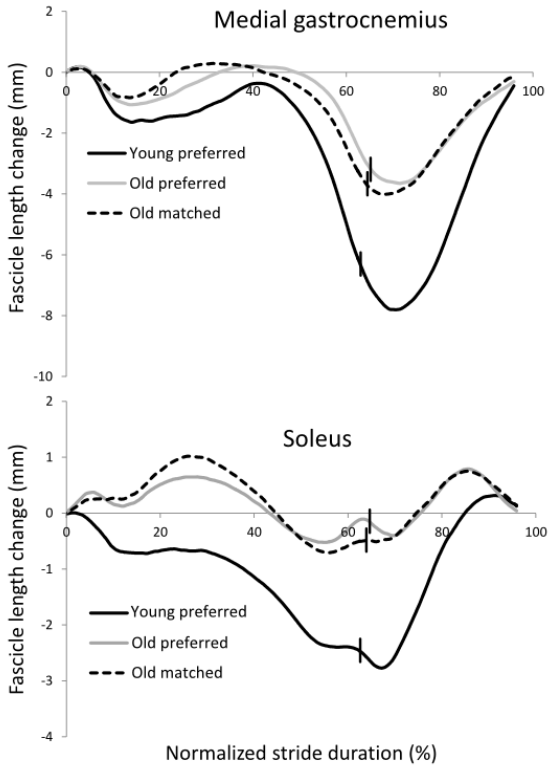
Introduction and Objectives: Aging is associated with alterations in Achilles tendon mechanical properties [1]. This could lead to alterations in triceps surae muscle function in walking, even if walking kinematics are preserved with aging. Altered triceps surae muscle function with aging could partly explain the pronounced deficit in ankle joint power production observed in older compared to younger adults [2]. The aim of this study was to compare medial gastrocnemius (MG) and soleus muscle fascicle behavior in healthy young and older adults in walking.

Methods: 10 young adults (18-30 years old) and 11 older adults (70-80 years old) participated in the study. Subjects walked over a 10 meter force platform at their preferred speed while MG and soleus fascicles were scanned with ultrasonography at 80 Hz. In addition to the preferred speed, older adults walked at a speed that was matched to the mean walking speed (1.4 m/s) of young adults. Average walking speed was determined using photocells at the start and end of the force platform. Muscle fascicle length was tracked from the ultrasonography videos using an automatic tracking algorithm [3]. Gait cycles were separated based on ground reaction force data and normalized to 100 data points. Fascicle length was normalized to the length at heel strike and averaged across gait cycles. Fascicle length (relative to heel-strike) at toe-off and amount of fascicle shortening (peak-to-peak amplitude of fascicle length) during ground contact were calculated for each subject. Differences between young and older adults were compared with independent samples t-test and differences between preferred and matched speed within older adults were compared with paired samples t-test. Level of statistical significance was set at $\alpha<0.05$.

Results: The preferred walking speed was significantly faster in young compared to older adults (1.4±0.1 vs. 1.1±0.1 m/s, $p<0.001$) but the matched walking speed was similar between the groups (1.4±0.1 vs. 1.4±0.0 m/s, $p=0.443$).

Both in young and older adults, MG fascicles showed first shortening and then lengthening from heel strike to mid-stance. From mid-stance to toe-off the fascicles shortened consistently (figure 1). In older adults, soleus fascicles first elongated during mid-stance and then shortened during push-off. At mid-stance, soleus fascicles in young adults showed near isometric muscle function. Despite 20 % increase in walking speed from preferred speed to matched speed in older adults, fascicle length changes were only minimally altered. Neither fascicle length at toe-off nor fascicle shortening during ground contact significantly changed in either muscle between the speeds. Fascicle length at toe-off was significantly shorter in young compared to older adults at preferred speed for both muscles (MG $p=0.027$, soleus $p=0.002$) but at matched speed only for soleus ($p=0.005$). MG shortened significantly more during ground contact in young compared to older adults at preferred speed ($p=0.021$) but not at matched speed ($p=0.063$). No significant differences between the groups were observed in peak-to-peak amplitude of soleus fascicle length during ground contact at either speed.

Figure:



Caption: Figure 1. Average fascicle length changes in young and older adults across the mean stride (heel contact to heel contact). Fascicle length is normalized to length at heel contact. Short vertical line crossing the fascicle length data indicates instant of toe-off.

Conclusion: The main result of the study was that older adults showed less length changes in MG fascicles in walking at preferred speed compared to young adults. In addition fascicle length relative to heel strike was shorter at toe-off in young adults compared to older at preferred speed in both muscles and in soleus at matched gait speed.

In general older compared to young adults showed less shortening in triceps surae muscle fascicles during ground contact in walking. The observed difference may reflect decreased functional capacity of triceps surae muscles in older adults and consequential compensation by other muscle groups such as hip extensors [2, 4]. Triceps surae muscles should be taken into account when designing interventions for improving or maintaining mobility in old age.

REVEALING QUADRICEPS INHIBITION IN MALES AND FEMALES WITH KNEE OSTEOARTHRITIS USING A SIMPLE MUSCULOSKELETAL MODEL

Daniel L. Benoit [1 2,*] Heather J. Bigham [1] Mohammad S. Shourijeh [1]

[1]Faculty of health Sciences, [2]Faculty of Engineering, University of Ottawa, Ottawa, Canada

Introduction and Objectives: Quadriceps weakness and increased muscle activation is commonly reported in healthy, older females and those with knee osteoarthritis (OA), [1]. Loss of muscle mass and arthrogenous muscle inhibition contribute to a decrease in muscle strength, and in response it has been suggested that normalised muscle activation increases to compensate. Musculoskeletal models are commonly used to predict muscle forces and provide more in-depth information on joint mechanics in various populations, including this vital information of voluntary activation deficits will result in more reliable predictions. As quadriceps play an important role in providing general stability to the knee joint, it is vital to understand the level of activation deficit in various populations. Therefore, we propose the use of a subject-specific model to determine the quadriceps and knee flexor level of voluntary activation deficit in older males and females with and without OA.

Methods: Peak knee extension and knee flexion torque (MVIT) data were collected on a *Biodex* dynamometer from twelve females with OA (64(6) years; 27.0(3.2) kg/m^2), sixteen healthy females (60(5) years; 23.1(2.7) kg/m^2), fourteen males with OA (69(7) years; 25.2(3.8) kg/m^2), and sixteen healthy males (64(8) years; 25.4(2.7) kg/m^2), along with EMG of eight muscles crossing the knee joint.

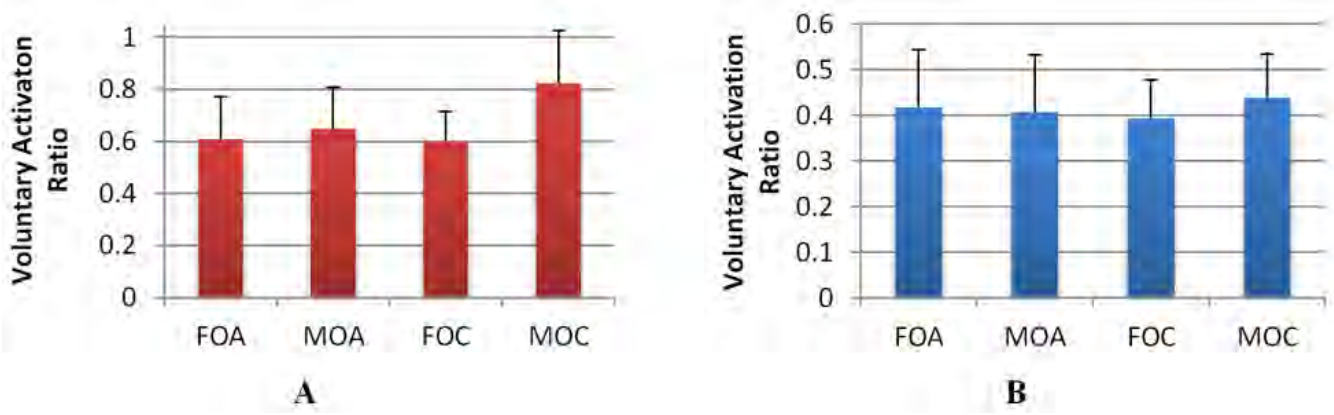
The OpenSim Gait2354 model was used to extract moment arms of these muscles with the hip (30° flexion), knee (30° flexion), and ankle (10° plantar flexion) positions corresponding to the MVIT tests. Within a mathematical framework [2] using optimization, maximum isometric force parameter F_0^{max} of the muscles was tuned to minimize the error between the simulation and the MVIT with initial values set so that F_0^{max} corresponded to those of [3]. A strength ratio representing the level of voluntary activation was defined as: $a_s=T^B/T^I$, where T^B is the *Experimental* peak torque (MVIT) and T^I is the *Ideal* peak torque calculated for each participant, to determine quadriceps and knee flexor strength deficiencies (lower value represents greater level of activation deficiency). The *Ideal* peak torque had all agonist muscles set at 100% of their potential force with no antagonist force production.

Results: Based on the optimal model-derived force production capability of the subjects, the mean level of voluntary activation of the quadriceps was significantly lower in OA participants and healthy females compared to healthy males ($p<0.03$) (Fig. 1A), representing quadriceps strength deficiencies in these groups. Mean±SD quadriceps muscle contribution ratios were not different between groups ($p>0.05$); however, standard deviations were high in all groups, suggesting this variable is subject-specific.

Ratios of mean±SD knee flexion voluntary activation were not different between groups ($p>0.05$; Fig. 1B). The lower activation ratios may be due to a lack of semimembranosus in the model and the gastrocnemius muscles never achieving 100% during the knee MVIT experimental tests and conclude the these values are not representative of hamstrings

activation deficits. However, the similarity between groups indicates that hamstring voluntary activation level is similar in older adults irrespective of sex and the presence of OA.

Figure:



Caption: 1A: Mean voluntary activation ratios (VAR) of the quadriceps in females and males with OA (FOA, MOA) and healthy controls (FOC, MOC); 1B: Mean VAR of the knee flexors in of FOA, MOA, FOC and MOC groups. Error bars represent standard deviation.

Conclusion: This study presents a novel method for estimating strength deficiencies during maximum effort at the knee and produced subject-specific estimations of voluntary activation deficits similar to those determined with supramaximal stimulation techniques in OA males [4], allowing us to quantify quadriceps inhibition as the deficit in level of voluntary activation achieved compared to the quadriceps' capacity to produce maximum knee extensor torque. Healthy females had similar levels of quadriceps inhibition than those with OA suggesting this may be an etiological factor that increases their risk of OA development. As our results support the notion that quadriceps inhibition is present in older males and females with and without OA. We suggest generic musculoskeletal models should make necessary adjustments of this variable to improve the validity of their model output predictions for these populations.

MULTI-CHANNELS FUNCTIONAL ELECTRICAL STIMULATION WALKING SYSTEM INSPIRED BY PURE REFLEXIVE CONTROLLER

Lin Meng [1,*] Bernd Porr [1] Henrik Gollee [1]

[1]Biomedical Engineering, University of Glasgow, Glasogw, United Kingdom

Introduction and Objectives:

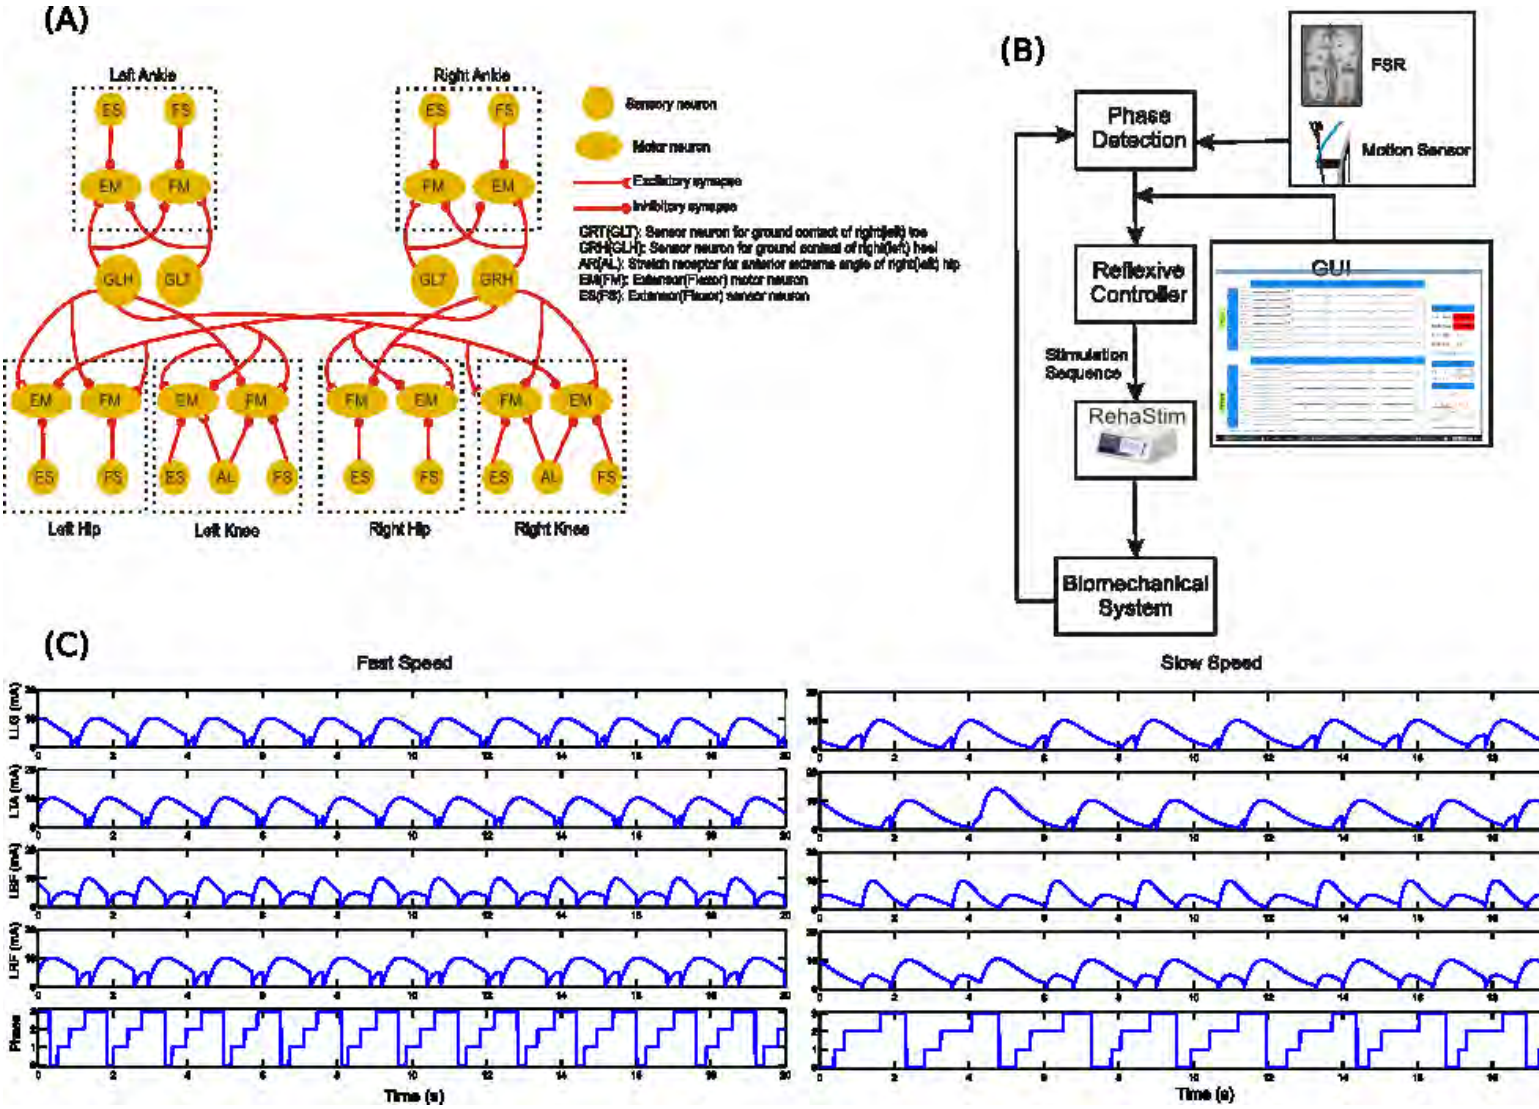
Most commercialized functional electrical stimulation (FES) walking systems are designed based on open-loop control [1] due to the issues of sophisticated closed-loop controllers including high computational power request, difficulties in implementing the control strategy on a human model[2]. However, an automatic FES system has a large potential market if it is able to free the subject's hands and manage to generate an adaptive gait pattern. A bio-inspired approach provides a way to exploit simple but efficient, robust control methods by abstracting the control principles from animals [3]. The Runbot is the first biped robot with pure reflexive controllers [4]. It is driven by local reflexes without zero moment control algorithms or central pattern generators. We created an abstract robot controller based on actual human walking in [6] by exploring the causal relationship between the foot contact information and the muscle activation (EMG). In this paper, we will present a multi-channels reflexive FES controller derived from the robotic model for use to gait rehabilitation.

Methods: A reflexive neural controller is utilized to generate locomotion of a robot [4], and is built based on reflexive mechanisms in humans [7]. The controller has a hierarchical structure where the sensor neurons contact the motor neurons directly (Fig.1 A). Foot contact information is the main feedback modulating the stepping, while the hip anterior extreme angle (AEA) triggers the ipsilateral knee extensor in swing. The EMG estabilishes the relationship to the biomechanical movement as it correlates with the muscle tensions [8]. It can be related to the joint movement in a ballistic locomotion which indicates the possibility to transfer the robotic controller to FES of muscles[6]. Four muscles were selected due to their functional roles in human walking (Tibialis Anterior (TA), Lateral Gastrocnemius (LG), Biceps Femoris (BF) and Rectus Femoris (RF)). Based on the previous work [6], we determine the timing for each muscle during one gait cycle (Table.1). Five gait phases are used in our model – heel strike (HS), foot flat (FF), heel off (HO), Toe off (TO), late swing (LS) when the hip reaches its AEA. For the detection of gait phases, the system replies on the combination of two types of sensors. The force sensitive resistors (FSRs) (Interlink Electronics, Camarillo, CA, USA) are embedded in standard shoe insoles, and will indicate when the foot contacts the ground and when not. The motion sensors (MPU9150, InvenSense) measure the hip angle in the sagittal plane. The whole system structure is shown in Fig.1 B. The detected gait phases are transmitted via the reflexive control model which sends the updated stimulation parameters to the programmable electrical stimulator (RehaStim, HASOMED, Germany). Filter transfer functions are used to generate the reflex responses. An user-friendly GUI window allows to control all parameters in real-time.

Results: The purpose of the experiment was to test the feasibility of the FES system with reflexive controller. In particular, we were interested in determining if the timing of the stimulation is appropriate for various walking speeds. One subject was asked to walk with different speeds (slow 1 km/h, fast 3.0 km/h) on the treadmill. The system worked successfully

and provide the stimulation sequences at correct timing in all conditions (as seen Fig.1C). A video demonstrates this proof of concept can be accessed at https://www.youtube.com/watch?v=-_AjptV9wcw

Figure:



Caption: (A) The reflexive controller of Runbot. (B) The structure of FES reflex walking system. (C) The stimulation sequences generated by gait phases

Conclusion:

We successfully adapted the simple reflex control model employed in the Runbot into a FES controller for gait rehabilitation. The automatic electrical stimulation system is simple, but effective, efficient and robust. The gait phases detected by FSRs in shoe insoles and motion sensors give the correct time for triggering specific muscles during walking. The GUI allows to individualize the stimulation patterns for different subjects and control stimulation parameters in real-time. In future, we will study the benefit of this reflex FES system for the walking of incomplete SCI patients.

IDENTIFICATION OF KINEMATIC AND CLINICAL FEATURES THAT PREDICT EXERCISE INTERVENTION OUTCOMES FOR TREATMENT OF PATELLOFEMORAL PAIN.

Ricky Watari [1,*] Dylan Kobsar [1] Angkoon Phinyomark [1 2] Blayne Hettinga [1 2] Reed Ferber [1]

[1]Kinesiology, University of Calgary, [2]Running Injury Clinic, Calgary, Canada

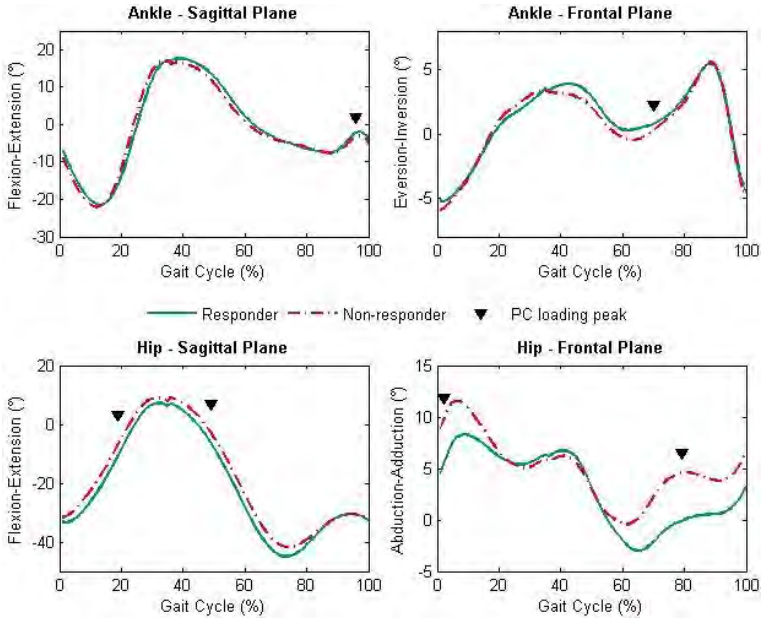
Introduction and Objectives: Exercise interventions are widely used for treatment of patellofemoral pain syndrome (PFPS) [1]. However, controversy remains on the effects of exercise therapy in pain reduction. It has been postulated that the inconsistent responses to an exercise therapy may be due to different gait profiles and kinematic patterns within this PFPS group. The aim of the current study was to retrospectively select parameters from sagittal and frontal plane gait kinematics, and self-reported pain and function measures, to predict the response of runners with PFPS to an exercise intervention protocol.

Methods: Data from 49 recreational runners with PFPS were collected prior to and following a 6-week muscle strengthening exercise protocol. The data collection included lower limb 3-D kinematics while running on an instrumented treadmill, knee function from the Anterior Knee Pain Scale (AKPS), and pain from a Visual Analogic Scale (VAS). Subjects were classified into Responders and Non-Responders based on their improvement on AKPS and VAS [1]. Pre-intervention gait and clinical data underwent three steps: (i) data reduction, using Principal Component Analysis (PCA); (ii) feature selection, based on effect size of the Principal Components (PCs) between Responders and Non-Responders, and (iii) supervised classification, with linear discriminant analysis (LDA), from which the combination of PCs with the highest classification accuracy were selected using a leave-one-out cross-validation method.

Results: The best classification model between Responders and Non-Responders when comparing the baseline data used 4 predictors; 2 clinical PCs (Clinical PC1 and PC2) and 2 gait PCs (Gait PC3 and PC24) to achieve 87.8% classification accuracy and explain 72% of variance of the treatment outcome. Clinical PC1 represented the amplitude of VAS and AKPS, while Clinical PC2 was a difference feature, with low scores indicating a worse VAS compared to AKPS. Gait PC3 was generally related to ankle and hip frontal plane angles in late swing and initial contact, and hip extension angles in mid-stance and early swing phases, while Gait PC24 was related to ankle dorsiflexion angle prior to initial contact. Compared to Non-Responders, Responders had higher Clinical PCs and Gait PC24 scores while Gait PC3 scores were lower. Overall, Responders were characterized as having a significantly higher pain VAS at baseline ($p = 0.001$), but no significant differences in functional measure of AKPS ($p = 0.732$). In contrast with our results, past studies on treatment response prediction have found higher pain scores at baseline to be predictive of poor treatment outcome [2]. Regardless, factors chosen by a prediction model are highly specific to the adopted interventions and sample population. Furthermore, Gait PCs indicated that, compared to Non-Responders at baseline, Responders exhibited greater ankle inversion angles in late swing, more abducted hip angles in late swing and initial contact, greater hip extension angles in mid-stance and early swing phases, and reduced ankle dorsiflexion angles prior to initial contact. In the current study, hip and ankle frontal plane kinematics during swing are represented by Gait PC3, confirming the importance of these features. Inconsistencies in literature may be due to heterogeneity among PFPS subjects,

considering the existing differences in response to treatment. For example, Responders had greater ankle inversion and hip abduction as compared to Non-Responders. Also, as Gait PC24 had a large influence in the LDA model, this finding supports previous research indicating that discrimination of running kinematics is a complex classification problem, reflecting relationships among many kinematic variables [3].

Figure:



Conclusion: Principal components that represent self-reported baseline pain and function, along with hip and ankle kinematics were able to predict the outcome of exercise intervention for PFPS treatment with 87.8% accuracy.

Table:

	Discrete variable	Responder (n=17)	Non-Responder (n=32)
Clinical PCs	VAS (cm)	5.9 (1.1)	3.7 (2.2)
	AKPS (score)	75.8 (8.4)	73.5 (10.3)
Gait PC3	Ankle inversion at 70% gait cycle (°)	0.79 (2.97)	0.24 (3.72)
	Hip adduction at 1% gait cycle (°)	4.49 (4.33)	8.83 (6.91)
	Hip adduction at 80% gait cycle (°)	0.07 (5.88)	4.53 (8.03)
	Hip extension at 20% gait cycle (°)	10.57 (6.34)	6.73 (7.64)
	Hip extension at 50% gait cycle (°)	6.60 (5.94)	3.01 (7.25)
Gait PC 24	Ankle dorsiflexion at 95% gait cycle (°)	2.17 (2.60)	3.21 (3.36)

Caption: Mean (SD) of discrete variables that represent the Principal Components (PC) used in the Linear Discrimination Analysis. Joint angles were extracted from the instant in gait cycle when the PC had a peak in loading coefficient.

EVALUATION OF HIP POSITION IN THE DEVELOPMENT OF STRENGTH AND ELECTROMYOGRAPHY RESPONSE OF THE RECTUS FEMORAL MUSCLE. SUMMARY TITLE : EVALUATION OF FORCE AND ELECTROMYOGRAPHIC RESPONSE IN RELATION TO THE HIP POSITION .

Paulo Veiga [1,*]

[1]University of Pernambuco, Recife, Brazil

Introduction and Objectives: The rectus femoral muscle is known as a bi -articular muscle. Its efficiency is significantly influenced by the position of the two joints, in accordance with the principles governing the relations of length - muscle tension. To understand the function of the rectus femoral muscle in relation to the hip position .

Methods: The sample consisted of 30 volunteers of both sexes, aged 18 and 25, which underwent strength testing and electromyographic evaluation of the rectus femoris muscle in three positions: (seated with the hip at 90 ° and knees flexed to 90°, seated with the hip and knee flexed 45 ° to 90 °, lying with the hip and knee flexed 0 ° to 90°). Movement of knee extension , with maximum power for 10 seconds at each position, with a time of 2 minutes of rest between them was asked. The data were stored in individual records for further inferential statistical analysis. Considered the level of significance where p-value ≤ 0.05.

Results: It was observed in the study, no statistical significance of strength and electromyographic response of the rectus femoris muscle in relation to the hip position.

Conclusion: Comparing the analysis of force and electromyographic response of the rectus femoris muscle in relation to the position of the hip assessed in the respective angles 90 ° , 45 ° and 0 ° , there was no statistical significance. However, they showed up differences between genders. Given this, the authors emphasize the need for more studies on the subject .

EFFICACY OF PHARMACOLOGICAL AND NON-PHARMACOLOGICAL STRATEGIES TOWARDS CEREBRAL PALSY INDUCED SPASTICITY

Dinesh Bhatia [1,*] Bablu Lal Rajak [1] Protima Nomo Sudro [1]

[1] Biomedical Engineering, North-Eastern Hill University, Shillong, India

Introduction and Objectives: Pharmacological and non-pharmacological (repetitive Transcranial Magnetic Simulation (rTMS), Transcranial direct current stimulation) strategies are being widely used in therapeutic and investigative studies. Both these strategies have been extensively used in patients suffering with multiple sclerosis, stroke, spinal cord injuries and cerebral palsy (CP). Various studies have examined both these strategies and yielded effective results like medicines for relaxing muscle spasms, control pain, seizures and improvement in range of movement. Due to the velocity-dependent increase in muscle tone, various issues like tendon jerks, clonus, spasms and hyper-excitability resulting from stretch reflex were observed in patients with muscle spasticity. Based upon the number of affected joints and muscles leading to the impairment of activity limitation, spasticity is categorised as focal spasticity and multi-focal spasticity. The paradigm of treatment for them also varies according to the impairments around a specific joint or multiple joints. The aim of this study is to comprehensively review both the pharmacological and non-pharmacological approaches towards cerebral palsy induced spasticity patients and study the effects of different techniques (long term potentiation, long term depression, activity dependent metaplasticity, shift in excitability and so on) employed on remedial treatment till date for neuro-rehabilitation. The group is presently working on sponsored projects from the government to study effects of r-TMS on muscle spasticity in CP kids. This review/study would be beneficial in working towards this objective.

Methods: This review reports the medication techniques of many identified studies involving excitation, inhibition, motor evoked potential (MEV) size, stimulation parameters like low and high frequency, time, angle of stimulation, region of stimulation (target area) and stimulation responses. Innumerable novel stimulation paradigms have been developed consisting of significant potential for altering respective cortical excitability thereby minimizing spasticity in CP patients. However, further research as per literature reviewed till 2013 shows that different innovative paradigms such as Botulinum neurotoxin, posterior rhizotomy, neuromuscular electric stimulation and dynamic bracing are being carried out to attain optimum stimulation techniques in order to overcome central nervous system (CNS) disorder causing balance and movement problems. This would help in people suffering from the above mentioned diseases.

Results: Of all pharmacological and non-pharmacological medications, rTMS being a non-invasive technique utilizing the principle of non-invasive brain stimulation by exploiting electromagnetic induction was found to be very effective for the treatment of muscle spasticity in CP kids (Gunduz A, et al. 2013). Abdelkader. A.A. et al. 2013, specified that rTMS has the potential to contribute improvement in spasticity which ultimately improves the quality of patients life. Terreaux L, et al. 2013 exhilarates the effects of rTMS in reducing reflex excitability and stiffness of ankle-plantarflexors in patients affected from muscle spasticity. Valle A.C. et al. 2007 found that high frequency rTMS is beneficial in reducing spasticity in children with CP and it was later on proved by many clinical trials on these subjects. Cabre et al. 2005 provide the juncture influencing spinal excitability and modify descending corticospinal influences in controlled manner by using rTMS

Conclusion: From these results, it can be concluded that r-TMS would be beneficial in treating spasticity in above population group thereby improving their quality of life and enabling them to perform activities of daily ADL tasks in an effective manner.

Keywords: Pharmacological and non- pharmacological strategy, spasticity, cerebral palsy and rTMS.

COMPARISON OF TWO DIRECT KINEMATIC MODELLING APPROACHES FOR SPORT-SPECIFIC UPPER LIMB MODELLING

Denny Wells [1,*] Cyril Donnelly [1] Bruce Elliott [1] Jacqueline Alderson [1]

[1] The School of Sport Science, Exercise and Health, The University of Western Australia, Perth, Australia

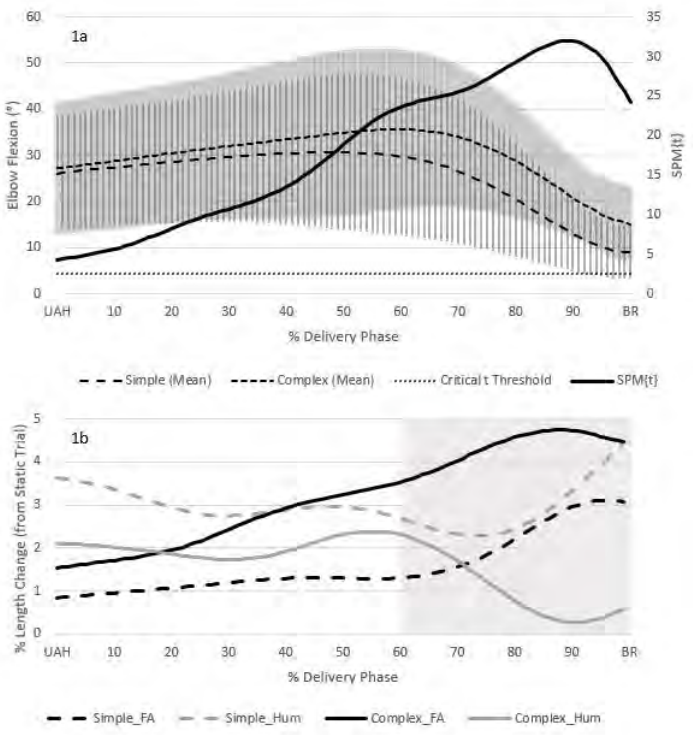
Introduction and Objectives: Since the publication of the Calibrated Anatomical Systems Technique (CAST)[1], modelling approaches, generally speaking, can be segregated into those that use this approach (*complex*), and those that do not (*simple*). There is however, a paucity of research that has directly compared the kinematic estimates of both models. In a sport such as cricket, where strict limitations are placed on elbow extension range (EER) during the bowling delivery, the modelling approach used could inadvertently influence the rulings on a bowler's legality. The aim of this research is to compare the upper limb kinematic estimates and ruling of cricket bowling legality between one *simple* and one *complex* modelling approach.

Methods: Two marker sets were simultaneously applied to nine bowlers who each bowled 24 trials together with two static/neutral trials. The *complex* approach stored joint centre (JC) estimates relative to technical co-ordinate systems (triads of markers). The shoulder JC was calculated as per Campbell[2,3], and stored in the proximal upper arm and acromion triads; elbow JC as the midpoint of the medial and lateral epicondyles, stored in distal upper arm triad[4]; wrist JC as the midpoint of two markers on either side of the wrist during the static trial, stored in distal forearm triad. The *simple* modelling approach calculated the JC as the midpoint of two markers placed on either side of each joint. Kinematic variables were calculated from upper arm horizontal (UAH) to ball release (BR) (delivery phase): 1) segment (forearm and upper arm) lengths and 2) elbow flexion/extension (FE) angles. Elbow FE angles were further analysed by a) a traditional zero dimension (0D) statistic - ANOVA - investigating specific elbow FE events (UAH, maximum flexion, minimum flexion, BR, EER), and b) across time with one dimensional statistical parametric mapping paired t-test (SPM1D)[5].

Results: The 0D analysis of *simple* and *complex* dynamic bowling trials found no difference (and high correlation) in elbow FE events at the beginning of the delivery phase (UAH), then significant differences at each event for the rest of the delivery: Maximum Flexion (*simple*: 34.8°; *complex*: 39.9°; $p < 0.001$), Minimum Flexion (*simple*: 7.3°; *complex*: 14.0°; $p < 0.001$) and BR (*simple*: 8.9°; *complex*: 15.7°; $p < 0.001$). Importantly, there was no significant differences (and high correlation) to EER between *simple* and *complex* modelling approaches. The International Cricket Council enforced 15° EER[7] limit was applied to each of the deliveries within the dataset to find what the recommendation of bowling legality would be made. Four of 216 (2%) deliveries did have different results with the application of the 15° elbow extension rule. In each case the *simple* approach returned illegal (>15° EER); the *complex* approach legal (<15° EER). Three separate participants were affected and had conflicting legality rulings (1/3 total participants). The SPM1D analysis shows the *simple* and *complex* elbow FE modelling approaches produce different elbow FE results for the whole delivery phase. The smallest difference is at UAH (where 0D analysis shows no difference), greatest difference at approximately 90%. The accelerations and large range of motion experienced by the shoulder during this phase result in STA, which is supported by the presence of fluctuating segment lengths[6]. Upper arm and forearm segments for both modelling approaches

changed length throughout the dynamic trials (average 2.34%). The combination of large scapula movement during the overhead movement and STA present in the second half of the delivery phase (specifically 60-100%) coincides with the greatest differences found by the SPM1D analysis. Cricket bowlers are subject to EER limits and can be banned for exceeding EER limits. It is recommended future research looks to improve the dynamic modelling of the shoulder JC and investigate the use of inverse kinematics for modelling the upper limb during cricket bowling.

Figure:



Caption: Figure 1a: Mean and SD plotted on left axis, SMP1D analysis on the right.

Conclusion: *Simple* and *complex* modelling approaches produce different estimates of elbow FE during cricket bowling. This is due to STA and the relatively simplistic model of the shoulder during dynamic sporting tasks like cricket bowling. When the modelling approaches produced conflicting legality recommendations the *simple* always returned illegal EER whilst the *complex* returned legal EER.

ACCURACY OF GLENOID PLACEMENT IN REVERSE SHOULDER ARTHOPLASTY. CAN SURGEONS CORRECT THE PRE-OPERATIVE GLENOID DEFORMITIES IN OSTEOARTHRITIC SHOULDERS?

Julien Berhouet [1] Lawrence Gulotta [1] Xiang Chen [2] Andreas F. S. Kontaxis [3,*]

[1]Sports Medicine devision, [2]Biomechanics, [3]Leon Root Motion Analysis Laboratory, Hospital for Special Surgery, New York, United States

Introduction and Objectives: Reverse shoulder arthroplasty (RSA) is a popular option for treating patients suffering from cuff tear arthropathy, complex humerus fractures and failure of primary shoulder prostheses (2). Clinical and biomechanical studies have shown the benefits of RSA (2,3). RSA procedure remains technically challenging for the surgeon. The management of pathologic glenoid with bone deformities and defects makes it difficult to identify reliable anatomical landmarks, and consequently accurately position the glenoid component with a good primary bony fixation. Glenoid component placement during RSA on an arthritic eroded glenoid remains challenging for orthopaedic surgeons. Clinical results have shown that glenoid version and tilt should be corrected to anatomical values after the joint replacement. The objective of this study was to investigate whether surgeons can achieve glenoid version and tilt correction during RSA when they cannot visually assess the scapula orientation

Methods: This study included CT data from 24 pre-operative pathologic shoulders with highly eroded glenoids. All 3D-CT scapula reconstruction were created using Mimics®, Materialize. Glenoid version and tilt was defined by a single operator according to the recommendations of Friedman et al.,(2). RSA virtual surgery was performed in all shoulders using a virtual 3D model of the Biomet Comprehensive® Reverse Total Shoulder prosthesis. The focus of this study was the placement of the glenoid baseplate which was performed by two surgeons with experience in RTSA with two different techniques/methods:

i) In the first method the 3D geometry of the scapula was fully visible and the surgeons could interactively choose the placement of the baseplate in 3D and in 2D CT planes (named ‘interactive method’.

ii) In the second method the surgeons placed the glenoid baseplate while only the glenoid, acromion and coracoid were exposed (named ‘blind method’).

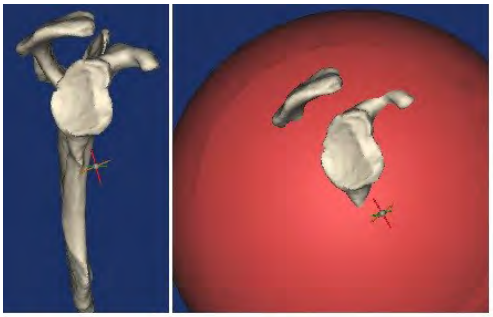
In both methods the surgeon’s objective was to position the glenoid baseplate as inferiorly as possible but to also correct the version and tilt of the eroded glenoid to anatomical values. The accuracy in glenoid component alignment was determined by the correction of the pre-operative glenoid version and tilt. Repeated measures ANOVA with post hoc analysis was used to determine the differences on glenoid correction (version and tilt) between pre and post-operative methods (interactive vs blind).

Results: The average pre-operative glenoid version and tilt were 8.4° (SD: 7.7°) and 9.8° (SD: 9.5°), respectively. The average version and tilt after the surgery with the ‘interactive method’ were 0.5° (SD: 0.7°) and 0.4° (SD: 0.4°), which means that it corrected the glenoid version of the highly eroded glenoids. When the surgeons used the ‘blind method’ (they could not see the orientation of the scapula) they placed the baseplate in 6.1° (SD: 6.0°) version and 12.4° (SD: 7.8°) tilt. Results showed that the two surgeons were not different ($p>0.05$) from each other and did not significantly

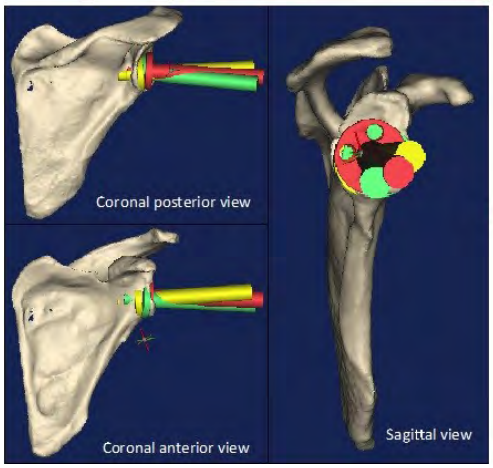
correct the pre-operative glenoid version and tilt (p>0.05). In 11 out of the 24 scapulae the baseplate placement resulted in glenoid volt violation by the peg of the baseplate.

The positioning of the glenoid plate showed that in average the two surgeons (that used the 'blind method') chosen almost the same inferior position as the operator of the 'interactive' method (Figure 2). That was probably because this study did not simulate the soft tissue that surrounds the glenoid or the narrow window that surgeons usually operate during shoulder replacement.

Figure:



(a)



(b)

Caption: (a) Two surgeons placed the glenoid baseplate with two methods: i)with scapula fully visible 'interactive method' (right picture), ii) with the body of the scapula hidden 'blind method' (middle picture). (b) The results showed different placement for the two methods

Conclusion: The results of this study suggest that when surgeons operate on highly eroded glenoids, where they cannot assess accurately the position of the scapula in space, they risk not correcting the post-operative glenoid alignment. Misalignment of glenoid fixation in total shoulder arthroplasty can affect load transfer and result in loosening. As a general conclusion, the study suggests that pre-operative planning with surgical navigation or specific tools/guides should be used to help the surgeons achieve accurate glenoid placement.

AS-0189

SHOULDER ROTATIONAL RANGE OF MOTION PATTERN IN ELITE VOLLEYBALL AND HANDBALL PLAYERS

Augusto G. Pascoal [1,*] Andrea Ribeiro [2] Sofia Neves [1]

[1]University of Lisbon, Faculty of Human Kinetics, CIPER, LBMF, Lisbon, [2]Fernando Pessoa University, Faculty of Health Sciences, Porto, Portugal

Introduction and Objectives: Shoulder adaptive morphological and functional changes have been described on overhead-throwing athletes [1]. The throwing shoulder, when compared to the non-throwing shoulder, exhibits a significantly increased humeral external rotation (external rotation gain) and a significantly decreased humeral internal rotation (glenohumeral internal rotation deficit) while the total range of motion (external rotation + internal rotation) is kept the same. Although the extensive research about kinetics and kinematics of overhand throwing motion, most of the published studies have focused on baseball, while few studies focused specially on handball or volleyball. Thus, the purpose of this study was to compare humeral rotational changes among groups of overhead athletes who participate in two different sports (handball and volleyball) and non-overhead athletes.

Methods: Ninety healthy subjects participated in this study, divided into three groups (N=30): handball group (20.7±1.4 years;76.8±4.1kg;184±4cm); volleyball group (20.7±1.0years;65.7±8.25 kg;177.7±6.1cm); and the control group, with non-overhead athletes (19.5±1.9years;64.3±4.3kg;174.8±3.4cm). An electromagnetic tracking device was used to record 3D shoulder kinematics (100Hz) with a set-up of 3 sensors: thorax-sensor attached to the skin over T1; arm-sensor fitted on a cuff and firmly adjusted to the subject's lateral arm and scapular-sensor, attached to the superior flat surface of the acromion process. A fourth sensor mounted on a hand-held stylus (±65cm) was used for bony landmarks digitalization to link sensors to local anatomical coordinate systems (LCS) and subsequently calculate segments and joint rotations according to the shoulder ISB standardization protocol [2]. In a seated position and the dominant arm at 90º of humeral elevation at scapular plane, subjects were asked to actively reach maximal internal and external shoulder rotation, keeping the scapula stable. The end-range value of internal and external arm rotation with respect to the thorax and the scapula was used to calculate the internal, external and total rotation arcs in the LCS of the thorax (IRth, ERth and TAth) and scapula (IRgh, ERgh and TAgh). Internal and external arcs were defined as the absolute angular difference between the rotational end-range and the neutral rotation. The total arc corresponds to the sum of both internal and external arcs. The neutral rotation corresponds to the point when both humeral epicondyles had the same orientation as the Y-axis of the thorax or the scapula LCSs. A one-way ANOVA with post hoc testing (alpha=0.05) was applied to compare dependent variables between groups.

Results: Volleyball group had significantly ($p<.05$) greater ERgh (volleyball=81.3º±12.8º; handball=71.0º±8.8º; control=55.4º±9.9º) and significantly less IRth (volleyball=33.1º±9.3º; handball=41.5º±16.8º; control=43.2º±2.5º) compared to handball and control. The volleyball group showed also had a significantly greater ERth (volleyball=67.1º±11.1º;handball=63.4º±11.2º;control=51.3º±9.5º) and less IRth compared to control. The handball group had significantly greater ERgh and ERth compared to control ($p<.05$). Volleyball group had significantly greater TAgh (volleyball=114.4º±15.6º;handball=112.5º±10.5º;control=98.5º±10.5º) and handball group a significantly greater TAth

(volleyball=96.2º±14.7º;handball=105.6º±9.8º;control=89.8º±11.9º), compared to the control. Taken the control group as reference, the external arc of rotation (glenohumeral and thoracohumeral) represents 55% (range:49-61%) of the total active arc of motion. This percentage were significantly greater on volleyball (71%) compared to handball (60%) and control (55%) groups.

Conclusion: The glenohumeral external rotation gain observed on throwers in comparison with control agrees with previous reports [e.g 3]. However the glenohumeral internal deficit was observed in volleyball players but not in handball players. Results showed a sport-related effect that must be considered on the assessment and/or rehabilitation of throwers athletes. Further studies about kinetic and kinematics sport pattern of motion are required in order to full understanding the adaptive changes on the throwing shoulder. In conclusion, the handball and volleyball groups showed humeral rotational changes with respect to control. Those changes identified an increased active glenohumeral and thoracohumeral external rotation motion. The glenohumeral and thoracohumeral internal rotation deficit was only observed in volleyball group. A glenohumeral external rotation shift and a thoracohumeral internal rotation deficit were observed on volleyball in comparison to handball group.

ACCURACY OF PRE-OPERATIVE PLANNING IN REVERSE SHOULDER ARTHROPLASTY

Andreas F. S. Kontaxis [1,*] Julien Berhout [2] Daniel Choi [3] Chen Xiang [3] Lawrence Gulotta [2]

[1]Leon Root Motion Analisys Laboratory, [2]Sports Medicine Devision, [3]Biomechanics, Hospital for Special Surgery, New York, United States

Introduction and Objectives: Reverse total shoulder arthroplasty (RTSA) is a popular option for treating patients suffering from cuff tear arthropathy (1) or other challenging arthropathies (4). Clinical and biomechanical studies have shown the benefits of RTSA (1,2) in pain relief and functional recovery, but concerns still remain regarding impingement and the presence of scapular notching on the scapular inferior border(3).

Recent studies have highlighted the importance of accurate glenoid prosthesis placement (3) and reported the use of patient-specific guides in aim to improve accuracy in glenoid positioning for RTSA. However there are no direct comparisons of how glenoid placement of a standard RTSA surgery compares to a guided RTSA surgery in cadavers and whether it results in better functional outcomes. The objective of this study was to investigate whether using a musculoskeltal model (for pre-operative plan) and a guided surgery can achieve larger impingement free range of motion (ROM) compared to a standard RTSA surgery.

Methods: This study performed RTSA surgery in 20 cadaveric specimens with two methodologies i) traditional procedure where glenoid baseplate placement is determined with the help of standard surgical instrumentation ii) a subject specific-guide where aids the surgeon in glenoid placement according to a pre-operative plan.

Surgeries were performed from a single surgeon with experience in RTSA. The Biomet Comprehensive RTSA (Biomet, Warsaw, Indiana) was used in the study (size: 28mm glenoid baseplate; 36mm diameter standard glenosphere; 44mm diameter standard onlay humeral tray)

For the standard procedure the standard instrumentation set was used to place the steinman pin on the glenoid. For the guided surgeries, a pre-operative position was defined using an interactive shoulder model, the Newcastle Shoulder Model (NSM) (2). The NSM was customized to describe a virtual RTSA surgery and the placement of the glenoid sphere was modified to maximize impingement free range of motion. Specific guides were manufactured by a 3D printer. The objective of the guide was to place the Steinman pin into the desired glenoid position based on the anatomical landmarks of the anterior glenoid border and coracoid foot.

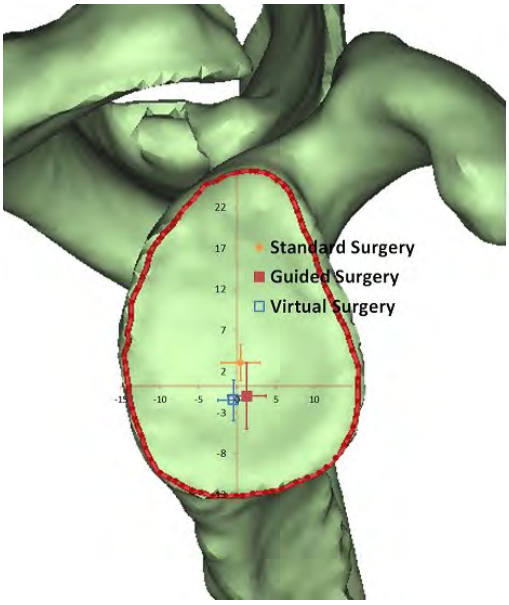
Pre and post-operative CTs were used to assess the glenoid version and tilt after the surgery as well as the position of the baseplate. The impingement free ROM was evaluated with a motion analysis system post-operatively for i) scapula plane elevation and ii) internal external rotation in 30 degrees of glenohumeral abduction.

Results: The average age and BMI of the specimens in the ‘standard procedure’ were 31.4 (SD) and 71.0 yo (SD 8.0) respectively and for the ‘guided procedure’ were 31.0 (SD 7.2) and 71.4 yo (7.0). The results of the glenoid alignment showed that in average both standard and guided RSA surgeries changed the post-operative glenoid version and tilt, but none of the changes were statistically significant ($p>0.05$).

In contrast, the guided surgery had a significant impact on the placement of the glenoid baseplate (Figure 2). Results showed that the guided surgeries placed the baseplate in average 4.2 mm (SD 4.0) more inferiorly compared to the standard procedure ($p<0.05$).

This difference in baseplate placement had also an effect on the impingement results. The average inferior impingement was recorded at 10.4° (SD 4.3) and superior impingement averaged at 67.9° (SD 4.3) for the guide surgery specimens. Even if the results were different from the pre-operative plan (the virtual surgery with the model showed no inferior impingement), it was better than the cadavers that received surgery with the standard instrumentation tools (average inferior impingement: 29.6 deg, SD 13.7, average superior impingement 59.3 deg SD 1.54, $p<0.05$). Rotation range of motion was 113 deg (SD 15.0) for the specific guide group and 63.3 deg (SD 27.4) for the standard guide group ($p<0.05$)

Figure:



Caption: Results of the glenoid placement for the different procedures. Glenoid placement with subject specific guides resulted in more inferior glenoid baseplate placement (red 'Guided Surgery' vs orange 'Standard Surgery'). The specific guides placed the glenoid close the pre-operative plan – model's virtual surgery (blue 'Virtual Surgery')

Conclusion: The guided surgeries provided a glenoid placement that was close to the pre-operative plan that was designed with the model. The specimens that received the guided surgery achieved a more inferior glenoid placement compared to the specimens that had the standard surgery. The latter translated in a better functional outcome with a larger free impingement range of motion.

Musculoskeletal models and custom surgical guides can be used to create pre-operative plans and help surgeons maximizing functional outcomes in RTSA.

A COMPARISON OF ARTIFICIAL NEURAL NETWORK AND REGRESSION MODELS FOR PREDICTING MANUAL ARM STRENGTH BASED ON HAND LOCATION

Nicholas L. La Delfa [1,*] Jim Potvin [1]

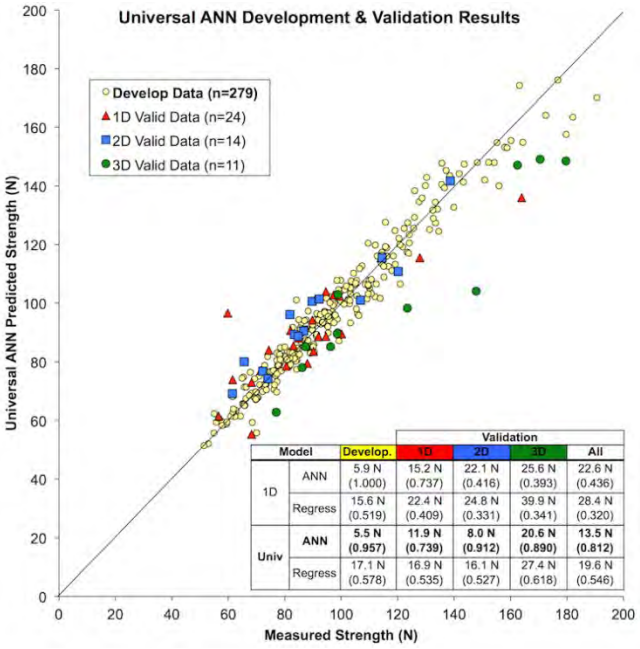
[1]Kinesiology, McMaster University, Hamilton, Canada

Introduction and Objectives: The accurate estimation of manual arm strength (MAS) is an important component of ergonomic task evaluation. Strength prediction has typically been accomplished using complex linked segment biomechanical models, and estimates of strength about each axis of the wrist, elbow and shoulder joints. However, it has recently been shown that multiple regression approaches, using the simple task-relevant inputs of hand location and force direction, may be a better method for predicting MAS [1]. Alternatively, the use of artificial neural networks (ANNs) has seldom been used to predict strength, despite being shown to be a valuable data-fitting tool for small and noisy data sets [2]. Therefore, the main objective of this study was to perform a direct comparison between ANN and regression models, by evaluating their ability to predict identical sets of development and validation MAS data.

Methods: The MAS data from 71 female participants, with an age-range representative of the working population, were compiled from previous studies in our lab (see [1] for further details). These data consisted of MAS measurements in the six primary force directions (i.e. up, down, anterior, posterior, medial, lateral – termed '1D' forces) in 28 hand locations within the reach envelope. In addition to the 1D data, 42 of the participants also performed maximum force exertions in combinations of two (2D, eg. up & anterior) and three (3D, eg. up, anterior & lateral) of the six primary force directions. These additional measurements were obtained from 8 of the hand locations (Table 1). ANN & regression models were developed using: 1) all of the MAS data (Universal models), and 2) only the 1D data (1D models). Both the Universal and 1D models were developed using a random, but identical, sample of 85% of the Universal and 1D datasets, respectively. The remaining 15% of the data were used to validate each of the four models, by determining how the models would predict MAS values not included in their development. The ANN models were developed in Matlab (v2014b) using a double-layer feed-forward network, trained using the Bayesian Regularization algorithm. The multiple regression equations were developed in SPSS (v21) using a stepwise approach. The coordinates of the hand (relative to the shoulder) and the direction cosines of the manual force vector, were used to create 20 input variables for developing and evaluating each model. Model performance was evaluated using Pearson's correlation analysis and evaluation of root mean square errors (RMSE).

Results: Overall, the ANN models explained more variance, and had lower errors, compared to the regression models (Figure 1). Both ANN models had a mean RMSE of 5.7 N, compared to a mean RMSE of 16.4 N for the regression models. The 1D ANN model had a higher explained variance compared to the Universal ANN model (1.000 vs. 0.957, respectively), but the Universal ANN model had a lower RMSE. In the validation test, both Universal models (regression & ANN) predicted MAS better than the 1D models, with the Universal ANN model producing a 30.7% lower RMSE, and a higher correlation, compared to the Universal regression model.

Figure:



Model		Develop.	Validation 1D	Validation 2D	Validation 3D	Validation All
1D	ANN	5.9 N (1.000)	15.2 N (0.737)	22.1 N (0.416)	25.6 N (0.393)	22.6 N (0.436)
	Regress	15.6 N (0.519)	22.4 N (0.409)	24.8 N (0.331)	39.9 N (0.341)	28.4 N (0.320)
Univ	**ANN**	**5.5 N (0.957)**	**11.9 N (0.739)**	**8.0 N (0.912)**	**20.6 N (0.890)**	**13.5 N (0.812)**
	Regress	17.1 N (0.578)	16.9 N (0.535)	16.1 N (0.527)	27.4 N (0.618)	19.6 N (0.546)

Caption: Figure 1: Scatter plot of the Universal ANN model, which was the best performing model of the four that were developed (RMSE = 5.5 N, r-squared = 0.957). The model's prediction of 1D, 2D and 3D validation data are also shown on the scatterplot. The inset table shows the RMSE & r-squared values (in parentheses) of all development models, and their validation results. Cells that are bolded indicate the model that exhibited the lowest RMSEs for each column.

Conclusion: ANNs provided a viable method for accurately predicting MAS, and this will be particularly beneficial for ergonomics analyses. Though regression approaches have shown promise for predicting MAS, particularly for one exertion direction, it appears that ANNs may be a more universal approach when exertion direction is included as a predictor variable. This will allow future MAS models to predict average strength capability for a force vector oriented in any possible direction, rather than being limited to the six primary force directions. Furthermore, all models were more robust in the validation test when they were developed using Universal data (i.e. 1D, 2D & 3D data). Therefore, these models can likely be further improved by including more universal strength data from more hand locations within the reach envelope.

Table:

Type of Data	# of Subjects	# of Hand Locations	# of Exertion Directions	Total # of Conditions
1D	71	28	6	168
2D	42	8	12	96
3D	42	8	8	64
			Total:	328

Caption: Table 1: Details of the MAS used in the development and validation of the regression and ANN models.

AGE, GENDER, TRAINING AND ARM DOMINANCE – IMPLICATIONS FOR KINAESTHESIA AND MOVEMENT PERFORMANCE IN THE UPPER EXTREMITIES

Sybele Williams [1,*]

[1]Department of Physics, The University of the West Indies, St. Augustine, Trinidad and Tobago

Introduction and Objectives: The use of the upper extremities in the efficient performance of the activities of daily living is highly dependent on the joints' functionality and associated kinaesthesia for the goal-directed movements of the limbs, movement correction and locating limbs without visual control. One aspect of kinesthesia is proprioception or joint position sense (JPS). The bony structure of the glenohumeral joint facilitates a large range of motion however it often comes at a price since the joint is predisposed to pain and sensory disturbance due to overuse or injury. This leads to dysfunctional proprioceptive ability and JPS which can compromise an individual's safety and negatively affect the sense of security and quality of life when carrying out the activities of daily living (ADL) [1]. As such when investigating the functional capacity of a joint it is important to understand that characteristics of the subject collective e.g. JPS may be uniquely influenced by age, gender, training and arm dominance.

Methods: In this study, 6 male patients (mean age: 60.6 ± 13.0 yrs.) and 9 female patients (mean age: 62.8 ± 6.9 yrs.) with diagnosed SAIS were screened to determine the degree to which the dysfunction in the glenohumeral joint affects the functional capacity of the joint. The patient group was compared with three groups: healthy counterparts in the same age group (40 – 79 years), healthy younger groups and healthy trained athletes (handball players) in the age group 18 – 39 years. The group of healthy counterparts consisted of 14 males (mean age: 42.8 ± 2.5 yrs) and 12 female subjects (mean age: 46.4 ± 6.2 yrs). The group of healthy, untrained, young subjects was composed of 2 males (mean age: 29.0 ± 5.7 yrs.) and 7 females (mean age: 27.4 ± 5.1 yrs.) while the group of handball players consisted of 8 males (mean age: 26.3 ± 3.6 yrs.). For the investigation of the functional capacity of the joint a three-dimensional motion analysis system was used. For the assessment of the JPS of the glenohumeral joint each subject actively reproduced 6 standardised joint positions: abduction 50°, 65° and 80° as well as anteversion 50°, 65° and 80° under standardised conditions [2]. Two modalities were investigated, firstly all joint angle reproductions were tested with visual control (WVC) then the subjects were blindfolded i.e. no visual control (NVC) and the joint position sense was re-tested for each of the joint positions. The difference from the target joint angle was averaged over the three repetitions for each joint position reproduced. Multi-factorial unrelated analysis of variance (ANOVA) was used to determine group differences.

Results: Considering the dominant arm of male subjects it was found that the proprioceptive ability assessed according to the WVC modality was best for the athletes and worst for the patients. However healthy, untrained male subjects aged 18 – 39 years demonstrated proprioceptive abilities which were similar to patients under the same test. Additionally, it was found that performance worsened for the anteversion test angles set. Female subjects tested under the same modality showed no significant differences for any of the tests. With respect to the proprioceptive tests performed according to the NVC modality athletes once again demonstrated the best proprioceptive ability while patients displayed impaired joint position sense. However healthy, untrained male subjects aged 18 - 39 yeas and healthy, untrained males aged 40 – 79

years exhibited similar proprioceptive ability. Under the same modality the joint position sense of females was worse than that for males. An increasing inability to correctly re-position the arm was also displayed over the six test movements and their associated angles with a peak occurring at anteversion 65°.

Conclusion: The early identification and management of chronic joint disorders e.g. subacromial impingement syndrome (SAIS) in the glenohumeral joint are extremely important in managing the joint health of the affected person. This can be attained through the objective and quantitative assessment of individual movement patterns [3]. However the performance of daily movements is dependent on the kinaesthetic senses of the subject. In the case of complex, multi-joint daily movements a fuller understanding of the factors which may affect the biomechanical and coordinative strategies of healthy subjects and patients is important with respect to successful intervention approaches and rehabilitative therapies.

FATIGUE AND RECOVERY IN THE SHOULDER COMPLEX WHILE PERFORMING SIMULATED REPETITIVE WORK

Alison McDonald [1,*] Calvin Tse [1] Peter Keir [1]

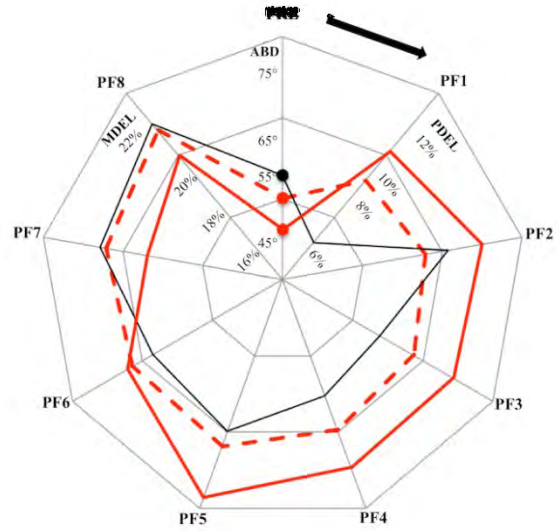
[1]Kinesiology, McMaster University, Hamilton, Canada

Introduction and Objectives: Low load, repetitive work is common in modern workplaces and these demands can contribute to the development of musculoskeletal disorders[1]. The anatomy and mobility of the shoulder complex allows kinematic and muscular adaptations to maintain performance despite fatigue-reduced capacity. Multi-joint compensations in the upper extremity have been employed to maintain performance during repetitive tasks[2]. How people utilize opportunities for kinematic and muscular variability and adapt during fatiguing work could change their physical exposure and risk for injury at work. The purpose of this study was to examine kinematic and muscular adaptations during continued performance of submaximal, repetitive work following a fatiguing protocol.

Methods: Twelve male participants completed a sequence of three protocols: (1) 20 pre-fatigue work cycles, (2) anterior deltoid fatigue protocol, (3) 60 post-fatigue work cycles. Each work cycle was 60 seconds and consisted of 4 tasks: (1) power grip handle pull (10 x 2 kg), (2) knob turn (5 rotations), (3) anterior drill press (10 s, 50% max), (4) power grip handle push (10 x 2 kg). The fatigue protocol was completed after 20 work cycles. The protocol was designed to fatigue the anterior deltoid muscle using static and dynamic exertions. Fatigue was quantified through changes in strength, ratings of perceived exertion (RPE), decreased EMG frequency and increased EMG amplitude during submaximal, static, reference exertions. Activity of 14 muscles of the upper extremity, back and chest were collected with surface electrodes at 2000 Hz (Delsys Inc., Boston, MA, USA). Kinematics were tracked with a passive motion capture at 100 Hz (Motion Analysis Corporation, Santa Rosa, CA) using 26 reflective markers and a custom scapular tracker[3]. For the data analysis, the work cycles were decomposed into the 4 tasks and the handle pull and push tasks were further divided into loading and return phases. Multiple repeated measures ANOVAs and preplanned Tukey HSD tests were used for the statistical analysis (SPSS Statistics 20.0, IBM, NY, USA).

Results: Immediately following the fatigue protocol, there were significant signs of muscle fatigue and reduced physical capacity (Table 1). These changes were accompanied by significant muscular and kinematic adaptations in the work tasks during the post-fatigue work cycles (PF1-8) ($p<0.05$). Although the handle push and handle pull tasks were quite constrained, there were several kinematic and muscle activity changes in both the loaded and the return phases of the tasks. Scapular changes, including increased superior rotation and decreased internal rotation were seen during the performance of different tasks throughout the recovery process. Amongst other changes following fatigue, reduced glenohumeral flexion was seen during the drill task ($p<0.05$). Concurrent with this was an increase in middle and posterior deltoid activity and a trend of increased glenohumeral abduction (Figure 1). At the end of the 60 post-fatigue work cycles, indicators of fatigue developed in the middle deltoid, however participant ratings of perceived exertion returned to pre-fatigue levels.

Figure:



Caption: Glenohumeral abduction (ABD - black line) increased along with middle (MDEL- solid red line) and posterior (PDEL - dashed red line) deltoid muscle activity (%MVE) during the drill task in the post-fatigue work cycles (clockwise pre-fatigue (PRE) to post-fatigue 8 (PF1-PF8)). By the end of the post-fatigue work-cycles the middle deltoid exhibited significant signs of muscle fatigue ($p<.05$).

Conclusion: We found that participants used kinematic and muscle recruitment adaptations following the fatigue protocol to maintain task performance for 60 post-fatigue work cycles. Although these adaptations allowed for recovery in some muscles, fatigue persisted and developed in other muscles by the end of the post-fatigue work cycles, despite subjective ratings of perceived exertions returning to pre-fatigue levels. If people are unable to perceive negative behavioural changes during repetitive work, they may be at greater risk of developing workplace injuries.

Table:

Measure	Baseline	Pre-Fatigue	Post-Fatigue	Post-60 Cycles
RPE	0.17 (0.32)*	2.41 (1.22)	5.88 (2.13)*	2.17 (1.56)
Strength (kg)	14.9 (2.6)	12.9 (2.2)	9.2 (3.0)*	13.8 (2.9)
Fatigued Muscles	N/A	N/A	Anterior deltoid, Posterior deltoid, Latissimus dorsi, Serratus anterior	Anterior deltoid, Middle deltoid, Serratus anterior

Caption: Fatigue was quantified by changes in RPE, strength and muscle fatigue (significant increase in EMG amplitude and decrease in median power frequency). Pre-planned comparisons were made between the pre-fatigue values and the other time points. * denotes statistically significant difference from “Pre-fatigue".

THE VACUUM PHENOMENON WITHIN A TOTAL SHOULDER REPLACEMENT CAUSING GLENOID COMPONENT DISSOCIATION – A NOVEL OBSERVATION

György Kocsis [1,*] Donal McNally [2] Angus Wallace [3]

[1]Shoulder and Elbow Unit, [2]Engineering, University of Nottingham, [3]Shoulder and Elbow Unit, Nottingham University Hospitals, Nottingham, United Kingdom

Introduction and Objectives: The Nottingham Total Shoulder Replacement (TSR) System is an anatomical shoulder prosthesis design, primarily intended for use with a metal glenoid baseplate. It is made up of the following components. A metal glenoid baseplate is inserted onto the bony glenoid after bone preparation. There is a humeral stem, onto which an artificial humeral head is assembled. Between the two metal components is a liner or bearing that is made of Ultra High Molecular Weight Polyethylene. The Nottingham TSR socket was designed to be fully congruent with the artificial humeral head. The design of the baseplate and liner was intended to ensure that the liner is clipped solidly and irreversibly onto the metal glenoid baseplate.

With the Nottingham TSA system glenoid liner disassembly from the metal glenoid baseplate became a relatively frequent complication. In our unit 32 dissociations were recorded in 464 primary and revision arthroplasty cases (6.89%), with the glenoid implant dissociation ranging from 2 months to over 7 years postop. We have explored the hypothesis that these dissociations are a consequence of the vacuum forces between the glenoid liner and the artificial humeral head. A model to measure the vacuum forces was developed, and fatigue tests were also carried out to assess the strength of the clip-on mechanism between the metal glenoid baseplate and the glenoid liner.

Methods: The measurement of the vacuum forces - A new Nottingham metal glenoid baseplate, polyethylene glenoid liner and a humeral head was mounted on an Instron 3367 tensile test machine. The artificial joint components were surrounded by a commercially available latex condom to simulate the joint capsule. Within the restraint, bovine synovial fluid was introduced. The space between the artificial joint components was free of air bubbles. The radius of curvature of the glenoid liner was the same as that of the humeral head prosthesis. The head component and the glenoid components were initially compressed with approximately 10N, then quickly moved away from each other along an axis perpendicular to the plane of the baseplate, and the forces were measured. Control measurements were completed using the same setup but using air instead of the synovial fluid.

The fatigue tests - A new Nottingham metal glenoid baseplate was mounted on an Instron 3367 machine. The plastic liner was clipped on, and using rods, the plastic liner was repeatedly pushed out of the baseplate along an axis perpendicular to the metal baseplate. The endpoint of the test was the complete disassembly of the liner from the baseplate. The tests were carried out using 40, 60 and 80N forces.

Results: The vacuum tests showed a peak force of 50.44N (SD 3.844) from which an average of 10.2N (SD 0.0145) was attributed to the resistance of the experimental system at the peak force. This proves that in our experiment about 40N of vacuum force was present.

The plastic liner disengaged from the metal glenoid baseplate after 25000 cycles using 40N of push out force in the fatigue tests. Using 60N of force the dissociation happened after 11000 cycles, using 80N force resulted in the disengagement of the plastic liner after 187 cycles.

Conclusion: Although the existence of vacuum forces is a generally accepted factor in the stability of a native shoulder joint, vacuum forces were not considered to be important during the design of the Nottingham prosthesis. Publications on failures of other designs of shoulder prosthesis do not mention this potential mechanism.

A very obvious explanation for the glenoid component disassembly would be surgical error, improper assembly of the components. In our experience surgical error leads to early disassembly of the glenoid components, within days after surgery. The temporal distribution of our disassembly cases does not support surgical error being the cause in the majority of cases.

Our in vitro tests verified two important conclusions. In our experimental setting vacuum forces of up to about 40N could be observed. This means that vacuum forces could also be important in vitro, and that these forces would need to be taken into account during artificial joint design. The other conclusion is that the clipping mechanism between the plastic glenoid liner and the metal glenoid baseplate of the Nottingham TSR System is a poor design, as dissociation can happen with a force as little as 40N after only 25000 cycles.

A weakness of our study is that the in vivo conditions might be significantly different from our experimental setup, however, our results are a viable explanation for the dissociations which have occurred in our clinical practice.

HUMERAL HEAD REPLACEMENT- DOES IT WORK?
A KINEMATIC STUDY OF SHOULDER MOTION FOLLOWING COPELAND® SHOULDER RESURFACING ARTHROPLASTY

Arpit Jariwala [1] Iain Hyndman [2,*] Linda Johnston [1] Weijie Wang [1] Graham Arnold [1] Carlos Wigderowitz [1] Rami Abboud [1]

[1]Department of Orthopaedic and Trauma Surgery, Tayside Orthopaedic and Rehabilitation Technology (TORT) Centre, Ninewells Hospital and Medical School, [2]School of Medicine, Ninewells Hospital and Medical School, University of Dundee, Dundee, United Kingdom

Introduction and Objectives: Copeland® shoulder resurfacing arthroplasty (CSRA) proponents suggest that it replicates the normal joint anatomy by providing restoration of the humeral head structure in terms of offset, version, angulation and shape. Most studies note the clinical improvement after CSRA but lack objective kinematic assessment. The aim of this study was to investigate the changes in motion analysis in patients following CSRA for range of motion (ROM) tasks namely; flexion, abduction, external and internal rotation. In addition, all patients were kinematically assessed on their ability to perform three activity of daily living (ADL) tasks namely; reaching behind the head, reaching for the contralateral shoulder and reaching behind the back.

Methods: Twenty-three shoulders (19 patients) with glenohumeral osteoarthritis agreed to participate in the study. Pre-operatively, patients underwent a clinical assessment, pain scoring (VAS 0-10) and shoulder scoring with Constant-Murley (CS) and Oxford Shoulder Score (OSS) by an independent nurse practitioner. Subsequently, patients underwent motion analysis, which involved placement of reflective markers on their upper torso that accurately recorded specific parameters of shoulder movement using eight high-tech three-dimensional (3D) Vicon cameras. The markers were placed according to the International Society of Biomechanics (ISB) guidelines. The same set of assessments was postoperatively recorded at 4 and 12 months for both ROM and ADL tasks.

Results: Nineteen shoulders (15 patients) completed the study. There were 15 female and 4 male shoulders. Two patients were unwell to return for analysis and one patient moved away. The mean age of the patients was 72 years (range 52-84). The VAS pain score improved significantly post-operatively ($p<0.001$). Both CS and OSS improved significantly following surgery at both follow-up periods ($p<0.001$).

Clinically both flexion and abduction improved significantly post-operatively ($p<0.001$). However, the motion analysis data showed that only abduction improved significantly post-operatively ($p<0.001$). Flexion improved significantly ($p<0.007$) by 4 months post-operatively but thereafter a loss of flexion was noted at the 12 month mark. Both external and internal rotation significantly improved post-operatively ($p<0.05$) when comparing the pre-operative value to the two post-operative assessments both clinically and kinematically.When analysing the three ADL tasks kinematically significant improvements in movement (both flexion-extension and abduction-adduction planes) were noted post-operatively ($p<0.05$) when compared to the pre-operative value for the reaching behind the head and behind the back tasks. The contralateral shoulder tasks did not show a significant improvement when comparing pre-operative measurements to either of the two post-operative assessments (4 and 12 months) in any plane.

Conclusion: This present study is the first research to utilise objective biomechanical tools in addition to clinical measurements and outcome scores to assess overall CSRA outcomes. In addition, the present study also investigated the effect the CRSA procedure had on the ability of patients to undertake ADL. It confirmed substantial improvements in shoulder motion by state of the art kinematic analysis methods, which compliments the enhanced clinical scores in patients undergoing CSRA. We have shown in the present prospective study that CSRA provided significant improvement in pain, range of motion, functional tasks and outcomes scores making it a viable alternative to conventional stemmed shoulder arthroplasty in a select group of patients. The finding that the scores and function following CSRA continue to improve with time up to one year is important to know as this will help clinicians and therapists to plan the future management of post-operative patients and allow them to investigate those patients who do not follow the trend.
This study fully supports the use of 3D motion analysis as a useful tool for assessing and monitoring treatments and surgical procedures providing independent, objective, standardised and sensitive analysis of outcomes. The results from the study also complement those reported elsewhere in the literature. The ability to pick up loss of flexion with time exclusively by the kinematic method as noted in the present study is an important finding. It highlights the ability of the kinematic methods to pick up small but significant changes in shoulder motion which may have important clinical implications. Its strength to analyse complex motion of joints especially in upper limb will encourage its use as a vital tool in future orthopaedic assessment practice.

EMG

AS-0196

NORMAL SHOULDER BIOMECHANICS: AN EMG STUDY

David Hawkes [1,*] Omid Alizadehkhaiyat [2] Anthony Howard [1] Simon Frostick [1]

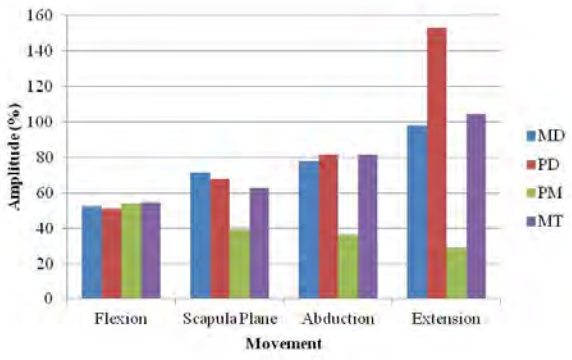
[1]Musculoskeletal Science Research Group , University of Liverpool, [2]Sport and Exercise Science, Liverpool Hope University, Liverpool, United Kingdom

Introduction and Objectives: The shoulder is a multi-axial ball and socket synovial joint. Due to its limited bony constraint, the humeral head can translate on the glenoid fossa when the powerful shoulder girdle muscles contract. Therefore, precisely modulated muscle activity is required to achieve and maintain a stable fulcrum for arm movement. The aim of this study was to define, using EMG, normal muscle activation patterns during arm elevation throughout the globe of shoulder movement

Methods: Twenty healthy participants with a normal clinical examination and no history of musculoskeletal problems were studied. Bipolar surface electrodes were used to record EMG from 10 shoulder girdle muscles (anterior, middle and posterior Deltoid, upper, middle and lower Trapezius, Serratus Anterior, Teres Major, Latissimus Dorsi and Pectoralis Major). The activity of the Supraspinatus, Infraspinatus, Subscapularis and Rhomboid Major was recorded using indwelling fine wire electrodes. Participants completed 10 cycles of shoulder elevation in 4 different planes: Flexion, Scapular Plane Elevation, Abduction and Extension. Mean EMG amplitude was compared for each muscle between movements using a repeated measures ANOVA.

Results: Table 1 presents the mean amplitude for all muscles. There were significant differences between movements for the middle and posterior Deltoid, middle Trapezius and Pectoralis Major (Figure 1). Mean amplitude (± standard error of the mean) was 52±2%, 72±5%, 78±5%, 98±8% for the middle Deltoid in Flexion, Scapular Plane Elevation, Abduction and Extension, respectively. Significant differences were seen between all movements (p=0.02 - <0.001). Similarly, significant differences in mean amplitude were seen for the Posterior Deltoid: 51±2%, 68±5%, 81±7%, 153±19% between the above movements respectively (p=<0.01-0.02). The activity in the Middle Trapezius significantly increased as subjects progressed from Flexion to Extension: Flexion 55±3%, Scapula Plane Elevation 63±4%, Abduction 82±13% and Extension 104±10% (p=<0.01-0.02). Significantly higher activity was seen in the Pectoralis Major during Flexion (54±3%) as compared to Scapula Plane Elevation (39±5%), Abduction (37±4%) and Extension (29±3%) (p=<0.01-0.01).

Figure:



Caption: Mean muscle amplitude during the different planes of shoulder elevation

Conclusion: The normal shoulder girdle muscle activation patterns during shoulder elevation through the globe of shoulder movement have been comprehensively defined. Significant differences between movements were found for the middle and posterior Deltoid, middle Trapezius and Pectoralis Major. Higher activity in the posterior Deltoid during Extension was expected given its line of action. Similarly, higher activity in middle Trapezius reflects scapula retraction during shoulder Extension. Significantly higher activity was seen in the Pectoralis Major during Flexion which was anticipated given its accepted role as a flexor of the shoulder joint. The results provide a comprehensive basis for better understanding of the muscle activation alterations associated with shoulder pathologies.

Table:

	Mean Amplitude (%)			
Muscle	**Flexion**	**Scapula Plane**	**Abduction**	**Extension**
Anterior Deltoid	59±2	69±4	71±5	69±6
Middle Deltoid	52±2	72±5	78±5	98±8
Posterior Deltoid	51±2	68±5	81±7	153±19
Upper Trapezius	62±2	75±6	74±5	98±12
Middle Trapezius	55±3	63±4	82±13	104±10
Lower Trapezius	59±4	57±4	68±10	78±12
Serratus Anterior	58±2	60±3	57±3	52±5
Pectoralis Major	54±3	39±5	37±4	29±3
Teres Major	61±2	64±4	62±3	69±4
Latissimus Dorsi	58±2	67±3	63±4	72±8
Supraspinatus	57±4	78±11	88±14	90±19
Infraspinatus	57±3	64±13	74±15	72±12
Subscapularis	58±2	56±5	59±5	57±9

SHOULDER INSTABILITY TESTS AS EFFECT MEASURES AFTER SHOULDER INTERVENTIONS – AN INTER-EXAMINER RELIABILITY OF THE CLINICAL TESTS

Henrik Eshoj [1,*] Camilla Marie Larsen [1] Kim Gordon Ingwersen [1] Birgit Juul-Kristensen [1 2]

[1]Institute of Sports Science and Clinical Biomechanics, Faculty of Health Sciences, University of Southern Denmark, Odense M, Denmark, [2]Department of Health Sciences, Institute of Occupational Therapy, Physiotherapy and Radiography, Bergen University College, Bergen, Norway

Introduction and Objectives: Shoulder instability is a common problem due to the large range of motion, which in general compromises the stability. Consequently highly active people in their second and third decades are often experiencing shoulder problems related to instability. In order to decide the optimal intervention precise diagnosis of shoulder instability is fundamental and mostly performed. To obtain an accurate diagnosis clinical tests need to be reliable. Hence, the objective was to investigate the inter-examiner reliability of six specific selected and standardized clinical shoulder instability tests.

Methods: A standardized protocol for carrying out reliability studies was used, containing a training, an overall agreement and a study phase. Male and females between 18-60 years of age were eligible for this study. Participants with an instable shoulder were included if they had at least one positive clinical instability test out of six, besides answering yes to either having a sense of shoulder instability and/or a prior shoulder injury. Shoulder healthy participants with no prior shoulder injury and no actual shoulder pain were included as shoulder healthy participants. Two examiners with six-months clinical experience performed the clinical tests and were blinded to both their independent test results and the status of the involved subjects. The clinical tests for shoulder instability were load and shift, apprehension, relocation, surprise, Gagey and the sulcus sign. Cohens kappa and Prevalence-and-bias-adjusted-kappa (PABAK) values, corresponding to adjustments for not reaching 50% of the index condition, were used in the analysis and interpreted according to Landis and Koch: 0.0-0.40 (poor); 0.40-0.75 (fair to good); and 0.75-1.00 (good to excellent).

Results: 40 participants (11 males, yrs 27±8), 13 with shoulder instability and 27 with unimpaired shoulders were included in the final study phase. Overall, kappa values varied from 0.39 to 0.77, corresponding to poor to excellent reliability. Gagey was the only test with good to excellent reliability (kappa 0.77). The load and shift, apprehension and surprise tests had fair to good reliability (kappa 0.50, 0.66, 0.66) whereas the relocation and sulcus sign tests had poor reliability (both with kappa 0.39). However, calculation of PABAK, improved the overall kappa-values to range 0.74-0.94. Hence, Gagey were joined by load and shift, apprehension and surprise in the group with good to excellent reliability and relocation and sulcus sign improved to the group with fair to good reliability.

Conclusion: When using PABAK kappa values increased to good to excellent. This means that with a standardized protocol for reliability studies, including a training, an overall agreement and a study phase the current clinical tests for assessing shoulder instability are reliable.

MUSCLE CO-CONTRACTION AT THE SHOULDER DURING THE DYNAMIC RELOCATION TEST: A CROSS-SECTIONAL STUDY WITH ASYMPTOMATIC INDIVIDUALS

Daniel C. Ribeiro [1,*] Jonathan Shemmell [2] Carrie Falling [1] Gisela Sole [1]

[1]School of Physiotherapy, [2]School of Physical Education, Sport and Exercise Sciences, University of Otago, Dunedin, New Zealand

Introduction and Objectives: The dynamic relocation test (DRT) was designed to test the patient's ability to recruit the rotator cuff muscles, and can be used as an exercise to enhance the control of such muscles [1]. The test consists of applying a gentle longitudinal traction to the humerus, while asking the patient to counterbalance this traction by retracting the humerus [1]. Patients may present with reduction in symptoms after 10 accurate executions of the DRT within the same session. The patient is deemed to have good control of the rotator cuff if no contraction of superficial muscles such as pectoralis major (PM) is observed. The clinician manually monitors activity, and verbally discourage contraction of PM. Nevertheless, muscle co-contraction may still occur. Due to motor redundancy, the central nervous system has an infinite number of possible motor strategies for performing a specific task. At early stages of motor learning, co-contraction is commonly observed, and it is expected to decline as learning occurs [2]. The DRT is a novel and unusual task for most individuals. It is reasonable to expect a reduction on co-contraction levels between infraspinatus and PM muscles.
The aims of the study were to: (i) quantify the co-contraction between infraspinatus and PM during successful executions of the dynamic relocation test over ten trials; and (ii) compare co-contraction levels between the 1st and 10th execution of the DRT. We hypothesized that co-contraction levels would reduce after ten trials.

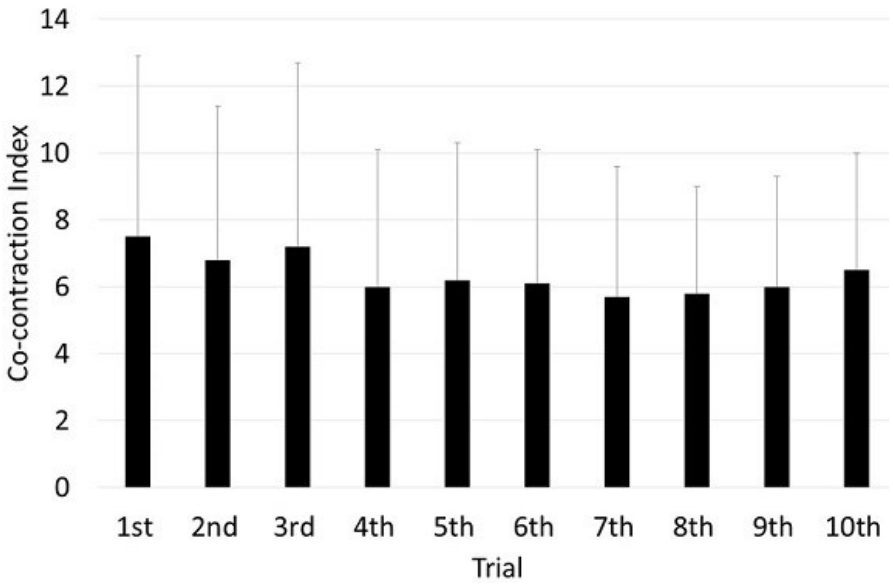
Methods: A cross-sectional study design with sample of convenience was used. Asymptomatic individuals from a university community were recruited for the study, approved by the University of Otago Human Ethics Committee. Participants performed maximal isometric voluntary contraction (MIVC) for each monitored muscle. Then they were requested to perform the DRT, sustaining it for 10 seconds, with an interval of 5 seconds. To enhance external validity, only successful trials (n=10) were recorded. For a trial to be considered successful, participants had to sustain an isometric contraction with minimal recruitment of superficial muscles (e.g. PM). As per clinical practice, successful trials were defined as those in which the clinical researcher could not manually identify contraction of the PM.
Surface electromyography (SEMG) was used to measure activity of infraspinatus and PM, following SENIAM guidelines [3]. Myoelectric signals recorded using a 16 channel wireless Noraxon TeleMyo 2400T G2, at a 1500 Hz sampling frequency with a gain of 500. The analog bandpass filter was set for 10-500 Hz, and the common mode of rejection ratio was set at 100dB. SEMG data was processed using MyoResearch XP, Master Edition. SEMG recordings were reduced to eliminate ECG artifact spikes, root mean square smoothed using a 50-millisecond average window. The SEMG recordings were then normalized by the MVIC.
The primary outcome measure was the co-contraction index (CCI), which was calculated as:
$CCI = 2 \times I_{PM}/I_{total} \times 100\%$

Where I_{PM} is the integral of total activity of PM, and I_{total} is the integral of the sum of PM and infraspinatus during each DRT execution. The CCI was calculated using MATLAB 7.12.

Statistical analyses were performed using R software. Paired t-test was used for assessing differences in CCI between the 1st and 10th DRT execution, with data bootstrapped 2000 times.

Results: A total of 30 participants (12 male/18 female) took part in the study. The mean age was 23±4 years, and mean BMI of 23.8±2.7 kg/m^2. Mean (standard deviation) CCI values over the ten trials are presented in Figure 1. No significant differences were found for CCI between the 1st and 10th DRT execution (mean difference = 0.18, 95% confidence interval: -1.23 to 1.61).

Figure:



Caption: Figure 1. Co-contraction index mean and standard deviation for 1st and 10th trials..

Conclusion: Co-contraction between infraspinatus and PM is present during successful DRT trials, and that does not change over ten trials. These findings suggests that 10 repetitions is potentially insufficient for motor learning to occur. Contraction of PM may be small and difficult to manually identify. It is possible that the net result of shoulder muscle synergy will help increasing glenohumeral joint stability. Co-contraction may be required for fine-tuning of torque production or shoulder moment balancing [4].

QUALITATIVE AND QUANTITATIVE CRITERIA FOR ASSESSING THE TEMPORAL STRUCTURE OF INDOOR ROWING TECHNIQUES

John S. Fothergill [1,*]

[1]Computer Laboratory, University of Cambridge, Cambridge, United Kingdom

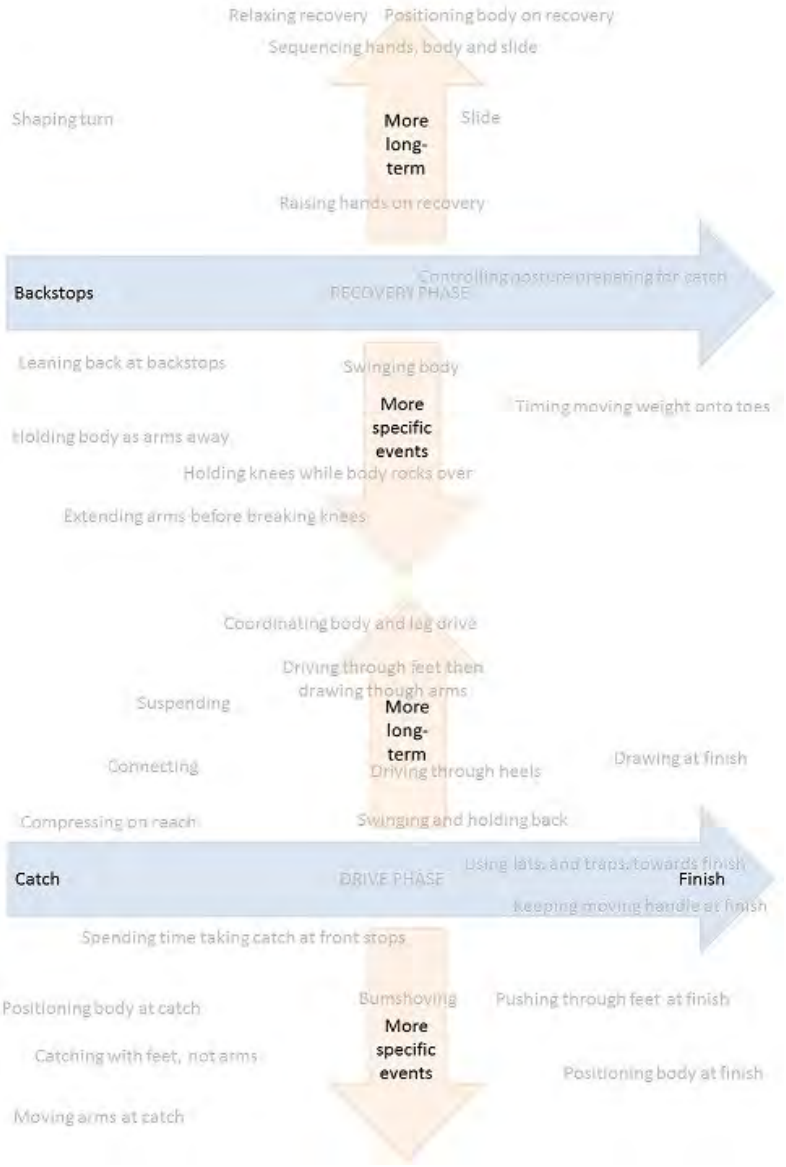
Introduction and Objectives: Bridging the gap between objective performance metrics and coaches' qualitative assessments of motor-skill techniques, promotes a deeper understanding of sporting performances, leading to more efficient and safer training [1]. Coaches' descriptions of athletes' performances come from developing their selective attention and mental models of technique. Six experienced rowing coaches described the technique in 26 videos of indoor rowing. Aspects of technique they referred to were identified through inductive content analysis of their natural-language comments [2]. A temporal structure to the aspects emerged (Fig. 1): Multiple aspects start and end at different times during a rowing stroke; the duration of aspects ranged from momentary, to the complete stroke.

We choose objective performance metrics that measure the temporal structure: This study thresholds the times between intra-stroke events to distinguish between strokes from new and experienced rowers. Metrics indicative of rower experience are used to focus and elaborate on the qualitative assessment criteria. Rowers of different abilities have been classified from stroke kinetics [3]. No work compares correlations of intra-events times with rowers' experience or unites quantitative and qualitative assessment.

Methods: Sensors were fixed to a Concept 2 ergometer; signals were time-stamped using the same clock; each stroke was segmented at the finish. The 3D positions of the handle and seat, aligned to the anatomical coordination system, were recorded at 100Hz to between 2x10-3m and approximately 1x10-2m, using a bespoke tracking system [4]. The dimension of handle motion with largest variance (hande_m) was used to compute metrics. The force applied to the handle (handle_f) was also used, measured using a Concept 2 monitor at 20Hz, as was the force applied through the balls of the left (l_foot) and right (r_foot) feet, recorded at 200Hz using thin FSRs attached to the foot stretcher [5]. Participants (18-35, 75% male) were 8 new rowers, providing 224 strokes after basic instruction and 8 experienced rowers, providing 202 strokes from regular training. Ergometers usefully simulate on-water rowing but don't record oar angle or rower movement on the recovery [6]; we focus on the drive. Intra-stroke events were the onset, offset and peaks of sensor signals. Times between events are normalised by stroke duration. The mean percentages of strokes classified as the correct rower-class were calculated over the rowers left out of a 16-fold cross-validation, with optimal thresholds exhaustively determined for the N-1 rowers (Table 1). Signals were resampled to the same rate and classification repeated at 200, 100, 10, 5, 2 and 1Hz.

Results: The variance in accuracy over rowers was high. Two-tailed, paired Student-t tests with a Bonferroni correction (a=0.12), over the left-out rowers, showed only the time between the peak handle force and catch (threshold: new rowers > 21%) to be significantly more accurate than any other metric. The ratio of drive to recovery time had a similar overall accuracy of 80%. These accuracies were consistent above 5Hz.

Figure:



Caption: The temporal hierarchy of aspects coaches use to qualitatively assess rowing strokes.

Conclusion: Designing performance metrics that reflected humans' assessment criteria gave key indicators of rowers' experience that can objectively track progress during training with 80% accuracy. Such summaries may not overwhelm athletes under pressure. Binary assessment of ability is useful to screen athletes. The metrics can be automatically provided when coaches are unavailable using our system. Aspects used by coaches refer to the period between the catch and peak handle force more than any other section of a stroke, suggesting their attention is appropriately focused. That the objective analysis encourages early application of force, clarifies the purpose of the aspects that begin the drive, such as "Connecting" and "Catching with feet, not arms". A deeper understanding of rowing performance and technique has been possible from uniting qualitative and quantitative analytical approaches, finding key biomechanical metrics and considering how they relate to practical coaching.

Table:

Metric	Accuracy (%)
Handle_f, handle_m peaks	80.0
Handle_f, l_foot peaks	60.4
Handle_f, r_foot peaks	51.0
Handle_f peak, r_foot release	35.5
Handle_f peak, r_foot onset	49.1
SeatOnset	68.7
Handle_f peak	60.5
Handle_m peak	77.1
StrokeDuration	70.2

COORDINATION ANALYSIS BETWEEN OPPONENT TENNIS PLAYERS USING VECTOR CODING TECHNIQUE.

Tiago Pereira [1] Felipe A. Moura [1,*]

[1]Sports Sciences Department, State University of Londrina, Londrina, Brazil

Introduction and Objectives: A very important step studying tennis as a dynamical system is to identify the collective variables that reflect the invariance and the change in players' comportment during the match. A simple analysis of tennis match can gives us some clues of how to understand tennis in a dynamical perspective. During a tennis match, the players are constantly moving away to hit a ball and returning to the middle of the court waiting for the next one, resulting in constant to-and-fro displacements from that home position that renders the players as oscillators. A fundamental property of oscillators is the phase synchronization. One only study investigated tennis from a dynamical approach [1], using Hilbert transform, and found that there are just two patterns of synchronization between the lateral displacement between opponent players: in-phase and anti-phase. However, time-series relative phase analysis using continuous relative phase (CRP) or other techniques such as Hilbert transform may not allow interpreting which oscillator is leading the time series and which is lagging relative to the other oscillator. At this point vector coding technique [2] may offer additional information about tennis' dynamics. Therefore the purpose of this study was to investigate the coordination between opponent tennis players during official matches. Specially, we were interested in to determine which player leads the behaviour of the other one (the serving player or the returning one) and if there are differences of behaviour between different proficiency levels.

Methods: We analyzed two matches, one during a professional single tournament organized by the association of professional tennis players (ATP) and the other during a junior world circuit organized by the International Tennis Federation (ITF). The matches were filmed by two digital cameras. Player positions as a function of time were obtained with an automatic tracking method. Vector coding analysis was computed for players lateral displacement, to identify the coordination patterns during 103 and 60 rallies of the junior and professional matches. The coupling angles were divided in four coordination patterns: anti-phase, in-phase, serving player phase and returning player phase. Data normality was tested using Lilliefors test. Two-way analysis of variance was used to compare the percentage of time spent in each condition according two factors: phase (with four factor levels) and level (professional and junior). Data are expressed in terms of mean and standard deviation.

Results: Table 1 presents the percentage o time in each phase condition during rallies of the professional and junior matches. The statistical analysis presented no effect between levels ($F(1, 644) = 0.67$; $p = 0.2$) and for the interaction between levels and phase ($F(3,644) = 0.24$; $p = 0.8$), and there was not a significant difference among the phases ($F(3,644) = 1.08$; $p = 0.3$). The results showed no coordination differences between players of different levels which suggests that tennis' dynamics is the same, independently of level of proficiency. Although no significant differences were found among coordination patterns, it seems that there is a tendency of the returning players in to lead the time series in relation to the serving players. This behaviour may be related to the advantage of the serving player has in relation to returning one. The serving player has the possibility of starting point command, performing more powerful and well

directed serves, making the returning player move firstly to return the serve. For this reason the displacements performed by the returning player may be happening in response to the strokes performed by the serving player. Thus probably the time series is led by returning player because the serving player is being more offensive and is constantly shifting his opponent.

Conclusion: Vector coding technique allowed identifying additional coordination patterns between players' lateral displacement, providing further information about players' interaction during rallies. Although no differences were found between levels and among coordination patterns, results indicated that, generally, the lateral displacement coordination between players is leaded by the returning player. Further studies may investigate if the success during rallies is determined by different coordination patterns than the ones of the present study.

Table:

Coordination Pattern	Professional	Junior
Anti-phase	22.2 (17.4)	22.1 (18.4)
In-phase	23.3 (19.0)	21.3 (16.3)
Serving player phase	14.3 (15.3)	14.8 (15.1)
Returning player phase	40.0 (22.1)	41.7 (22.5)

Caption: Percentage of time spent in each coordination pattern during the rallies.

AS-0201

OPTIMUM TECHNIQUE FOR MAXIMISING ROTATION IN A ROCHE VAULT

Fred Yeadon [1,*] MIchael Hiley [1]

[1]Sport, Exercise and Health Sciences, Loughborough University, Loughborough, United Kingdom

Introduction and Objectives: In the handspring group of vaults the gymnast rotates forwards onto the vaulting table in the pre-flight phase and continues this forwards rotation during the contact and post-flight phases. In the handspring double somersault vault (Roche) the gymnast performs two and a half somersaults during the post-flight phase (Figure 1). The aims of this study were to optimise touchdown orientation and configuration together with contact technique in order to maximise rotation potential in forward rotating vaults and to identify realistic limiting vaults.

Methods: In order to investigate the effects of initial conditions and table contact technique on vaulting performance a torque-driven computer simulation model was used. The model simulated the interaction between a seven-segment gymnast and a single-segment vaulting table during the table contact phase of the vault. An evaluation of the model was conducted by assessing how accurately simulations matched the recorded performances of three recorded vaults.

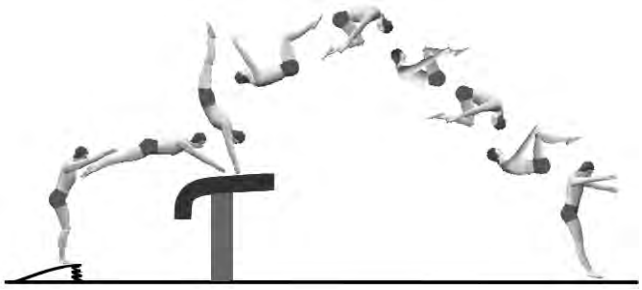
Three optimisations were carried out in order to maximise the rotation potential (RP) in post-flight under different conditions. RP was calculated as the product of the angular momentum about the mass centre at take-off and the post-flight time, normalised to give the number of straight somersaults (ss) possible in the post-flight phase. In the first optimisation the table touchdown configuration and orientation were varied whilst torque activations from the matched simulation were maintained. The second optimisation used the touchdown configuration and orientation from the recorded performance and the torque generator activation parameters were varied in order to determine the potential improvement arising from contact phase technique changes. In the third optimisation the configuration, orientation, and torque generator activation parameters were allowed to vary in order to maximise RP. The model was constrained to stay on the parabola defined by the gymnast's horizontal and vertical velocity at springboard take-off in all optimisations.

In order to investigate limiting vaults estimates of maximal horizontal pre-flight velocity in handspring double front vaults were obtained from Takei et al. (2003) and the vaults re-optimised.

Results: The post-flight RP of the recorded vault was 1.16 ss. When the configuration and orientation at touchdown were varied (optimisation 1) the post-flight RP increased to 1.33 ss. When just the torque generator activation parameters were varied (optimisation 2), the post-flight RP increased to 1.48 ss. In the third optimisation where the touchdown configuration, orientation and table contact activations were allowed to vary (optimisation 3) the post-flight RP increased to 1.60 ss (Table 1).

When the pre-flight horizontal velocity was increased by 0.25 m/s and then 0.5 m/s, the optimised RP increased from 1.60 ss to 1.65 ss and 1.70 ss, respectively, allowing more complex vaults to be simulated.

Figure:



Caption: Figure 1. The handspring double somersault vault (Roche).

Conclusion: When the initial configuration and orientation of the model were allowed to vary along with the table contact technique (optimisation 3), there was a considerable increase in post-flight RP from 1.16 to 1.60 ss. Both table contact technique touchdown configuration and orientation made substantial contributions to this increase. In optimisation 3 the initial configuration and orientation changed from those adopted by the gymnast (Table 1). Yeadon et al. (2014) demonstrated that having an angle at the shoulder and the hip hyper-extended at touchdown was optimal for generating post-flight height since more work could be done during table contact. From the present study, however, it appears that having the arm in line with the trunk and the hip flexed at touchdown is optimal for generating maximum RP.

Table:

Simulation	Gymnast	Opt1	Opt2	Opt3
Touchdown angles				
torso [°]	-3°	1°	-3°	38°
shoulder [°]	128°	137°	128°	180°
hip [°]	181°	192°	181°	162°
Post-flight				
peak height [m]	3.00	2.95	2.81	2.76
rot. potential [ss]	1.16	1.33	1.48	1.60
time [s]	1.04	1.02	0.95	0.98

THE EFFECTS OF ALTERED FOREFOOT BENDING AND TORSIONAL STIFFNESS ON THE BIOMECHANICS OF CURVED RUNNING

Ryan Madden [1,*] Nicole Schrier [1] Doug Kondro [1] Rosemary Grover [1] John Wannop [1] Darren Stefanyshyn [1]

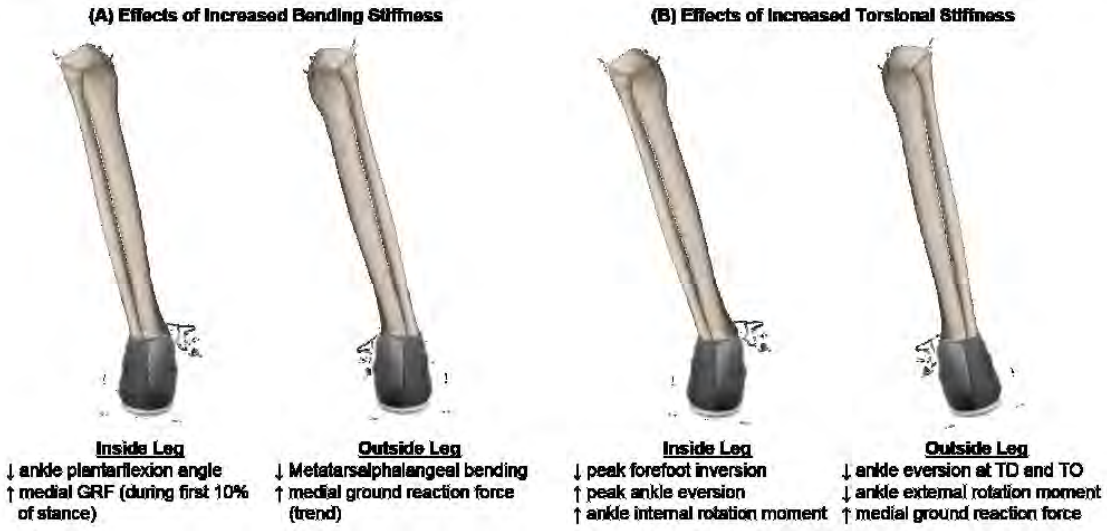
[1] Kinesiology, University of Calgary, Calgary, Canada

Introduction and Objectives: Many competitive running events incorporate curves on the racecourse. Despite this, the main focus of previous running research has been straight-line movements. Shoe characteristics such as bending and torsional stiffness can alter running biomechanics, however, no studies have attempted to clarify the influence of shoe bending and torsional stiffness on curved sprinting. Therefore, the purpose of this study was to investigate the effects of bending and torsional stiffness on maximal effort curved running.

Methods: Six varsity track athletes performed maximal-effort curved sprinting (r=36.5 m, ~9 m/s) in three shoes: (i) low bending stiffness and low torsional stiffness (L_bL_t), (ii) low bending stiffness and high torsional stiffness (L_bH_t), and (iii) high bending stiffness and high torsional stiffness (H_bH_t, Table 1). Kinetics and kinematics of the feet and shanks of both the inside and outside leg were collected. Two successful trials were obtained for each shoe/foot (inside/outside) combination. Data were analyzed for the stance phase of running in each condition. All comparisons were made using paired t-tests with a Holm-Bonferroni sequential correction to account for multiple comparisons (α_1=0.0167, α_2=0.025, α_3=0.05).

Results: Increasing the bending stiffness acting on the inside foot resulted in reduced dorsiflexion at touchdown and greater plantarflexion at takeoff ($p<0.001$ H_bH_t vs. L_bL_t, $p=0.068$ H_bH_t vs. L_bH_t). Limited forefoot bending combined with the changes in ankle kinematics would shift the ground reaction force (GRF) anteriorly, increase the moment arm about the ankle joint and possibly improve sprint performance [1,2]. High bending stiffness also tended to increase peak medial GRF during the first 10% of stance for the inside foot ($p=0.023$ H_bH_t vs. L_bL_t, $p=0.091$ H_bH_t vs. L_bH_t). Increasing medial GRF on the inside foot would direct the athletes away from the intended direction of travel and may therefore be detrimental. Interestingly, the only observed effect of increasing the forefoot bending stiffness of the outside shoe during curved running was a decrease in peak MTP extension angle ($p=0.004$ H_bH_t vs. L_bH_t, $p=0.017$ H_bH_t vs. L_bL_t). There was a trend towards an increasing medial GRF with increasing bending stiffness of the outside shoe ($p=0.087$ H_bH_t vs. L_bH_t, $p=0.091$ H_bH_t vs. L_bL_t). The increased outside foot medial GRF may be beneficial to performance by guiding the athlete around the curve. For the inside foot, high torsional stiffness resulted in decreased forefoot inversion ($p=0.004$ H_bH_t vs. L_bL_t, $p=0.013$ L_bH_t vs. L_bL_t), increased ankle joint eversion ($p<0.001$ H_bH_t vs. L_bL_t, $p=0.058$ L_bH_t vs. L_bL_t), and an increased transverse plane ankle joint moment ($p=0.001$ L_bH_t vs. L_bL_t, $p=0.002$ H_bH_t vs. L_bL_t). As increased eversion may limit plantarflexor force production and increased transverse plane ankle moments may increase athlete injury risk [3], high torsional stiffness may have a negative impact on the biomechanics of the inside foot. The response of the outside foot to alterations in torsional stiffness was markedly different. As torsional stiffness increased, there was a trend of decreasing ankle eversion at touchdown ($p=0.001$ H_bH_t vs. L_bL_t, $p=0.051$ L_bH_t vs. L_bL_t) and takeoff ($p=0.038$ H_bH_t vs. L_bL_t, $p=0.002$ L_bH_t vs. L_bL_t). Although not observed here, decreased ankle eversion may benefit performance by improving plantarflexor moment generation [4].

Figure:



Caption: Illustrated summary of main findings

Conclusion: Alterations in the torsional and bending stiffness of footwear influence curved running biomechanics in a side-dependent manner. The inside foot benefits most from a low torsional stiffness shoe, which improves ankle joint alignment and reduces transverse plane ankle joint loading. Conversely, outside foot ankle alignment is improved with a high torsional stiffness shoe that, along with high bending stiffness, also increases the medial GRF. Both the inside and outside feet may benefit from high bending stiffness shoes to maximize straight-line sprint, although further work is required to determine the appropriate level of bending stiffness for an inside foot shoe such that the positive effects are maintained while the increased initial medial GRF is minimized.

Table:

Footwear Condition		Bending Stiffness [N/mm]	Torsional Stiffness [Nm]
Low Bending Stiffness Low Torsional Stiffness	(L_bL_t)	18.1	1.75
Low Bending Stiffness High Torsional Stiffness	(L_bH_t)	14.3	3.51
High Bending Stiffness High Torsional Stiffness	(H_bH_t)	33.6	3.91

AS-0203

CONCEPT2 ROWING PERFORMANCE CAN BE IMPROVED WITH GREATER ROWING FREQUENCY AND LESS ROWING RESISTANCE

Xie Wu [1,*] Li Li [1] Matthew Holmes [2]

[1]Kinesiology, Shanghai University of Sport, Shanghai, China, [2]Health & Kinesiology, Georgia Southern, Statesboro, United States

Introduction and Objectives: Concept2 land rowing competition has become a worldwide sport. Commonly used rowing frequencies are ranged between 30 to 40 strokes per minute with a resistance level set at level 4 on the machine. The purpose of the study was to investigate the effect of increase rowing frequency and reduce rowing resistance on rowing performance. We have hypothesized that a higher frequency and lower resistance rowing pattern can increase rowing power output and improve rowing performance.

Methods: With the approval of local IRB committee we have recruited 14 male college students, 20 ± 3 years old, 178±7 cm tall, with body mass of 71 ± 6 kg. There were a total of nine rowing trials. Three rowing frequencies (40, 50, and 60 strokes per minute) were tested at each of the three different resistances at levels 2, 3, and 4. The order of the nine testing trials was randomized. The rowing tests were conducted on a Concept2 rowing machine (Concept2, Inc., Morrisville, VT, USA). Following the ticktack of the metronome, the participants were instructed to pull the handle as forceful as possible at every tick. The range of the pull was adjusted based on metronome to achieve the best possible synchronization with the targeted rowing frequency. Each rowing condition was tested for 20 seconds with a 5 minutes rest period in between. The effects of frequency and resistance on each of the outcome variables (distance, estimated 500 m time, energy expenditure and mean power output) were examined using two-factor (resistance X frequency) multivariate analysis of variance (MANOVA) with repeated measures. Post-Hoc analysis (pairwise comparison and trend analysis) used if necessary. Alpha level was set at .05.

Results: The observed rowing frequencies were 41.4±.2, 50.3±.3, 60.0±.4 when targeting at 40, 50, and 60 strokes per minute, those rates were significantly different from each other ($F_{2,13}$=0.426, p =.66). Rowing frequencies were not affected by resistances ($F_{2,13}$=0.426, p =.66). For rowing distance within 20 seconds, there was no significant resistance X frequency interaction observed. However, distance was significantly influenced by both resistance ($F_{2,13}$=6.64, p < .007) and frequency ($F_{(2,13)}$=7.22, p < .009). Further, the linear by linear contrast of resistance * frequency ($F_{1,13}$ = 4.777, p = 0.048) was significant. Here are the results for rowing distance (mean ± standard error of the mean) at three different levels of resistance: 85.3±1.1, 86.1±1.5 and 88.2±1.2 m for levels 2, 3, and 4, respectively. Rowing distance for resistance level 4 was significantly greater that of level 2. The rowing distances at three different frequencies were: 83.7±1.7, 86.8±1.4 and 89.1±1.3 m for 40, 50, and 60 strokes per minute, respectively. Greatest rowing distance was observed at the highest stroke rate (60), which was significantly longer than that of the lowest rate (40). The combination of highest frequency (60) with lowest resistance (level 2) resulted with the greatest distance (89.6±1.6 m), where the combination of lowest frequency (40) with lowest resistance (level 2) resulted with the least distance (81.3±1.4). The Estimated 500m Time exhibited the same results as the rowing distance, where the no significant interaction observed but

significant resistance ($F_{2,13}$=4.47, p < .05) and frequency ($F_{2,13}$=7.04, p < .004) influences observed. The estimated time for resistance levels 2, 3, and 4 were 118±1, 117±2 and 114±2, respectively. The estimated time for frequencies at 40, 50 and 60 strokes per minute were 120.3±2.6, 116.0±1.8, and 112.6±1.6 sec, respectively. The effects of the rowing frequency and resistance could be explained, partially, by the energy expenditure during the tests. Both energy expenditure and mean power output were increase with both frequency (Energy: $F_{2,13}$=6.67, p < .005; Power: $F_{2,13}$=6.64, p < .005) and resistance (Energy: $F_{2,13}$=7.79, p < .002; Power: $F_{2,13}$=7.92, p < .002). The linear by linear contrast of resistance*frequency for both energy and power were significant (Energy: $F_{1,13}$= 5.009, p = .042; Power: $F_{1,13}$=5.146, p = 0.041). The greatest energy expenditure (power output) occurred with the combination of highest frequency (60) with lowest resistance (level 2) at 1176±48 J (255±14W), where least energy expenditure (power output) occurred with the combination of lowest frequency (40) with lowest resistance (level 2) at 951±34 J (189±10W).

Conclusion: During 20 seconds all out rowing tests with Concept2 rowing machine higher rowing stroke per minute, combined with lower resistance, produced faster performance. This result is supported by greater power output observed with this condition.

EFFECT OF RUNNING SPEED ON INTRA-TRUNK ANGULAR DISPLACEMENTS EXHIBITED DURING TREADMILL RUNNING

Kathy J. Simpson [1,*] Yumeng Li [2] Marika Walker [1] Rumit Singh Kakar [3]

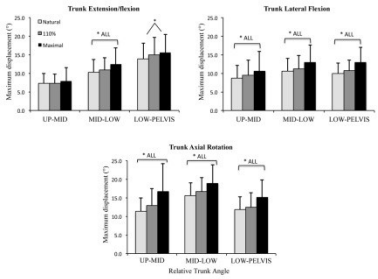
[1]Kinesiology, [2]University of Georgia, Athens, [3]Department of Physical Therapy, Ithaca College, Ithaca, United States

Introduction and Objectives: Our limited understanding of the trunk's role in producing running locomotion[1,2] is partly due to lack of knowledge of the intra-trunk motions and how these motions change with running speed. We expected increased intra-trunk motions at faster running speeds, particularly for segments with lower anatomical constraints[3]. Thus, the purpose of the study was to determine if intra-trunk displacements increase with greater running speed.

Methods: Participants (n = 20, age = 22.4 ± 3 yr; mass = 67.4 ± 12.9 kg, height = 1.7 ± 0.1 m, moderate to vigorous physical activity = 6 ± 3 hr/wk) ran on a treadmill at self-selected speeds of natural (range: 2.2 – 4.2 m/s), 110% above natural (2.5 – 4.7 m/s) and maximal (range: 2.9 – 5.4 m/s). Locations of 24 reflective markers placed on the trunk and pelvis were captured by a 7-camera Vicon system (120 Hz) for 10 strides. For all speeds and motion planes, relative angles between adjacent trunk segments (upper [UP]: C7 to T8; middle [MID]: T9 to T12; lower [LOW]: L1 to L5) and pelvis (PEL) were calculated; maximum angular displacements were averaged across 10 strides. Displacements were compared across speeds using one-way repeated-measures ANOVA, Tukey's HSD posthoc test ($p < 0.05$), and 95% confidence intervals (CI).

Results: Increased speed was observed from ANOVA for all maximum displacements except for UP-MID flex/extension. Posthoc tests (Fig 1) indicated that all other speed comparisons were significant (Fig 1); although for LOW-PEL ext/flexion, only natural and maximal speed displacements varied. For significant comparisons, CI ranges were 0.1° to 2.9° (LB) and 1.7° to 7.8° (UB).

Figure:



Caption: Fig 1. Means and SD of the relative angles between upper (UP), (MID) and lower (LOW) trunk and pelvis (PEL) by speed. Significant speed comparisons for given movement and relative angle ($p < .05$): * ALL: all comparisons are significant; *: natural and maximum speed are signficantly different..

Conclusion: Displacements increased at greater speeds, especially for non-sagittal plane motions. Previous investigators have suggested that, at faster locomotor speeds, greater trunk movement may help to produce increased trunk momenta to help cancel some of the greater total body angular momenta[1,4]; move the pelvis into positions that allow increased leg

rotations and longer step lengths[5]; transfer or generate mechanical energy to/from extremities[6]; and/or minimize nonessential COM motion via compensatory shifting of intra-trunk mass[7]. However, the magnitudes of the difference means were relatively modest (range: 0.6° to 5.3°; median difference between natural and maximum= 2.7°), suggesting that only low changes to intra-trunk rotations are utilized. As all of the displacement magnitudes at maximum speed were well within reported flexibility values of these segments[3,7], it is unlikely that increases of intra-trunk displacement were limited by structural-functional constraints of the spine and other trunk tissues. However, the modest increases may also be due to some individuals' low running speed ranges, running technique or skill; running on a treadmill; and/or our methodology.

In conclusion: At these self-selected treadmill running speeds, intra-trunk displacements increase at faster speeds, but only low changes to intra-trunk rotations may be desired or needed.

THE INTERFASCICULAR MATRIX ENABLES FASCICLE SLIDING AND RECOIL IN TENDON, AND BEHAVES MORE ELASTICALLY IN ENERGY STORING TENDONS

Chavaunne T. Thorpe [1,*] Marta Godinho [1] Graham Riley [2] Helen Birch [3] Peter Clegg [4] Hazel Screen [1]

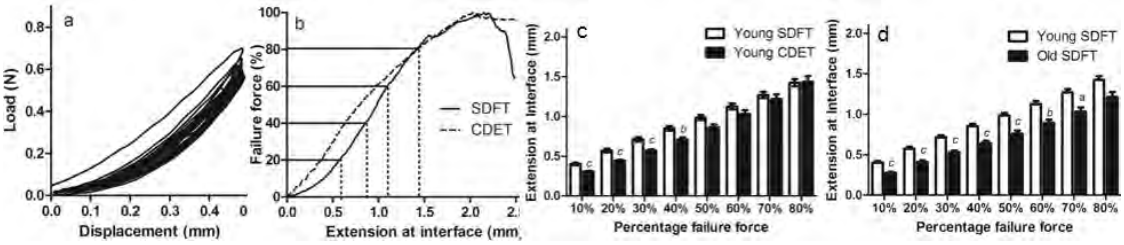
[1]School of Engineering and Materials Science, Queen Mary University of London, London, [2]University of East Anglia, Norwich, [3]UCL, Stanmore, [4]University of Liverpool, Neston, United Kingdom

Introduction and Objectives: Our previous work shows that the interfascicular matrix (IFM) is critical for tendon function, facilitating sliding between fascicles to allow tendons to stretch [1]. We have shown that this is particularly important in energy storing tendons such as the human Achilles tendon and equine superficial digital flexor tendon (SDFT), which experience strains as high as 16% during exercise [2], and therefore require the capacity for considerable inter-fascicular sliding. This capacity is not required in positional tendons such as the equine common digital extensor tendon (CDET). Further, we have shown that the IFM in the energy storing SDFT becomes stiffer with age, which may explain why aged tendons are more prone to injury [3]. While the failure properties of the IFM have been studied previously [1], it has not been established if the IFM is able to recoil and recover from loading. The aim of this study was therefore to assess the recoil capacity and failure properties of the IFM in the SDFT and CDET from young and old horses. We hypothesised that the IFM has the ability to recoil, and that elasticity is greater in the energy storing SDFT than in the positional CDET. Further, we hypothesised that the recoil capacity of the IFM decreases with ageing and the stiffness of the IFM increases, specifically in the SDFT.

Methods: Groups of 2 intact fascicles (bound together by IFM) were dissected from the SDFT and CDET from young (aged 3-7 years) and old (aged 17-20 years) horses. Using a polarised light microscope and a dissection rig, the opposing end of each fascicle was cut transversely, leaving a 10 mm length of intact IFM. Samples were preconditioned from 0-0.5mm for 10 cycles (Fig.1a), and then pulled apart to failure. Hysteresis and stress relaxation were calculated during preconditioning. A force-extension curve was derived from the failure test data, and IFM extension was calculated from 10-80% failure load (Fig.1b&c). Statistical significance was tested using an ANOVA.

Results: The IFM was able to recoil in both tendon types (Fig.1a). Hysteresis and stress relaxation were significantly greater in CDET than in SDFT IFM samples ($p<0.01$). IFM failure load and failure extension did not differ between tendon types. At and below 40% of failure force, there was significantly greater extension within the SDFT IFM than the CDET IFM ($p<0.01$, Fig.1b&c). Hysteresis did not change with age, but stress relaxation increased with ageing in both tendon types. Ageing resulted in decreased extension at the interface in SDFT samples ($p<0.05$, Fig.1d).

Figure:



Caption: Fig.1. Response of IFM to cyclic loading (a) and test to failure (b). IFM extension was calculated at different percentages of failure load (b). Extension at interface differed with tendon type (c) and with age (d).

Conclusion: The results support the hypothesis, showing that the IFM exhibits reversible deformation behaviour. Further, the IFM in the SDFT has a greater ability to recoil, with less hysteresis and stress relaxation than in the CDET, providing further evidence that the IFM is crucial for efficient function of energy storing tendons. The results also indicate that the IFM is less able to resist repetitive loading as it ages, becoming stiffer with age in the SDFT. Future work will characterise the fatigue behaviour of the IFM and determine how this influences whole tendon fatigue properties. Full understanding of IFM specialisation in energy storing tendons and the age-related changes that result in loss of function is important for the development of effective preventative measures and treatments for age-related tendon injury.

SHEAR WAVES ELASTOGRAPHY FOR BIOMECHANICAL ASSESSMENT OF ACHILLES TENDON

Thomas-Xavier Haen [1 2,*] Anthony Roux [2] Marc Soubeyrand [3] Charlotte Labruyere [2] Phillipe Rouch [2] Sébastien Laporte [2]

[1]Service de Chirurgie Orthopédique, Hopital Raymond Poincaré, Garches, [2]Arts et Metiers ParisTech, Institut de Biomécanique Humaine Georges Charpak, Paris, [3]Service de Chirurgie Orthopédique, Hopital de Bicêtre, Le Kremlin-Bicetre, France

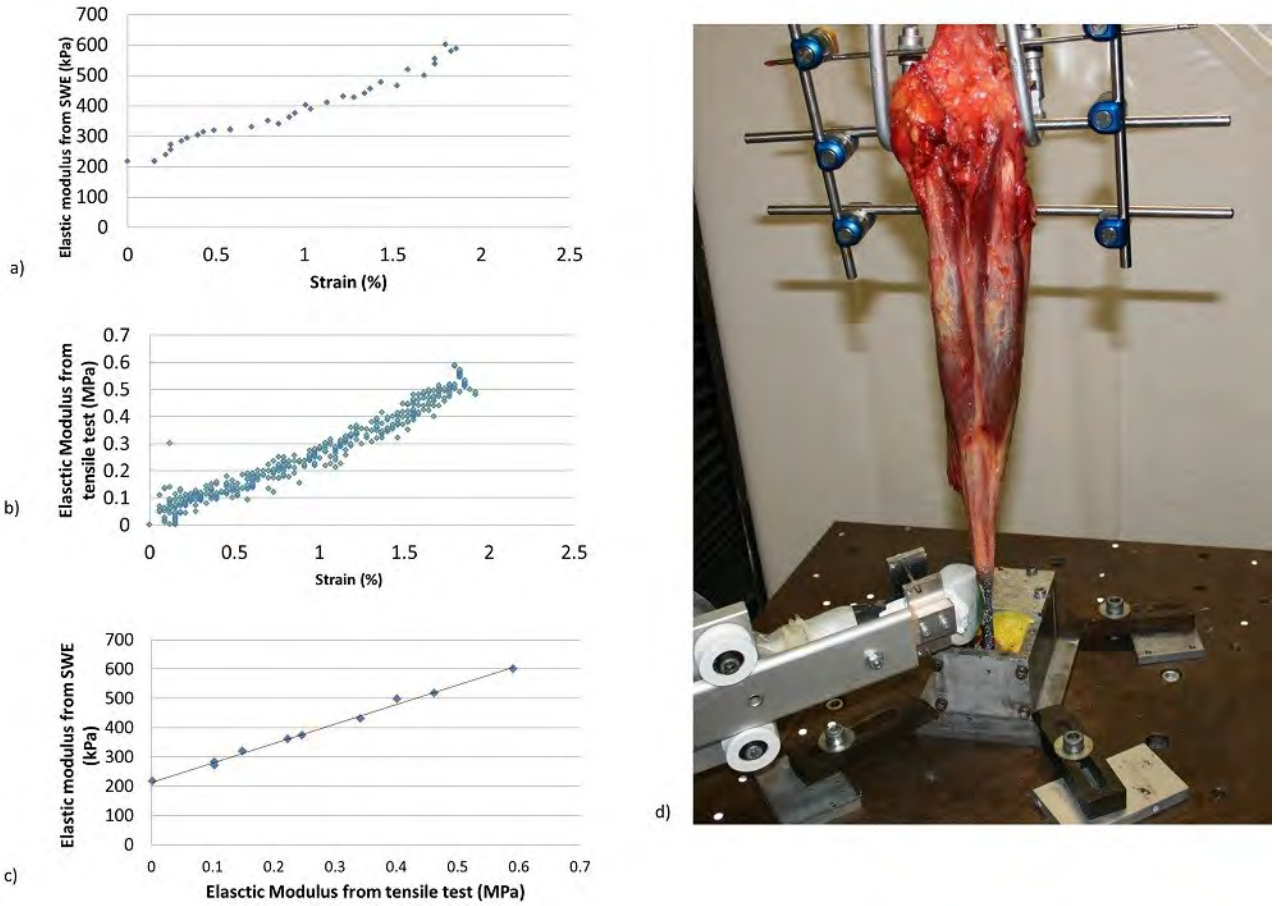
Introduction and Objectives: Achilles tendon (AT) represents the main site of tendon rupture in terms of frequency[1]. Treatment of AT rupture remains controversial. This controversy is due to certain extend to the lack of tools available for a clinical assessment of the healing tendon's mechanical properties. Shear Wave Elastography (SWE) is a new mode of ultrasound imaging which allows real-time and in-vivo assessment of the Young modulus within the soft tissues[2]. It has been previously proposed as a tool to assess biomechanical properties of the AT. Until now, no study has correlated SWE findings in human with biomechanical conventional testing. The aim of the present study was to (1) set up a reproducible and « bedside like » SWE protocol of the AT and (2) to correlate the findings of SWE with conventional tensile testing.

Methods: We used eight lower limbs of fresh frozen human cadavers (Age = 84 ± 5 years, mean ± SD). First, the AT was assessed with SWE (Aixplorer®, Supersonic Imagine, Aix-en-Provence, France) through a custom « bedside like » protocol. The latter consisted in assessing the AT with longitudinal and axial slices performed at three successive levels (0, 3 and 6 cm from the calcaneal insertion) and in three ankle positions (25° plantar flexion, rest and maximal dorsal flexion). Each assessment was performed blindly by three operators in order to determine repeatability and reproducibility. Then the triceps with the AT was isolated, where their femoral, tibial and calcaneal insertions were kept intact. The anatomic preparation was subjected to tensile tests (at 0.5, 1 and 2 mm/s, until 20 mm of elongation) during which a continuous SWE examination was performed. Tendon's displacement was recorded with an ultra-fast HD camcorder. At the end, a break strength testing (at 2 mm/s) was done.

Results: Our custom « bedside like » protocol had a high intra and inter-observer reliability for longitudinal slices, in the cadaveric model. Moreover, the stiffness increased with tensile load, in SWE measurements (figure1-a) and material testings (figure1-b). The correlation between the two modes was significant ($p<0.001$) and the regression coefficient was $R^2=0.99$ (figure1-c). During break strength test, no tendon rupture was observed, but a tear (4 ± 0.5 % strain, mean ± SD) in the muscle. Having maintained every bone insertions, our protocol was very close to the physiologic functioning (figure1-d).

To our knowledge, only manual elastography was described, in human cadaveric tendon, without biomechanical correlation [3]. In animal studies, one study showed increased shear waves speed with increasing strain, in porcine tendon [4], and one study showed good correlation between SWE and material testing, during tensile tests, in porcine muscle [5].

Figure:



Caption: Tensile test's data from a representative specimen: a) Elastic modulus from SWE vs. Strain b) Elastic modulus from tensile test vs. Strain c) Correlation between Elastic modulus from SWE and Elastic modulus from tensile test d) Experimental set-up (Ultrasoud transducer aligned with long axis of the Achilles' Tendon)

Conclusion: SWE used with our protocol allows to determine biomechanical properties of intact AT of fresh frozen cadavers and to link SWE to tensile tests' results.

THE INFLUENCES OF DEVELOPMENT AND PATHOLOGY ON THREE DIMENSIONAL HUMERAL SHAPE MORPHOLOGY THROUGHOUT THE PEDIATRIC AGE SPECTRUM

Frances Sheehan [1,*] Jesi Kim [1] Michael Pearl [2] Katharine Alter [1]

[1]Rehabiliation Medicine, National Institutes of Health, Bethesda, [2]Orthopaedic Surgery, Kaiser Permante, Los Angeles, United States

Introduction and Objectives: To understand the relationship between humeral morphology and pathology, developmental shape changes must be understood. Little data exist in regards how pathology and development influence 3D humeral shape. A pediatric cadaver study did establish humeral anterversion with age[1], but the lack of an ossified head in younger children (~ <5 years) prevented direct measures of humeral head orientation. Closing this knowledge gap is crucial for treating pathologies such as Obstetrical Brachial Plexus Palsy (OBPP), where the current trend supports earlier intervention (physical therapy, botulinum toxin injections, surgery) to rebalance muscle forces, prevent osseous deformities, and maintain function. The purpose of this study is to quantify the 3D humeral morphology in children across the pediatric age span (6 months-18 years old) with unilateral OBPP and documented internal rotation contractures in order to test the following hypotheses: 1) development alters 3D humeral for the unaffected arm; 2) the impaired arm has significant multi-planar shape deformities, relative to the unimpaired arm, which increase with age.

Methods: In total 29 bilateral 3D axial MR images of children/adolescents with unilateral OBPP were included in this study. The first set (n=17, age=1.5±1.2 years) was acquired as part of a pre-surgical evaluation protocol (author MLP). The second set of 12 subjects (age=11.8±3.3 years), was taken from a previously published study[2]. Both centers had IRB approval. The humeral head and shaft/elbow were segmented by manually outlining the outer cartilage and cortical bone surface, respectively[2]. The resulting point cloud was fitted with a 3D mesh and aligned to its principle axes. The epicondylar axis and the lesser tuberosity (LT) were identified on the 3D model (Fig 1).

The model was then converted back to a point cloud and imported into a customized Matlab program. This program determined the best-fit ellipsoid and cylinder to the humeral head and central shaft, respectively. From these data the inclination angle and two retroversion angles, **V1** and **V2** were calculated (Fig 1). Paired t-tests were used to identify significant ($p<0.05$) differences between sides. Pearson's correlations were run to determine the relationship of specific variables to age.

Results: The humeral head was significantly less retroverted (D**V1**= -10.3° and D**V2**= -16.9°, $p<0.008$), more elliptical ($p<0.001$), and smaller in all 3-dimensions ($p<0.001$) for the unimpaired arm. The decreased retroversion disagreed with the past 2D study in younger children[3], whereas all other results are supported by past 2D work[4]. Although **V1** was strongly correlated to **V2** ($r=0.83$, $p<0.001$), the variation in D**V1** and D**V2** and the more elliptical humeral head on the impaired side demonstrates that retroversion is associated with both the orientation of the humeral head realtive to the elbow and the shape of the humeral head itself. The level of pathology increased with age ($r=0.507$, $p=0.012$), which may explain the discrepancy in retroverstion when comparing to past work[3]. A longitudinal study is needed to identify how shape changes with age in individual subjects, yet the results indicate that intervening early may help prevent larger

musculoskeletal pathologies later in life. Although the inclination angle was not significantly different between sides, the results were noteworthy when analyzing patient specific changes. Six and five subjects showed declination and inclination, respectively, greater than one standard deviation away from the control average. This discrepancy suggests that patient-specific, 3D morphometric analyses will support optimal treatment. There was a significant correlation between humeral morphology and age for the control side (**V1**: r= -0.57; **V2**: r= -0.711; and inclination: r= -0.477, $p<0.05$). Numerous factors such as increases in the variety of tasks performed and changes to the external forces on the arm (e.g., the initiation of crawling) may influence the relationship between shape and age on the control side. These natural developmental changes must be taken into account when assessing pathology. In addition, these changes in shape influence the musculotendon moment arms[5], confirming the concept that musculoskeletal models must be tailored to the pediatric population and not be derived by simply scaling adult models.

Figure:

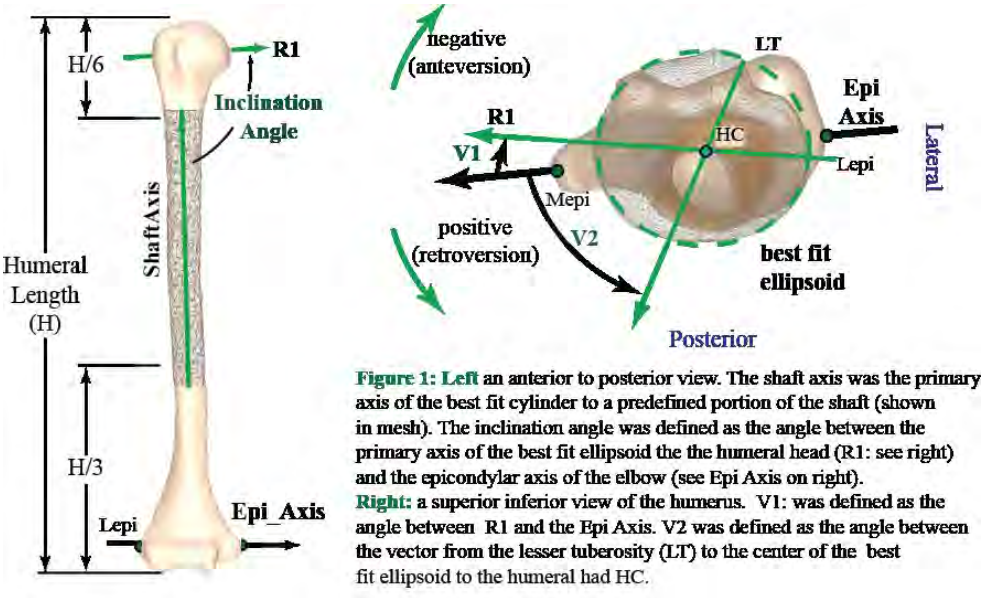

Figure 1: Left an anterior to posterior view. The shaft axis was the primary axis of the best fit cylinder to a predefined portion of the shaft (shown in mesh). The inclination angle was defined as the angle between the primary axis of the best fit ellipsoid the the humeral head (R1: see right) and the epicondylar axis of the elbow (see Epi Axis on right). **Right:** a superior inferior view of the humerus. V1: was defined as the angle between R1 and the Epi Axis. V2 was defined as the angle between the vector from the lesser tuberosity (LT) to the center of the best fit ellipsoid to the humeral had HC.

Conclusion: This study is the first to evaluate 3D humeral shape changes in OBPP across the full pediatric age span. It provides novel findings in terms of inclination. The increased understanding of 3D morphologic changes in both the control and impaired arms of children with OBPP can lead to improvements in determining the unique and optimal treatment options for an individual based on subject-specific 3D morphological analyses.

RELATIONSHIP BETWEEN MUSCLE FASCICLES BEHAVIOR DURING MAXIMAL ECCENTRIC EXERCISE AND SUBSEQUENT MUSCLE DAMAGE

Gaël Guilhem [1,*] Valentin Doguet [2] Lilian Lacourpaille [1] Hugo Hauraix [2] Marc Jubeau [2] Arnaud Guével [2] François Hug [3] Antoine Nordez [2] Sylvain Dorel [2]

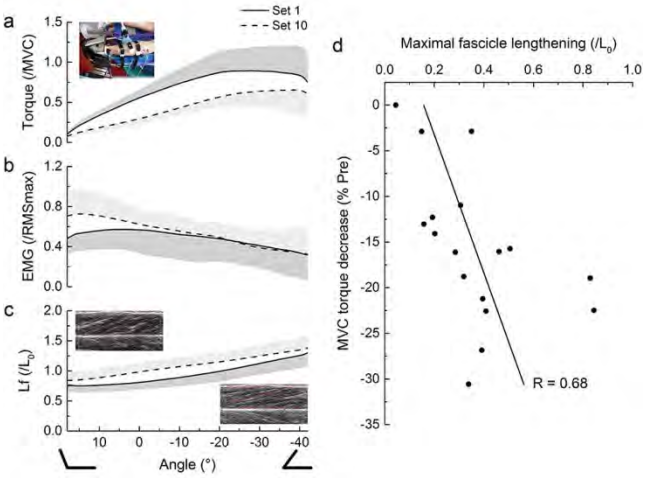
[1]Research Department, French National Institute of Sport (INSEP), Paris, [2]Laboratory Motricité, Interactions, Performance - EA 4334, University of Nantes, Nantes, France, [3]NHMRC Centre of Clinical Research Excellence in Spinal Pain, Injury and Health, University of Queensland, Brisbane, Austria

Introduction and Objectives: While current knowledge of the muscle dynamics during eccentric contractions has been mainly inferred from animal and in vitro studies [1], the advent of non-invasive techniques (i.e. ultrasonography) allows to explore human muscle mechanics that lead to exercise-induced muscle damage in vivo. Recent data obtained from the gastrocnemius medialis (GM) did not evidence a direct relation between muscle fascicle lengthening (18% of optimal fascicle length) during a submaximal eccentric exercise (i.e. backward walking) and the subsequent decrease in electrically-induced isometric torque [2]. The present study aimed to determine the potential relationship between changes in muscle fascicle length during maximal isokinetic eccentric contractions and the extent of muscle damage. We hypothesized that GM fascicle lengthening during maximal eccentric contractions would be higher than during backward walking and correlated to the decrease in maximal isometric torque.

Methods: Seventeen healthy subjects performed an initial test session two days before they performed a maximal isokinetic eccentric exercise of the plantar flexor muscles at 45°.s^{-1} on a Con-Trex isokinetic dynamometer over 60° until maximal dorsiflexion angle (0°=foot perpendicular to the tibia). The same test session was repeated 5 min and 48h after the exercise. During the exercise, torque and joint angle were collected from the dynamometer. Surface EMG activity of the gastrocnemius lateralis (GL), and GM fascicle length and pennation angle were continuously measured using ultrafast ultrasonography (100 Hz). During each test session, maximal voluntary isometric (MVC) torque, delayed onset muscular soreness (DOMS) and Achilles tendon active stiffness were measured. Separate one-way ANOVAs (time effect) with repeated measures and Newman-Keuls post-hoc procedures were applied to determine the effect of eccentric exercise on MVC torque and DOMS. Multivariate linear correlations were performed between muscle mechanics variables and the decrease in MVC torque at 48h. The significance level was set at $P<0.05$.

Results: Eccentric torque ranged from 11±5 N.m at 12° to 100±35 N.m at -28° during the exercise (Fig. 1a), with a significant 31±18% decrease in average torque from set 1 to set 10. EMG activity of GL muscle did not significantly changed from set 1 to set 10 (Fig. 1b). Overall, GM muscle fascicle lengthened from 35 ± 8 mm to 58±11 mm (i.e. 36±21% of optimal fascicle length) during the eccentric contractions (Fig. 1c). GM fascicle length increased from set 1 to set 10 (+12±5%). MVC torque significantly decreased immediately after maximal isokinetic eccentric exercise (-43±15%), and at 48h (-24±22%). DOMS significantly increased to 4.4 ± 2.8 at 48h. Multivariate correlations showed a significant relationship between maximal fascicle lengthening and MVC torque decrease at 48h ($R=0.68$, $P<0.5$; Fig. 1d). In addition, we observed a tendency for MVC torque to decrease as tendon active stiffness increased ($R=0.48$; $P=0.08$).

Figure:



Caption: Plantar flexor torque (a), EMG activity of gastrocnemius lateralis normalized to the maximal root mean square (RMSmax) value obtained during MVC (b) and gastrocnemius medialis fascicle length (c) during maximal isokinetic eccentric contractions performed over 60° until maximal dorsiflexion angle. Values are mean ± SD. The decrease in MVC torque was significantly correlated to the maximal fascicle lengthening (d).

Conclusion: Maximal isokinetic eccentric contractions of the pantar flexors elicited a fascicle lengthening twice superior to the one observed during backward walking (36% vs. 18% of optimal fascicle length). Our findings also evidenced progressive adjustments in muscle dynamics as illustrated by the significant decrease in torque and the increase in fascicle length throughout the exercise. This increase in fascicle length could be reflective of a reduction in active cross-bridges or contraction level due to fatigue occurrence, and/or a consequence of cytoskeletal alterations caused by eccentric contractions [3]. Such muscle mechanics resulted in muscle damage as shown by the 24% drop in maximal force-generating capacities at 48h post-exercise. Interestingly, the decrease in MVC torque was significantly correlated to maximal fascicle lengthening, which slightly differs from results obtained during backward walking [2]. This may indicate that active lengthening on the descending limb of the torque-length curve and the strain amplitude may influence the level of muscle damage, confirming previous data from in vitro studies that used higher fiber stretches. The correlation tendency between Achilles tendon stiffness and the extent of muscle damage confirms that elastic properties of tendinous tissue contribute to mitigate muscle strain during lengthening contractions in humans.

COMPARISON OF HIP MUSCLE FORCES OBTAINED USING A CALIBRATED EMG-INFORMED MODEL AND STATIC OPTIMIZATION IN A HIP OSTEOARTHRITIC POPULATION

Hoa X. Hoang [1,*] Claudio Pizzolato [1] Luca Modenese [1] Peter Mills [1] David Lloyd [1]

[1] Centre for Musculoskeletal Research, Griffith University, Gold Coast, Australia

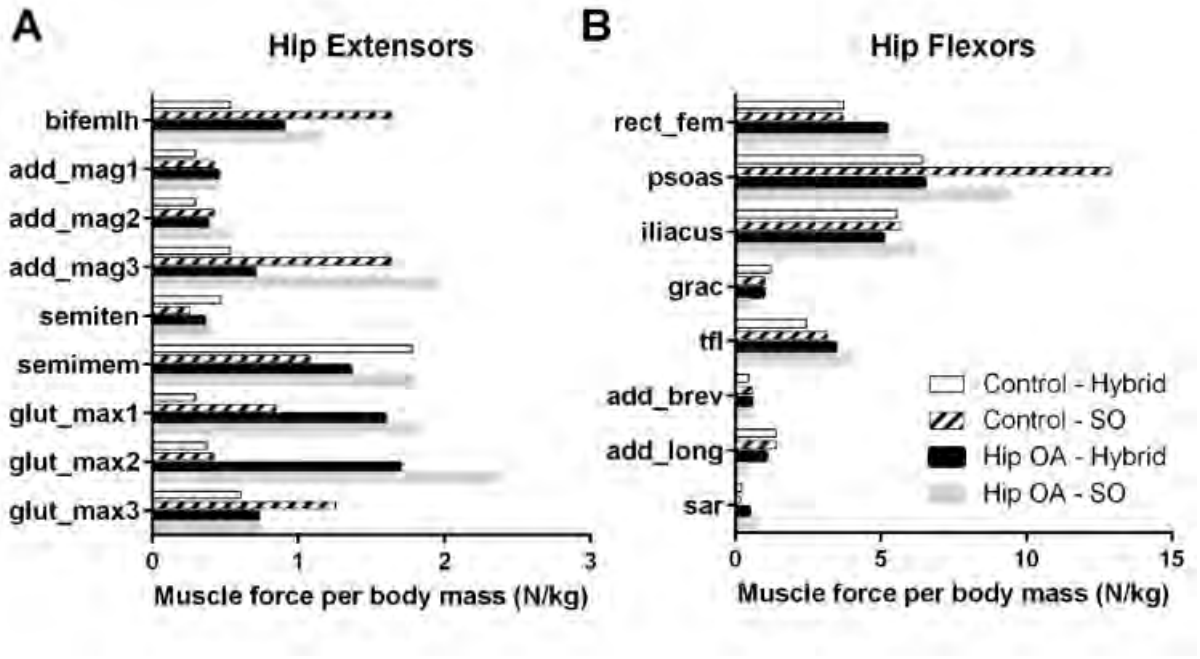
Introduction and Objectives: Hip osteoarthritis (OA) is a progressive and debilitating disease for which there is no cure and is the main reason for total hip replacements. Mechanical wear of the hip joint may be an key factor in the development of hip OA [1];however, hip joint disease is relatively under-studied and mechanical factors for the progression of hip OA are still poorly understood.Neuro-musculoskeletal (NMS) models can estimate muscle forces used to calculate internal joint contact forces (JCFs). However,these models have estimated muscle forces using static optimization (SO) that uses objective functions that are not physigiologialy based.We investigated the effect of using a Hybrid Calibrated EMG-Informed NMS (CEINMS-Hybrid) versus a SO approaches [2] to estimate muscle forces during walking in a hip OA and age-matched healthy populations.

Methods: We recruited and tested 26 individuals (> 45 years) with unilateral radiographic hip OA that has Kellgren-Lawrence (KL) score of 2 or 3 and 26 age-matched healthy participants used for controls. Participants were fitted with a full-body retro-reflective marker set and 16 surface EMG electrodes were placed on the affected leg of the hip OA participants while the side was randomly selected for the healthy participants. The system and data included: 10MX-camera Vicon system (200Hz), 2 AMTI force platforms (1,000Hz), and a 16-channel wireless EMG Cometa system. Participants performed a set of static trial and 10 walking trials. Hip joint centers were estimated using the Harrington regression equation while the knee and angle joint center were estimated using the midpoint of markers. Markers and ground reaction forces were filtered using a low-pass 4th-order Butterworth filter (6Hz). EMGs were processed by first a band-pass filtered with 4th-order Butterworth filter (30-300Hz), then full-wave rectified, and low-passed filtered using a 4th-order Butterworth filter (6Hz). The resulting linear envelopes were normalized to the maximum processed EMG values recorded from the entire set of trials. A full-body generic NMS model [2] was scaled in OpenSim to match each subject's anthropometry using the static trials. The model had 12 segments consisting of 19 DOFs across the lower extremities, pelvis, and trunk. The model included 34 muscle-tendon units (MTUs). In OpenSim, inverse kinematics (IK) was used to calculate joint angles for each walking trial while inverse dynamics (ID) was used to determine the net forces and torques at each joint. The musculotendon moment arms and fibre lengths for each MTU were calculated in OpenSim. The 16 experimental EMG signals were allocated to the 34 MTUs. Model parameters (musculotendon activation filtering coefficients, non-linear EMG to force relationship shape factor, tendon slack length, optimal muscle fibre length, muscle strength coefficient) were calibrated using the first 6 walking trials. Calibration was done by minimizing the predicted moments in CEINMS with the ID moments for the following degrees of freedom: hip flexion-extension, hip adduction-abduction, knee flexion-extension, and ankle plantar-dorsiflexion.Muscle forces were estimated from the remaining 4 walking trials with the CEINMS-hybrid approach using the recorded EMGs as inputs to drive the calibrated model [3]. The psoas major and iliacus did not have EMG recording as they were too deep for surface recordings; therefore, SO was

used to generate the excitations in the CEINMS-hybrid approach.Similarly,standard SO was also used to estimate muscle forces using an objective function to minimize sum of the activation squared.Muscle forces were normalized to each subject's body mass (N/kg).

Results: So far we have been processed data from 5 healthy female (61.3kg ± 6.6; 61.7y ± 11.9) and 5 hip OA female (69.9kg ± 9.9; 63.8y ±8.2) participants were processed during the stance phase of gait. The mean walking speed of the healthy and hip OA participants were 1.33m/s ± 0.13 and 1.13 m/s ±0.17, respectively. The CEINMS-hybrid approach estimated lower MTU forces muscles compared to SO (Fig.1).The average normalized hip MTU forces were generally higher in hip OA versus controls subjects.

Figure:



Caption: Muscle force normalized to body mass for the (A) hip extensor muscles, and the (B) hip flexor muscles

Conclusion: MTU forces estimated from SO were higher than the CEINMS-hybrid model for both groups. This suggests neurophysiologically based EMG-informed NMS modeling may be a promising alternative to SO in estimating muscle and joint contact forces, as SO over estimates hip joint contact forces.Lower estimated internal joint contact forces are expected using CEINMS-hybrid and is the focus of our current analyses.The hip MTUs of the hip OA group tended to be higher values than the healthy group,possibly to compensate for pain associated with OA.This also suggests that hip joint over loading may be a possible cause for rapid hip OA progression.

SHEAR WAVE SPEED IN PLANTARFLEXORS OF INDIVIDUALS WITH CEREBRAL PALSY

Sabrina Lee [1,2,*] Li-Qun Zhang [2] Deborah Gaebler [2] William Rymer [2] Katherine M. Steele [3]

[1]Physical Therapy and Human Movement Sciences, Northwestern University, [2]Rehabilitation Institute of Chicago, Chicago, [3]Mechanical Engineering, University of Washington, Seattle, United States

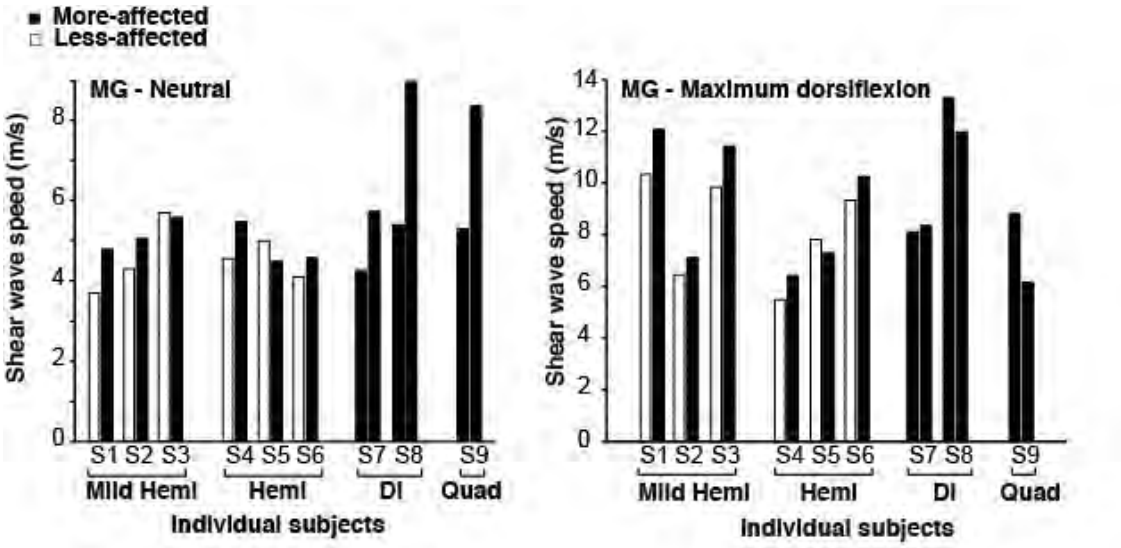
Introduction and Objectives: Individuals with cerebral palsy (CP) tend to have altered muscle properties such as changes in fiber architecture and fiber composition[1], but little is known about the changes in muscle material properties, specifically stiffness that evolve as the individual matures. Quantification of muscle material properties has been limited to invasive methods such as biopsies. Shear wave (SW) ultrasound elastography allows SW speed, which is related to stiffness, to be measured *in vivo* in individual muscles[2]. Earlier studies have measured SW speed in both healthy muscles[3] and muscles of individuals with neuromuscular dysfunction[4]. Building upon these results, the goal of this study was to evaluate SW speed of the medial gastrocnemius (MG) and tibialis anterior (TA) in children with unilateral and bilateral CP over a range of ankle positions and torques.

Methods: Nine individuals (6 males, 3 females; age, 10.3±3.6 yrs.; height,1.36±0.16 m, mass, 33.9± 12.0 kg; 2 diplegic, 6 hemiplegic, and 1 quadriplegic, GMFC scores: 1-3) participated in the study.

Subjects were seated in a device (Intelligent Stretcher, Rehabtek) with their knee in full extension and foot strapped to a foot-plate, which rotated the ankle. B-mode and SW elastography ultrasound measurements (Aixplorer, Supersonic Imagine) of the tibialis anterior (TA) and medial gastrocnemius (MG) muscles, as well as joint angle and torque measurements, were made with the ankle set at different angles (neutral, maximum dorsiflexion (DF), maximum plantarflexion (PF), and two other intermediary angles) while the muscle was passive. Mean SW speed was calculated from a 12mm by 12mm region of the ultrasound images.

Results: Our key findings were that we recorded greater SW speed in the MG of the more-affected limb of individuals with unilateral CP by 11% (more-affected: 9.09±2.45m/s; less-affected: 8.21±1.95m/s, p=0.043, Fig. 1), especially when the muscle was set at its longest length. SW speed in MG and TA increased with increasing ankle angle and joint torque (linear fit of SW speed versus torque for the MG with r^2=0.48 (p<0.001) and a quadratic fit of SW speed versus angle for MG and TA with r^2=0.59 (p<0.001) and r^2=0.30 (p<0.001), respectively). There was a significant correlation between SW speed of the MG and ankle range of motion as indicated by the maximum DF angle (r^2=0.35, p=0.01). There was no significant correlation between SW speed and functional impairment as indicated by the GMFCS levels.

Figure:



Caption: Figure 1. Mean shear wave speed of the less-affected (grey bars) and more-affected (black bars) medial gastrocnemius for individual subjects at neutral ankle angle and maximum dorsiflexion. Subjects are categorized as mild-hemiplegic (Mild Hemi), hemiplegic (Hemi), diplegic (Di), and quadriplegic (Quad) as diagnosed by the physician and GMFCS level. Both bars for the diplegic and quadriplegic are denoted in black as both limbs are affected.

Conclusion: We demonstrated that SWs travel faster in the MG of the more-affected than the less-affected side of individuals with CP, suggesting that the affected muscles have altered material properties, specifically greater stiffness. Significantly increased SW speed was observed in MG but not in TA, likely due to the more severe impairment in plantar flexor function, as compared to dorsiflexor function in this group of individuals. Possible sources of increased passive stiffness include increased collagen content in the extracellular matrix and other connective tissue, which has been shown to be correlated with clinical measurements of muscle spasticity[5]. Our result of increased SW speed with longer muscle lengths further suggests that increased passive tension is largely responsible for the changes in SW speed rather than muscle activity or hypertonicity. Moreover, greater SW speed was correlated with reduced ankle range of motion, indicating that increased stiffness of the MG was limiting DF range of motion for some individuals.

Use of SW elastography in the clinic may provide an additional means to quantify muscle material properties that are patient-specific, non-invasive, and occur in real-time. This is important for elucidating the complex nature of altered muscle properties that contribute to decreases in range of motion and force generation in individuals with CP. Being able to characterize altered muscle material properties is important for understanding the causes of abnormal muscle function, aiding diagnosis, and guiding treatment planning.

PREDICTING TIMING OF FOOT STRIKE FOR TREADMILL WALKING AND RUNNING WITH A PRINCIPAL COMPONENT MODEL OF GAIT.

Sean Osis [1 2,*] Blayne Hettinga [1 2] Reed Ferber [1 2]

[1]University of Calgary, [2]Running Injury Clinic, Calgary, Canada

Introduction and Objectives: The accurate detection of events during gait, such as foot strike, can be challenging without force measurements. Consequently, there are many disparate methods used to detect foot strike in walking and running by means of specialized marker sets [1,2,3,4]. Recently, a novel approach to this problem was developed based on the use of feature selection using principal component analysis (PCA), and when applied to running, demonstrated improved predictions of timing, irrespective of varying striking techniques [5]. Therefore, the purpose of this study was to evaluate the use of this previously developed method in predicting the timing of foot strike during treadmill walking.

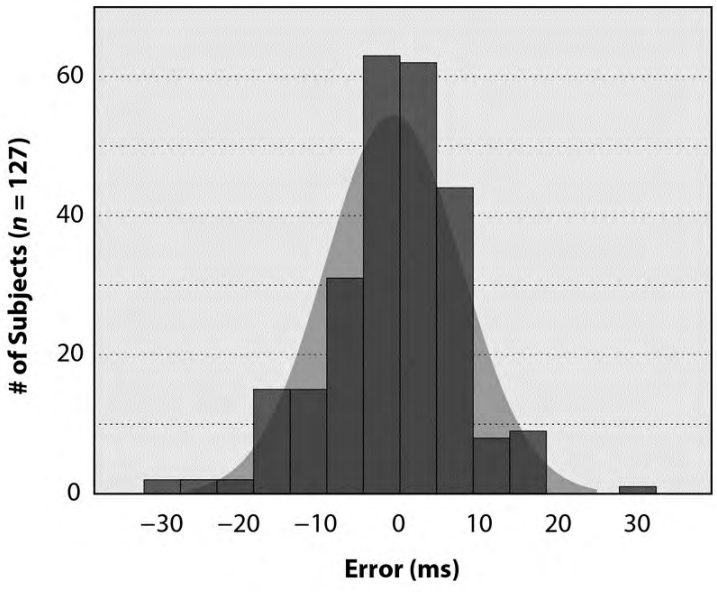
Methods: Kinematics were collected using eight high-speed (200 Hz) video cameras (Vicon, Oxford, UK), and retro-reflective markers. Kinetics were obtained from an instrumented treadmill (Bertec, Columbus, OH). Markers were placed over anatomical landmarks and a standing neutral trial was collected. Segment kinematics during walking were collected using clusters of markers strapped to the pelvis, thighs, shanks and feet.

Marker and kinetic data for n = 127 subjects (71 females; 38.3 +/- 10.1 years; 1.73 +/- 0.09 m; 70.1 +/- 12.4 kg; 1.12 +/- 0.01 m/s) were extracted from a database of walking biomechanics for analysis. Joint angles were calculated using a singular value decomposition approach, and a joint coordinate system. Gold-standard identification of foot strikes was based on a 10 N threshold of vertical force.

A previously developed PCA model [5] was applied to the current data by projecting sagittal plane joint accelerations into an existing principal component space. The resulting scores from the first PC were used to predict timing of foot strike according to the previously trained regression model [5]. The timing of predicted frames were then compared with the gold standard timing from kinetics.

Results: A bias of 7 frames in the distribution of errors was found after initial implementation, and was subsequently removed by subtracting 7 frames from the predicted frame of foot strike for each step. The resulting distribution of errors demonstrated good agreement with foot strike as determined by kinetics, with 90% of subjects having a median error less than +/- 3 frames, or 15 ms (Figure 1).

Figure:



Conclusion: The errors found in the current study are comparable to, or slightly more than, recent approaches in the literature ([3] 94% of errors within 17 ms; [4] 95% of errors within 7 ms). However, the current method has the advantage of not being reliant on specific marker sets for the prediction of gait events.

Interestingly, although the method was trained using data from running, it seems to apply equally well to walking. This result suggests that the underlying PCA model accounts for both gait type (walking vs running) and the previously reported striking technique (forefoot vs rearfoot) [5]. Therefore, this PCA method is a convenient and unified means of using joint kinematics to predict timing of foot strike during treadmill gait.

Caption: Figure 1 – Histogram of median error for each subject in the prediction of foot strike using the PCA regression model, as compared with detections of foot strike by kinetics.

OBJECTIVELY-MEASURED DAILY PHYSICAL ACTIVITY PATTERNS AND THEIR ASSOCIATIONS WITH BMI IN OLDER WOMEN

Emma Fortune [1,*] Shreyasee Amin [2] Kenton Kaufman [1]

[1]Orthopedic Surgery, [2]Rheumatology, Mayo Clinic, Rochester, United States

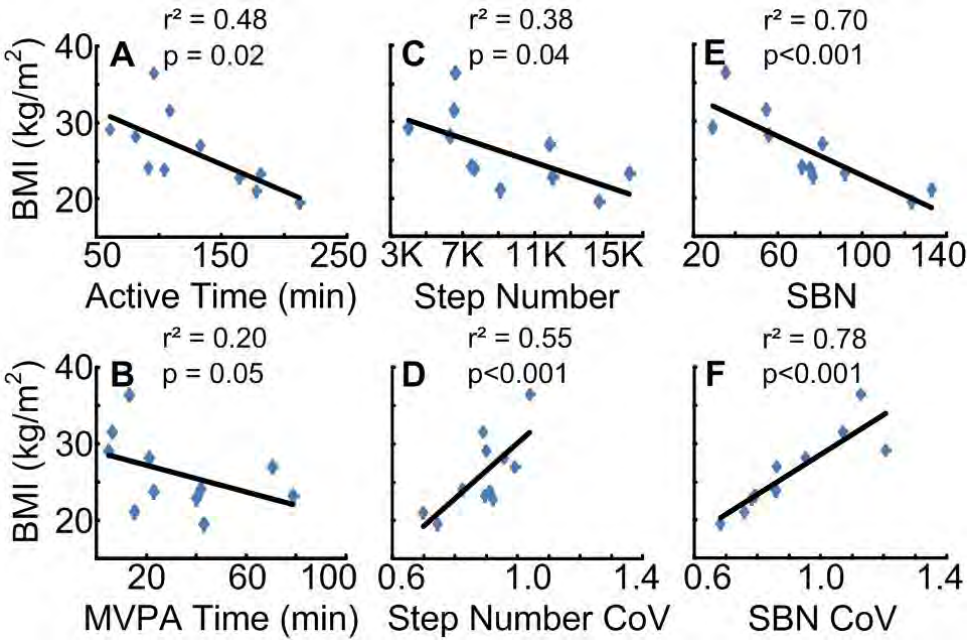
Introduction and Objectives: Regular physical activity (PA) with aging is critical for health and function [1]. It is recommended that 75-150 minutes/week of moderate-vigorous PA (MVPA) are performed to sustain a healthy weight [2]. As PA declines with age, accurate PA measurement in older community-dwelling adults is crucial when assessing health status, but challenging. Increasing evidence suggests that too much sedentary time and too little light intensity PA (LPA) can impose huge health implications for weight and cardiovascular health, independent of reaching current MVPA recommendations [3]. Recent reports also suggest that distributing PA throughout the day may be more beneficial to weight and cardiovascular health than meeting MVPA recommendations in concentrated periods of time [4]. However, current objective PA and sedentary time measures are simplified, considering only daily total PA or sedentary time, and use methods of limited accuracy [5]. An objective portable method for measuring PA patterns in the free-living environment is necessary to fully determine associations with obesity and its related diseases. Therefore, this study's objectives were to (1) examine both the daily amount and the variations of active time, step counts, and the number of times that sedentary time was broken up (sedentary break number; SBN) of 11 older women using custom-built activity monitors (AMs) in the free-living environment and (2) investigate the associations of these parameters with BMI to determine the importance of PA variations during the day for BMI management in older women.

Methods: Eleven older women (age 77±9 yrs; BMI 26±5 kg/m^2) wore AMs, each containing a tri-axial accelerometer (±16g, 100 Hz), on the waist and ankle for lab-based walking trials (for validation by comparison to video data simultaneously recorded at 60 Hz) and 4 days in the free-living environment. The protocol was approved by the IRB and written informed consent was obtained. Step counts, active time (classified as MVPA for cadence>92 steps/min [6]) and SBN (number of activity segments ≥30 s) were estimated from acceleration data using a previously validated algorithm [7]. Sensitivity and positive predictive value (PPV) were used to assess the algorithm's ability to accurately detect active time in seconds and steps and the Bland-Altman method was used to assess cadence as determined by the AM algorithm and video observation for the lab-based trials. The associations of the PA parameters' total daily values and the coefficient of variations (CoVs) of their hourly values (to quantify activity variation throughout the day) with BMI were assessed using linear regression with Pearson correlation analysis. The data were also analyzed after adjusting for age.

Results: Median sensitivity and PPV of active time and step detection were >98% for lab trials. Mean cadence error was <1%. The median (IQR) daily step count, cadence, and active time measured in the free-living environment were 7689 (5406) steps, 73 (16) steps/min, and 109 (81) min. Median step counts were higher than expected for older adults [2]. However, most subjects were self-reportedly very active and many algorithms cannot accurately detect steps at gait velocities <0.8m/s [7]. BMI was inversely associated with active time, MVPA time, step counts, and SBN (Fig. 1) consistent with associations of greater activity with healthier weight [2]. The higher association of active time compared to

MVPA time with BMI is consistent with suggestions that LPA should be considered in addition to MVPA [3]. BMI was positively associated with active time/hour CoV (r^2=.50, p<.001), step number/hour (Fig. 1D), and SBN/hour (Fig. 1F), with slightly higher r^2 values compared to these parameters daily totals, suggesting that activity variation may be important to consider in future studies with larger sample sizes. Both the SBN and the CoV of SBN/hour had the highest associations with BMI, agreeing with previous reports that abdominal obesity, which can be predicted from BMI, is affected by sedentary time [6]. Age was not significantly associated with any investigated variable (p_{age}>.17) other than the CoV of SBN/hour (adjusted r^2=.91, p_{age}=.03), with the association of SBN/hour CoV with BMI slightly decreasing as age increased.

Figure:



Caption: Figure 1. Associations of BMI with mean daily A active minutes, B MVPA minutes, C step number, D step number/hour CoV, E sedentary break number (SBN), and F SBN/hour CoV.

Conclusion: These data support suggestions to break up sedentary time with both LPA and MVPA and distribute PA throughout the day to sustain a healthy BMI.

EFFECTS OF FATIGUE AND ANTICIPATION ON THE KINEMATICS AND KINETICS DURING A SIDE CUT

Chris Richter [1 2 3,*] Kieran Moran [1 2] Enda Whyte [2]

[1]Insight:Centre for Data Analytics, [2]School of Health and Human Performance, Dublin City University, [3]Sports Medicine, Sports Surgery Clinic, Dublin, Ireland

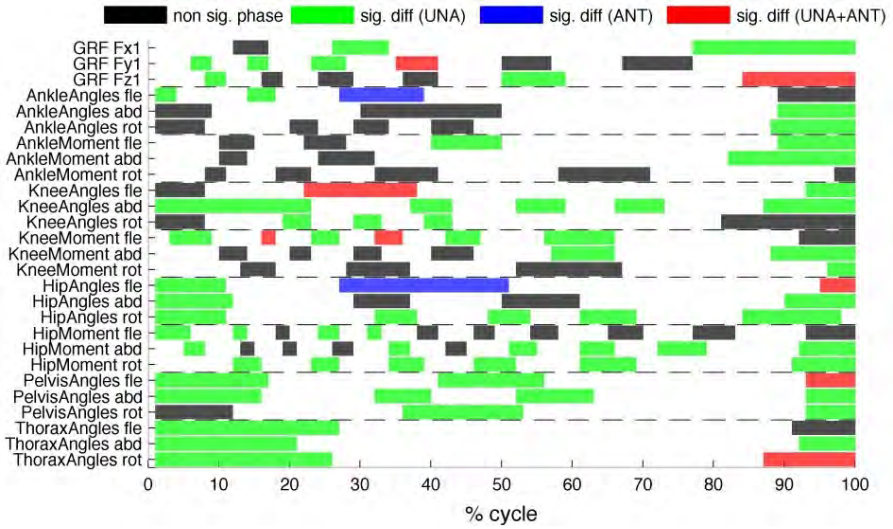
Introduction and Objectives: Uni-lateral multi-directional movements (e.g. cutting) are common in most sports and deficiencies in neuromuscular control have been identified as risk factors for injuries, e.g. ACL injuries[1]. Two factors that may decrease neuromuscular control are fatigue and anticipation. Previous research has shown that fatigue can neg. effect biomechanical variables that are associated with injury[2] and that injuries tend to occur when a person is fatigued, e.g. towards the end of a game[3]. Regarding anticipation, athletes have to respond instantaneously to external stimuli by selecting movement strategies. Hence, anticipation can influence the execution of a movement (e.g. the time between choosing a strategy and its execution may be too small in some instances), forcing the athlete to execute a non-optimal movement. To date, few studies have examined the effects of fatigue and anticipation of cutting tasks. Therefore, the aim of this study was to examine the effects of fatigue and anticipation on the biomechanics during a side cut.

Methods: Trunk and lower limb kinematics and kinetics were recorded for 30 healthy male during a side cut. Data was recorded for an anticipated (ANT) and unanticipated (UNA) condition before (PRE) and after (POST) exposure to an high-intensity exercise protocol[4]. A side cut was performed, with participants jumping horizontally (70% of their max. jump distance), landing on their dominant leg and performing a side cut at 45 degrees. In the ANT condition, a flashlight indicated the movement direction five seconds before the task was performed. In the UNA condition, the participant triggered this light by breaking an infrared beam during the jump. Kinematic and kinetic variables were recorded, over the full cycle of contact with a force plate, and examined for differences between the conditions using Analysis of Characterizing Phases (ACP), which generated subject scores from key phases (phases of variance) that were identified using principal components that captured >99% of the variance in the data[5]. Only the deceleration phase was examined, which was defined as the phase from initial contact to the first occurrence of propulsion forces. To identify statistical differences, a Repeated Measures ANOVA was performed. To measure the effect size of the statistical differences Cohen's D (d) was calculated. The alpha level was set to 0.05. Only significant findings for waveforms that had at least one key phase with a medium (.5>d>.8) or large effect (d>.8) are reported.

Results: Findings showed multiple significant effects of fatigue (ankle flexion angle, knee flexion angle and moment, hip and pelvis flexion angles as well as thorax rotation), supporting previous studies that examined the effect of fatigue during cutting movements[2,6]. However, none of these factors reached a medium effect, indicating a low effect of fatigue on biomechanical measures. When comparing ANT vs. UNA, findings matched previous studies that examined the effect of anticipation on cutting tasks[2] have been proposed to be risk factors for ACL injuries. However, most of these factors had a small effect (anterior GRF, ankle flexion and abduction angles and moments, knee flexion angles and moments, knee abduction moments, hip abduction angles, hip flexion rotation moments, pelvis angle flexion and rotation, thorax flexion and rotation angles). Interestingly, the identified factors with medium or large effects have not been examined/reported

previously (pelvis & thorax abduction angles, as well as non peak knee flexion moments). Factors with large effect sizes were only identified in this study due to the use of a continuous data analysis approach, which considers the whole waveform rather than selected discrete points, and has been shown previously to be more effective than the traditional analysis method of analyzing discrete data points (e.g. peak angle)[5]. Effect sizes indicated a medium to strong effect of anticipation on biomechanical measures.

Figure:



Caption: Key phases examined

Conclusion: Findings indicate both fatigue and anticipation can alter the biomechanics of a side cut, while the effects of anticipation have a much greater influence.

SENSITIVITY OF A DISTRIBUTIVE TACTILE SENSING DEVICE FOR THE ASSESSMENT OF ARM FUNCTION AFTER STROKE

Amir A. Mohagheghi [1,*]

[1]Department of Life Sciences, Brunel University, London, United Kingdom

Introduction and Objectives: In contrast to healthy individuals, stroke survivors flex their trunk to reach to targets located within the reach of the arm (near targets). For targets placed beyond the reach of the arm (far targets), both healthy and stroke individuals, flex their trunk to reach to the targets, and the magnitude of trunk flexion increases with increasing target distance. Contribution of trunk to reaching has been shown to be correlated to the level of motor impairments in stroke survivors. Moreover, a clinical threshold may exist at which trunk contribution to reaching alters as a result of changes in the severity of motor impairment [1]. Therefore, determination of trunk contribution to the reaching tasks might have a prognostic value in the rehabilitation after stroke. We have developed a Distributive Tactile Sensing (DTS) device which can provide a low cost (both analytically and financially) alternative to the traditional real-time optoelectronic motion analysis systems. The device works by detecting deformation responses of flexible surfaces (e.g. thin steal or plastic plates), when subjected to variable force stimuli provoked by the human body movement. Surface deformations are recorded by a small number of low-cost infrared displacement sensing elements (typically 3-5) placed under the surface at strategic points where the deflections are likely to be more pronounced. Different combinations of the sensors outputs (transients) can be used to detect the exact location of the force applied to the surface. In the same way, temporal profile of the applied force can provide information on the pattern of force application to the surface. The development proposed in the current study involved modification of a standard office chair integrated with a simple sensing system. In healthy and stroke participants, we assessed presence and magnitude of trunk contribution to a reaching task toward near and far targets, and compared the DTS device sensing transients and movement kinematics recorded using motion analysis. The aim was to assess the sensitivity of the DTS device as a clinical tool for the assessment of selective arm function after stroke.

Methods: A convenient sample of ten Healthy (H) adults and five chronic stroke survivors (S) whose upper limb (UL) were mildly to severely impaired took part in the study. Participants were instructed to sit upright in an instrumented chair and reach out to targets placed in front of them using their dominant (H) or paretic UL (S). Targets were placed at distances determined using different percentages of the length of the individual's arm. Specific features of the sensing transients from the DTS device were extracted, and associated with the UL segments and trunk kinematics using motion analysis. Movement was performed at a self-selected speed after a verbal cue. Wilcoxon signed-rank test was used to analyse data.

Results: For the H group, DTS transients showed minimal change compared to the baseline with movement of the UL segment in reaching toward near targets. For far targets, DTS transients showed specific characteristics (Figure) representing recruitment and level of involvement of the trunk. Peak-to-peak (p-p) amplitude of the transients (z=2.803; p=0.005) and trunk flexion angles (z=2.803; p=0.005) increased with increasing target distance. Importantly, DTS

transients characteristic started before the onset of trunk movement (mean range: 119-140 ms). For the S group, the characteristic DTS transients (and trunk movement) were present during reaching tasks for all near and far targets. Similar to the H group, p-p amplitude (z=2.023; p=0.043) increased with increasing target distance, and showed a similar trend for trunk flexion (z=1.826; p=0.068). Mean delay between onset of DTS transients characteristic and trunk movement was 195-288 ms.

Figure:

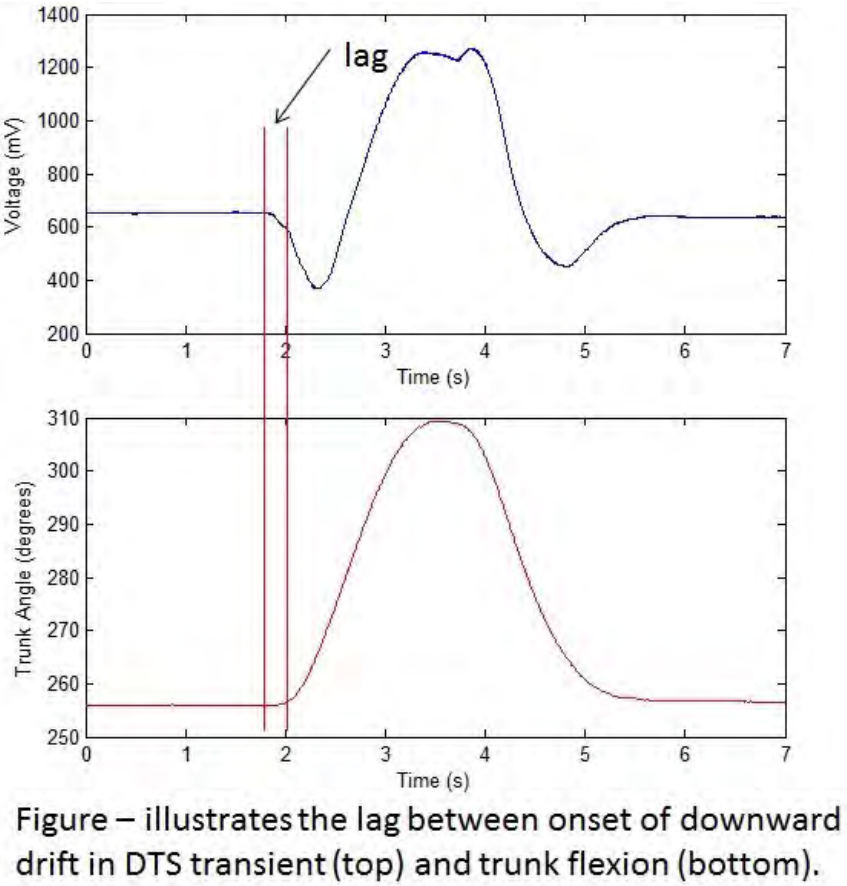

Figure – illustrates the lag between onset of downward drift in DTS transient (top) and trunk flexion (bottom).

Caption: Figure – illustrates the lag between onset of downward drift in DTS transient (top) and trunk flexion (bottom).

Conclusion: Conclusion: DTS device showed sensitivity to the presence and magnitude of trunk flexion. Presence and magnitude of trunk movement during reaching tasks to near targets is associated with the severity of motor impairment after stroke. Therefore, DTS device can be used for the objective assessment of arm function after stroke. The characteristic DTS transients started several milliseconds prior to trunk flexion in both groups. This lag may represent backward movements of the centre-of-mass and/or lower limb muscles activity providing stability before the onset of trunk flexion. It is likely that alteration of the lag is associated with alteration in the level of motor disability.

IS THE DYNAMIC COEFFICIENT OF FRICTION INDEPENDENT OF VELOCITY IN HUMAN GAIT?

Ilaria Pacifici [1,*] Ana F.R. Kleiner [1 2] Manuela Galli [3 4] Ricardo M.R. Barros [2]

[1]Luigi Divieti" Posture and Movemengt Analysis Laboratory, Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milano, Italy, [2]Laboratory of Instrumentation for Biomechanics, Faculty of Physical Education, University of Campinas, Campinas, Brazil, [3]"Luigi Divieti" Posture and Movemengt Analysis Laboratory, Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milano, [4]Gait Analysis Lab, IRCCS San Raffaele, Rome, Italy

Introduction and Objectives: Friction plays an important and necessary role in the activity of walking. Without friction we could not move from one place to another. To accomplish desired motion, the tangential forces associated with the accelerations of the body must be resisted by ground reaction forces. The study of friction is documented since the end of XIV century in the manuscripts written by Leonardo da Vinci, who discovered that the friction force is proportional to the load (normal force) and is independent of the area of contact. In 1875, Charles A. Coulomb affirmed that kinetic friction between two rigid bodies is independent of the sliding speed; it was referred as the third law of friction.

In the human locomotion, the required Coefficient of Friction (RCOF) is a parameter able to evidence a floor surface kinetic requirement, to support walking [1]. This coefficient is usually applied to analyze the happening of falls related to slips and it is determined by the resultant of the ground reaction forces generated during the gait, with the use of 3 axial force plates.

Considering the relevance of the COF for the human gait, it is important to verify if the COF is dependent on the walking speed. The purpose of this study was to examine the dependence of the dynamic coefficient of friction by the gait velocity.

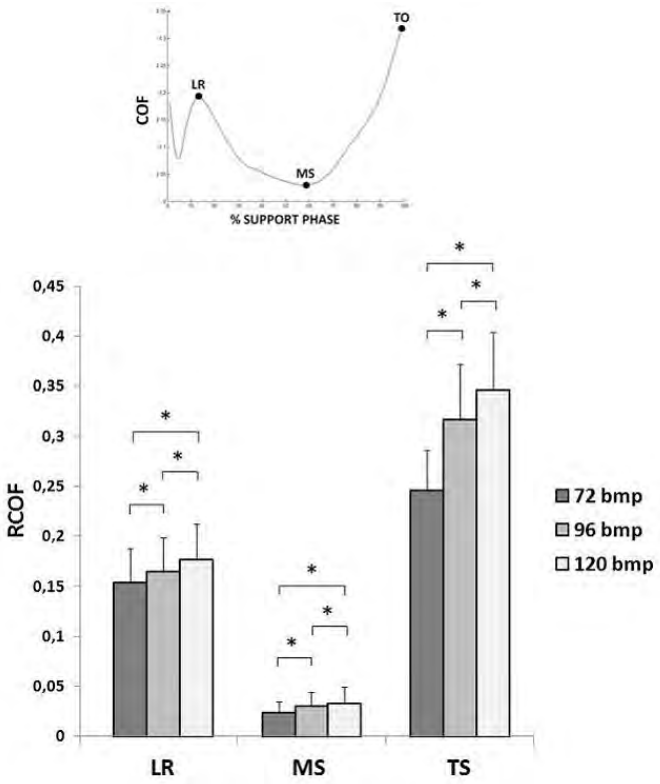
Methods: Seventeen healthy volunteers were recruited in this study (8 males and 9 females; 24.64±1.27 years old; 64.29±15.40kg; 172.17±11.67cm). The participant was oriented to walk barefoot at three selected cadences (72bpm, 96bpm, 120bpm) according to a metronome, along the pathway and over two force platforms (Kistler 9286BA), embedded in the data collection room floor. The force plate's ground reaction force (GRF) components (F_x, F_y, F_z) were normalized by the subject body weight and expressed in function of the percent of support phase of the gait cycle. Kinetic raw data were filtered using a 2nd order low-pass digital Butterworth filter, with a cut-off frequency of 10 Hz. An algorithm developed in Matlab was used to filter raw data and to calculate dependent variables. The COF curve was calculated as the ratio of the shear to normal GRF during stance [1, 2] - Equation 1.

$$COF = (F_Y^2 + F_X^2)^{1/2} / F_Z \quad (1)$$

F_Y is the anterior-posterior GRF, F_X is the lateral GRF and F_Z is the vertical GRF. Then, as illustrated in Figure 1a, the following parameters of the COF curves were calculated: the COF in the loading response (LR), mid stance (MS) and terminal stance (TS) phases. The nonparametric data was analyzed by Friedman test and the Bonferroni post-hoc test ($\alpha<0.05$). The software SPSS (version 19) was used to perform all statistical analysis.

Results: The Figure 1 presents the differences among the walking speeds (72 bpm, 96 bpm and 120 bpm) for the RCOF in the LR (F_2=32.760; p=0.0001), MS (F_2 =41.880; p=0.0001) and TS (F_2 = 219.893; p=0.0001) phases. In all three phases, the higher is the walking speed the higher was the RCOF value.

Figure:



Caption: Figure 1: (a) Illustration of COF curve variables ; (b)differences among velocities for loading response, mid stance and terminal stance

Conclusion: In this study the dynamic COF was observed with respect to adaptations to the walking velocity. The Coulomb's third law of friction, that assumes that the friction is independent by the velocity, is applicable for friction between two rigid bodies, but it does not explain the pedestrian friction. The foot-floor interface during the human gait requires a more complex viscoelastic model of friction in which the mechanisms of adhesion and rolling friction between surfaces should be better explained. Thus, these results show that the dependence of the COF by the walking speed have to be considered when the COF is applicable to study the gait features of normal and/or pathological subjects.

AS-0216

EFFECTS OF TWO FATIGUE PROTOCOLS ON LOWER EXTREMITY KINEMATICS AND IMPACT FORCES IN DROP LANDING TASKS

Rui Xia [1,*] Weijie Fu [1] Xi Wang [1] Xini Zhang [1]

[1] Key Laboratory of Exercise and Health Sciences of Ministry of Education, Shanghai University of Sport, Shanghai, China

Introduction and Objectives: Numerous studies have shown that prolonged and high-intensity exercise would induce neuromuscular fatigue of the human body. Altered neuromuscular control strategies during fatigue potentially contribute to the increased risk of sports injury [1]. No scientific consensus, however, has been reached yet to suggest which type of fatigue protocol results in greater biomechanical changes in the lower extremity during landing movement [2]. Therefore, the purpose of this study was to determine the changes in the lower extremity kinematics and ground reaction forces between two fatigue protocols when performing a landing task.

Methods: Eight trained male athletes (age: 21±1.1 years, height: 176.4±4.7 cm, mass: 70.8±6.3 kg) volunteered to participate in the study. Two fatigue protocols, i.e., long-term running fatigue protocol and functional short-term fatigue protocol, were used to induce fatigue randomly. Specifically, the long-term running fatigue protocol requested participants to run at 4.0 m/s on a treadmill until exhaustion. The functional short-term fatigue protocol requested participants to first perform five consecutive countermovement jumps within a height above 70% of their maximal vertical jump height. They subsequently completed the short-term fatigue protocol consisting a group of shuttle running (6×10 m) with their maximal effort. Participants needed to repeat the above process until the average height of five consecutive countermovement jumps was below 70% of their maximal vertical jump height. Before and after fatigue protocols, each participant was required to execute five successful trials of drop landings from a 60-cm platform. 3D kinematics (Vicon, 240 Hz) of the dominant leg and ground reaction force (Kistler, 1200 Hz) were measured simultaneously. The main variables included 1) the sagittal joint kinematics of the hip, knee, and ankle; 2) the peak vertical ground reaction force and peak loading rate (determined by the maximum slope of adjacent points of vertical GRF) during the impact phase of landings. Paired-tests were used to determine the influence of independent variable (fatigue) on each of the dependent variables (joint angle and GRF) in the two separated fatigue protocols using SPSS 13.0 (SPSS Inc., Chicago, IL, U.S.A.). The significance level was set at a = 0.05.

Results: For the kinematics, post-tests using functional fatigue protocol showed a significant decrease in the minimum angle of the hip (p = 0.008) and knee (p = 0.028) joints, and an increase in the range of motion of these two joint (hip: p = 0.004; knee: p = 0.002) compared to pre-tests. However, there were no significant differences in the lower extremity kinematics (pre- vs. post-test) using the long-term running fatigue protocol. Meanwhile, no changes were found in the peak vertical ground reaction force and peak loading rate between pre- and post-test for both fatigue protocols.

Conclusion: In this pilot study, we found the functional short-term fatigue protocol would induce an increase in hip and knee flexion, but not in ankle, resulting in a more flexed landing posture. In contrast, no significant effect of long-term running fatigue protocol was showed on sagittal kinematic changes in the lower extremity. These results will provide a preliminary reference for the selection of fatigue protocols in laboratory tests.

Table:

Joint	Kinematic variables	Long-term running fatigue protocol		Functional short-term fatigue protocol	
		Pre-test	Post-test	Pre-test	Post-test
Ankle	Maximum angle	125.9±8.4	123.9±12.3	123.8±10.5	123.8±9.1
	Minimum angle	80.2±5.2	80.6±5.9	82.8±4.9	82.4±9.3
	Range of motion	45.6±6.6	43.3±10.1	41.0±10.5	41.4±10.4
Knee	Maximum angle	164.0±5.9	160.8±10.4	158.8±6.7	160.6±7.1
	Minimum angle	94.9±19.5	88.6±26.1	87.9±18.4	75.6±20.4*
	Range of motion	69.2±15.1	72.2±17.5	70.9±14.8	85.1±14.4**
Hip	Maximum angle	147.0±10.4	142.5±16.1	143.4±9.3	144.0±13.3
	Minimum angle	103.9±29.1	94.3±35.2	93.6±22.0	80.8±22.2**
	Range of motion	43.1±19.7	48.2±19.7	49.8±15.8	62.3±15.4**

* Significantly different between pre- and post-tests in the same fatigue protocol with $p < 0.05$.

TIBIAL FRACTURE AFTER UNICOMPARTMENTAL KNEE REPLACEMENT: THE IMPORTANCE OF SURGICAL CUT ACCURACY

Elise C Pegg [1,*] Hemant G Pandit [1] Harinderjit S Gill [2] David W Murray [1]

[1]Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, Univeristy of Oxford, Oxford,

[2]Department of Mechanical Engineering, University of Bath, Bath, United Kingdom

Introduction and Objectives: Tibial fracture is a possible complication after unicompartmental knee replacement (UKR) which can have severe consequences for patient recovery and outcome [1]. It appears that the issue is not product specific, as peri-prosthetic fractures have been reported in numerous designs, both mobile and fixed. However, it has been suggested that cementless components might be at greater risk than cemented [2]. The exact causes of tibial fracture are unknown, although surgical factors are most commonly proposed in the literature [1,3].

The objectives of the study were to; (1) determine the range of positions and depths of the surgical cuts required to prepare the tibial plateau for a UKR, (2) use the measured parameters to create a representative range of finite element models, (3) statistically assess the influence of each surgical parameter on the risk of fracture.

Methods: Tibial plastic Sawbones (n=23) were prepared for mobile UKR during an instructional course. The parameters measured from the sawbones were: (a) the resection depth, (b) the angle between the horizontal and vertical cuts, (c) the distance between the vertical wall and the keel slot, how excessively deep the vertical cut and horizontal cuts were anteriorly (d and e, respectively), and posteriorly (f and g, respectively), and (h) the depth of the pin hole (Figure 1).

A parametric finite element model was created in ABAQUS software (v6.12, Dassault Systèmes) with an automated python script to create the surgical cuts. One hundred models were created, where the surgical cut parameters were varied within the distributions measured from the Sawbones. A mesh element size of 2.4 mm was used, selected as a result of a mesh convergence study. The tibia was modelled as a heterogeneous linear elastic material, with a Poisson's ratio of 0.3. The modulus of each element was assigned based upon the corresponding position of that element in the CT scan of the tibia. The equations used for this have been previously defined and the tibial model validated [4]. Muscle and joint loading of a tibia at 15% of the gait cycle was applied, corresponding to maximal medial contact force, and the distal portion of the tibial constrained in all degrees of freedom. The risk of fracture was quantified based upon the Maximum Principal Stress criterion equations defined by Schileo et al. [5].

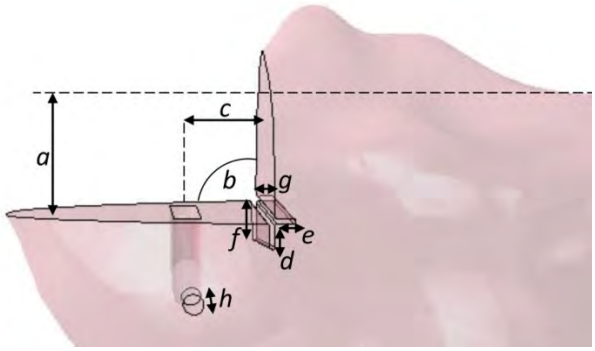
The influence of each surgical parameter on the risk of fracture was assessed using linear regression with R (r-project).

Results: In the tibial Sawbone measurements, the greatest surgical variation was observed in the depth of the posterior vertical cut and the pin hole, which had standard deviations of 3.9 and 6.8 mm respectively (Table 1).

The only surgical cut parameters which were found to significantly affect the risk of fracture were the resection depth, and the posterior depth of the vertical cut ($p=0.009$, and $p=0.000001$, respectively).

Some finite element models demonstrated a noticeable region at high risk of fracture, which extended diagonally from the vertical saw cut, past the base of the keel slot to the tibial cortex. This matched well with typical fracture paths observed clinically [1].

Figure:



Caption: Figure 1. The surgical cut parameters made on a right Sawbone tibia which were recorded were: the resection depth (a), the angle between the horizontal and vertical cuts (b), the wall to keel distance (c), how excessive the vertical and horizontal cuts were anterior (d, e) and posterior (f, g), and the depth of the pin hole for fixing the cutting guide (h).

Conclusion: This study has shown accuracy in the depth of the vertical cut made to prepare the tibial plateau for UKR, has the greatest clinical variation and has the greatest influence on the risk of fracture out of all the parameters assessed in this study. It is therefore important that instrumentation be designed to improve surgical accuracy for this part of the operative technique.

Table:

Parameter	Mean	Standard Deviation
A: Resection Depth (mm)	8.8	1.7
B: Angle between cuts (deg)	90.6	1.4
C: Wall to keel distance (mm)	8.5	0.7
D: Anterior depth vertical cut (mm)	0.5	1.0
E: Anterior depth horizontal cut (mm)	0.7	0.9
F: Posterior depth vertical cut (mm)	4.2	3.9
G: Posterior depth horizontal cut (mm)	1.3	2.1
H: Depth of pin hole (mm)	28.6	6.8

BIOMECHANICAL ANALYSIS OF THE UNIVERSAL 2 IMPLANT IN TOTAL WRIST ARTHROPLASTY: A FINITE ELEMENT STUDY.

Magnús K. Gíslason [1,*] Euan Foster [2] Marc Bransby-Zachary [3] David Nash [2]

[1]Institute of Biomedical and Neural Engineering, Reykjavik University, Reykjavik, Iceland, [2]Department of Mechanical and Aerospace Engineering, University of Strathclyde, [3]Department of Orthopaedic Surgery, Southern General Hospital, Glasgow, United Kingdom

Introduction and Objectives: Load mechanics of the implanted wrist are poorly understood. To date most surgeons would prefer to carry out partial or total wrist arthrodesis to treat the painful and unstable wrist joint opposed to using a total wrist prosthesis. The success rates of the wrist implants have been poor compared to the hip and knee implants. It has been demonstrated that partially fusing the wrist will alter the load mechanics and can potentially have detrimental effect on the untreated joints within the wrist [1]. Few wrist implant models exist [2] due to complex interaction between the carpal bones and the prosthesis. The presented study looks at the mechanical response of the Universal 2 wrist implant under loading. The Universal 2 wrist implant is the most commonly used implant in the UK.

Methods: The three dimensional geometrical model was created from a 7T MRI scan of a healthy human cadaveric model. The in plane resolution of the scan was 0.250mm and the slice thickness 1mm. The scans ranged from the proximal third of the metacarpals to the distal end of the radius and ulna. The segmentation of the scans were carried out using Mimics (Materialise). Three dimensional objects of the carpal bones were created and meshed using tetrahedral elements. An STL file of the Universal 2 implant was virtually implanted into the wrist and Boolean operators used to create the boundaries between the implant and the bones. The finite element model was assembled and solved using Abaqus (Simulia). The implant comprised of three components: a proximal stem attaching in the radius made from a CoCr alloy, distal carpal component attaching to the capitate made from a titanium alloy and a polyethylene spacer between the two components made from UHMWPE. The implant and bone material properties can be seen in Table 1. Additionally two screws on the radial and the ulnar side were modelled. Cartilage was manually created at each articulation within the wrist and surface to surface contact established between the bones. The implant components were modelled as being fully bonded to the bones. An illustration of the finite element model can be seen in Figure 1. Compressive loads were applied to the metacarpals and the proximal ends of the radius and ulna were kept fixed.

Results: The model was solved using the explicit solver. The results demonstrated that the majority of the load was transmitted through the proximal component of the radius. Little load was transmitted through the ulna as the procedure compromises the biomechanical stability of the ulnocarpal joint.

Figure:

Caption: Finite element model of the implanted wrist

Conclusion: The results demonstrated how finite element models can be used to simulate the in-vivo loading through the implanted wrist. The understanding of the load transfer mechanics can be fed back into the design process of the next generation of wrist implants in order to improve the design.

TOWARDS AN AUTONOMOUS REACTIVE FINITE ELEMENT MODEL OF THE HUMAN ARM

Dorian Salin [1 2,*] Pierre-Jean Arnoux [2] Kambiz Kayvantash [1] Michel Behr [2]

[1]CADLM, Massy, [2]LBA, IFSTTAR, Marseille, France

Introduction and Objectives: In biomechanics, Finite Element (FE) models have been wide spread in various domains like medicine and traumatology. However in the category of musculo-skeletal models a recurrent issue is the missing of muscle bracing. Some authors used experimental data to add muscle forces, but these models are not sensitive to boundary conditions modifications during the simulation. Thus, in this study we developed a reactive FE model of the upper limb integrating sensory motor loops. This model is then used to study the effects of various properties of these loops in the reaction process during well-known reflexive actions.

Methods: At first we developed a FE biomechanical model of the arm with realistic geometry of bones, muscles, and tendons in the LS-DYNA environment. The model illustrated in figure 1 is composed of 187491 elements (solids, shells and discrete) and 83768 nodes. Joints of the upper limb are simplified and allow only the extension-flexion of the elbow. The muscles contain contractile components allowing flexion and extension movements of the elbow. We then added to this model two types of proprioceptive sensors, i.e. muscle spindles and Golgi tendon organs.

The myotatic and inverse myotatic reflexes resulting from these sensors are also integrated with the help of an external software which allows to generate and manage data flows from various software platforms. We then studied sensitivity of the model reaction after the impact of a hammer on the biceps brachial tendon (stretch reflex). The parameters of this sensitivity analysis are listed in table 1.

The reflex delay, i.e. time between sensory information to muscular activation, is ranged from 5 to 40ms. The inverse myotatic reflex is alternatively switched On and Off to study the effect of Golgi Tendon Organs in the late phase of the stretch reflex. The agonist/antagonist coupling is the situation where the effects of a reflex (either excitation or inhibition) are applied to the relative muscle itself and to its agonists, and the opposite effect is applied to its antagonist. This coupling is alternatively switched On and Off to study its effects on the model reaction.

Results: The typical reaction of the model with a delay of 40ms, the inverse myotatic reflex and the agonist/antagonist reflex is: a first activation of the flexor muscles from 45ms to 60ms after the hammer impact, at high level (peak of 45% of maximal force), followed by a second activation from 60ms to 90ms at a lower activation level (peak of 15% of maximal force). These activations generate a flexion of the elbow of 5.5°. After this flexion the extensor muscle is activated at a low level from 90ms to 140ms (peak of 10% of maximal force) which bring back the elbow to a flexion of 3°.

The sensitivity analysis on the proposed sensory and motor loop model properties was realized and showed promising results. First of all a short reflex delay is not necessarily good for the stability of the arm, it can even induce instability for a delay as short as 5ms Because of the short delay, the vibration induced by the impactor is amplified by the muscular contractions and the arm results to be unstable. The inverse myotatic reflex provides an earlier return to the initial position and the agonist/antagonist coupling amplifies the reaction in the case of this stretch reflex test.

Figure:

Caption: Biomechanical model with sensors (muscle spindles in black, Golgi tendon organs in blue)

Conclusion: We developed a realistic FE model with autonomous reactive behaviour with human-based sensory and motor loops. The two main sensors intervening in human proprioception were integrated and the effects of various properties of the sensory and motor loops response were studied. This showed promising results and offers a good opportunity to jointly study neurosciences and biomechanics over the range of daily tasks and rather to unfamiliar and/or traumatic cases. The application domains of this model are automotive safety, sports, or medicine.

Table:

Sensory and motor loop properties	Variations
Reflex delay	Range from 5 to 40 ms
Inverse myotatic reflex	On/Off
Agonist/antagonist coupling	On/Off

A COMBINED EMG-CONSTRAINED AND ENTROPY-ASSISTED STATIC OPTIMIZATION MODEL OF THE INDEX FINGER

Alex Macintosh [1] Peter Keir [1,*]

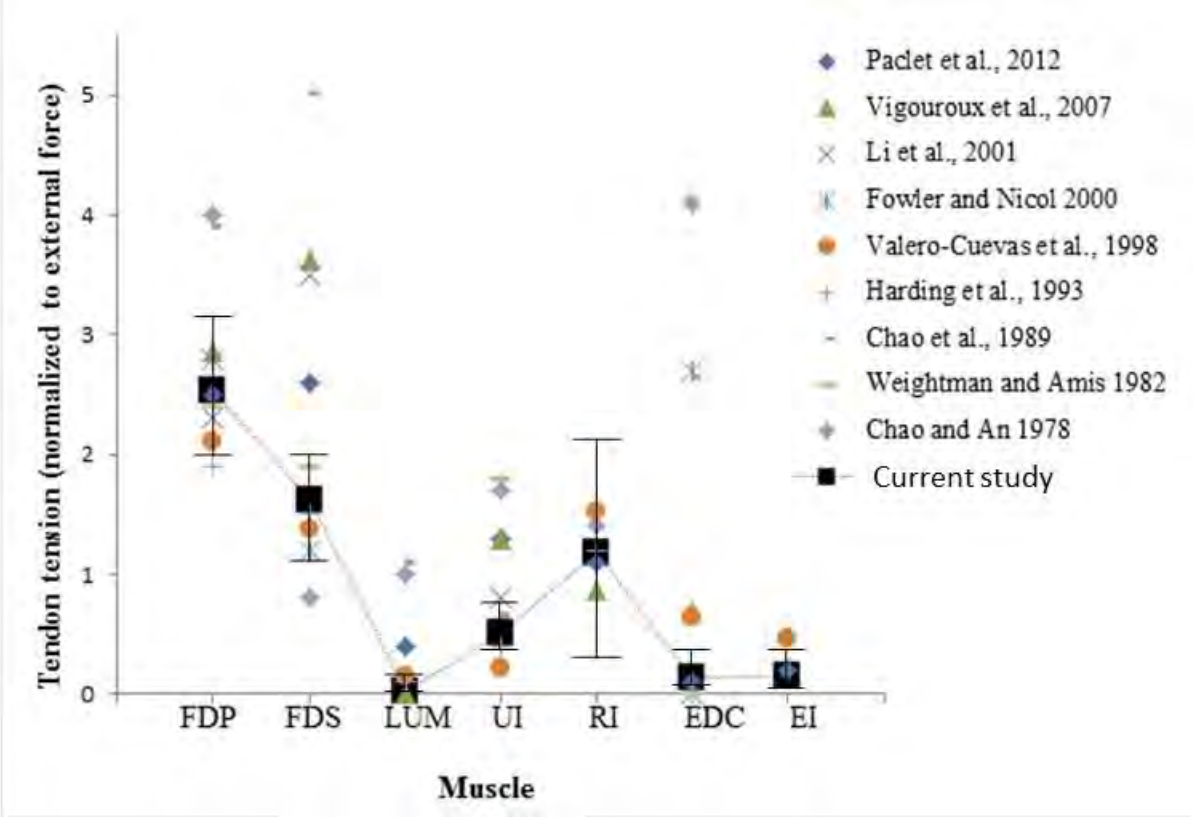
[1] Kinesiology, McMaster University, Hamilton, Canada

Introduction and Objectives: Determining tendon tension in the finger is essential to understanding forces that may be detrimental to hand function and accurate measurement of intrinsic muscle activity is particularly difficult. Modelling solutions are needed to account for intrinsic muscle contributions. The objective of this work was to improve muscle activity predictions during static pressing of the index finger by applying a novel combined EMG-constrained and entropy-assisted static optimization solution method.

Methods: A custom model of the index finger was built in OpenSim for this analysis. The model includes all extrinsic and intrinsic muscles controlling the index finger. The muscles are represented as multiple paths which extend to the central and terminal slips of the finger. To predict muscle activity, the OpenSim static optimization analysis tool was expanded in two ways. First, EMG constraints were programmatically incorporated. Predicted muscle activity was constrained to match the experimental activity ± 15% maximum voluntary exertion. Second, an entropy-assisted objective function (Jiang and Mirka, 2007) was compared with the default sum of squared activation objective function available through OpenSim. Ten right-hand dominant volunteers (five female, five male; 25.3 ± 3.1 years) performed a series of static finger pressing tasks. During static pressing tasks, participants pressed directly down into the force sensor from the pulp of the distal phalanx. Force was applied at three levels: 5, 15, and 30 N, and in three postures: all-flexed, PIP-flexed, and extended. In the all-flexed posture both the DIP and PIP joints are flexed, while in the PIP-flexed posture the DIP remained extended. Kinematics, contact forces, and extrinsic muscle EMG were collected. Muscle activity predicted from the two EMG-constrained objective functions (sum of squared activation and entropy-assisted) were separately compared to recorded muscle activity. Two dependent variables were used to assess fit between predicted and recorded activity: (i) coefficient of determination (r^2) as an index of shape similarity, and (ii) normalized root mean square deviation (NRMSD) to reflect differences in magnitude. Additionally, tendon tensions were calculated based on predicted activity, moment arm, and maximum isometric force of each muscle.

Results: Recorded muscle activity during static finger pressing ranged from 10.2 ± 3.6% in the EDC during 5 N straight finger pressing to 51.3 ± 18.1% in the FDP during 30 N bent finger pressing. Using the EMG-constrained entropy-assisted optimization, three of four muscles (FDS, FDP and EDC) gave lower NRMSD than the EMG-constrained solution alone ($F = 28.285$, $p = 0.046$). There was an interesting relationship between NRMSD and r^2. A decrease in NRMSD was accompanied by a decrease in the r^2 between predicted and experimental activity. The EMG-constrained sum of squared activation method averaged a higher NRMSD (7.0 ± 2.1) and r^2 (0.4 ± 0.15), while the combined EMG-constrained entropy-assisted method averaged a lower NRMSD (6.6 ± 2.1) and r^2 (0.3 ± 0.13). Predicted muscle activations were used to calculate normalized tendon tension for each index finger muscle during static pressing and compared to literature estimates (Figure 1).

Figure:



Caption: Tendon tension estimates for each muscle controlling the index finger. Current study estimates and standard deviations are averaged across trials and compared with previous literature.

Conclusion: The unique combination of EMG-constrained and entropy assisted optimization has improved muscle force distribution in the finger by more closely matching recorded extrinsic muscle activity while predicting intrinsic muscle activity. These findings support an increase in antagonist activity, known to be important for proper coordination during palmarly directed pressing (Valero-Cuevas et al., 1998). By further exploring the allowable deviations and weightings in the objective function further improvement may be possible. In this study, tendon loading estimates made across multiple pressing postures and forces correlated well with previous investigations. The combined approach developed here is useful for modelling a variety of manual tasks. Analysis methods that are robust enough to derive meaningful results from a variety of tasks are critical to developing rehabilitation strategies that enhance the functional ability of affected individuals.

MODELING COORDINATED JOINT RANGE OF MOTION OF THE HUMAN HAND -- CHARACTERISTICS OF COORDINATION AND GRASPING IN RELATION TO THE ROM BOUNDARY --

Natsuki Miyata [1,*] Satoshi Hagiwara [2] Yusuke Maeda [2]

[1]Digital Human Research Center, National Institute of Advanced Industrial Science and Technology, Tokyo, [2]Yokohama National University, yokohama, Japan

Introduction and Objectives: For deeper understanding of the human hand function, joint range of motion (ROM) should be measured and described precisely. Traditionally, ROM of the hand was defined by independently bounding each joint angle from observation of extreme posture. However, it is difficult to express actual human's complex ROM with such simple boundaries because human hand has multiple joints that move in coordination. Therefore, we have developed a new method to model ROM of the hand by defining outer boundary of collected various posture data through motion capturing.

Objective of this study is to find characteristics of the coordinated motion of the human hand by measuring and comparing several subjects ROM. In addition, grasping postures are analyzed in terms of location in ROM, which can be utilized to plan rehabilitation with quantitative goal.

Methods: The human hand is a multidimensional system that consists of many joints and its posture is expressed with multiple variables. It is difficult to directly deal with all the couplings among the joints at the same time. We therefore proposed a model of the range of motion of the whole hand as a set of all the relationships between two of the posture variables[1]. Each relationship between two of the joint angles was presented as a united area in which all the projected measured postures on the plane were minimally bounded using the alpha-shape algorithm. We call this smallest unit a coupled ROM. As can be seen in the examples in the Figure, each derived boundary occupies smaller area than a rectangle corresponding to the traditional ROM.

On motion measurement, we gave subjects the same set of 21 exercises selected to include various joint postures both in the middle and on the boundary. This was because our precedent observation showed the difficulty for the subjects to move widely across their ROM when instructed to “move arbitrarily.” Furthermore, it was necessary to evenly spread the variety of motions among the subjects as much as possible for proper comparison.

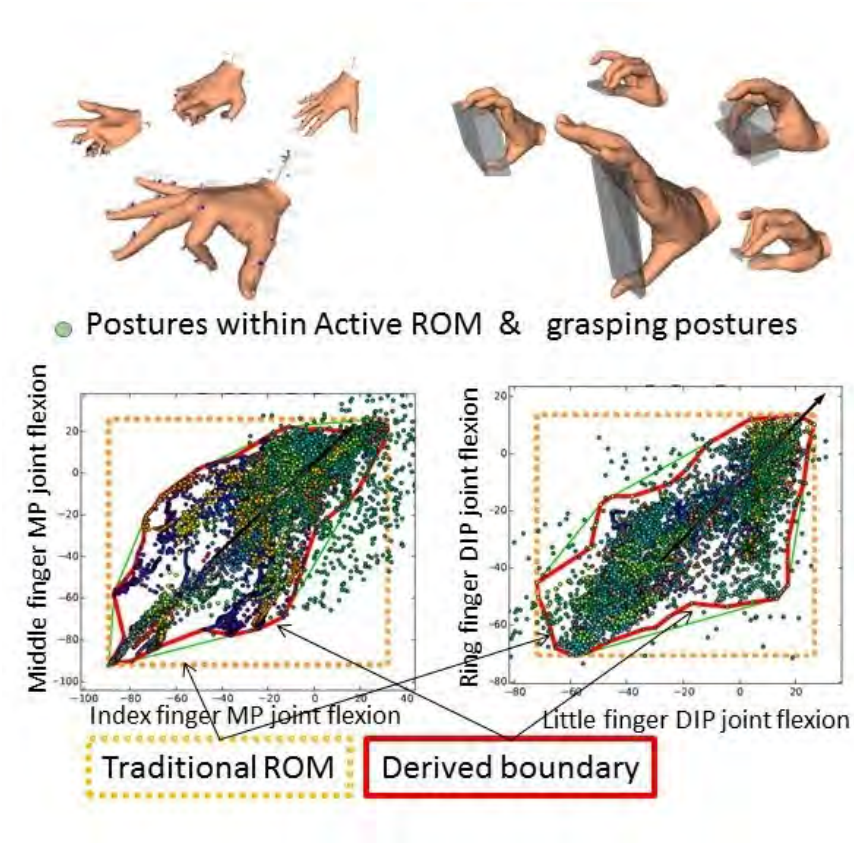
These exercises to model ROM are all unloaded motion. Such ROM can be called “active” ROM. The ROM would be slightly expanded when an external force is applied as in grasping. To analyze such grasping posture with our active ROM, we additionally collected 801 grasping postures. We determined grasping postures by adding variations to grasp taxonomy proposed by Feix [2] which considers contact regions when grasping.

Results: Measurement and modeling experiments on four subjects were conducted to analyze characteristics of the coordinated motion. To study the coordination of the joints of the hand, we ranked the coulpled ROMs for each subject by the index “Coord” defined in [1], which can be calculated considering the area reduction rate compared with traditional rectangle ROM and coefficient of determination. The comparison showed that strong coordination were observed similarly

for all the subjects in (1) the adjacent metacarpophalangeal (MP) joints and (2)proximal and distal phalangeal joints of the same fingers.

As for the grasping postures, some of the postures were located outside the active ROM as expected. In addition, our results showed that MP joints were largely extended when grasping (in the left graph of Figure).

Figure:



Caption: Two examples of the modeled active ROM with grasping postures. Some of the grasping postures were observed to lie outside the active ROM boundary.

Conclusion: This study analyzed the coordinated human hand motion by comparing active range of motion that modeled by appropriately deriving boundary from a variety of measured postures. Comparison based on the coordination index showed that the coordination categories were similar among subjects. Plotting of the grasping postures with the active ROM clearly showed the deviation of passive ROM difference from active one.

PREDICTION OF IN-VIVO KNEE KINEMATICS: DEVELOPMENT OF A PATIENT-SPECIFIC MUSCULOSKELETAL MODEL OF THE KNEE FOR CLINICAL APPLICATION

Malte Asseln [1,*] Ghaith Al Hares [1] Joerg Eschweiler [2] Klaus Radermacher [1]

[1]Chair of Medical Engineering, Helmholtz-Institute for Biomedical Engineering, RWTH Aachen University, [2]Department of Orthopaedics, Aachen University Clinic, RWTH Aachen University, Aachen, Germany

Introduction and Objectives: For a proper functional restoration of the knee following knee arthroplasty, a comprehensive understanding of bony and soft tissue structures and their effects on biomechanics of the individual patient is essential. Conventional intraoperative ligament balancing only considers passive knee kinematics, ignoring the fact that the majority of load and active kinematics in the knee are due to muscular forces. Musculoskeletal models have the potential, however, to predict dynamic interactions of the knee joint and provide insights into knee biomechanics [1]. Musculoskeletal models of the knee have been developed and used to simulate orthopedic procedures, such as osteotomies, tendon transfers and total joint replacements [2]. Although previous model-based studies helped to understand the complex biomechanics of the knee and have provided clinically useful insights, major hurdles for their broad clinical application remain. These include e.g. average data on function and morphology, idealized joint kinematics, modelling parameters obtained from cadaveric measurements, limitations in modelling of anatomical complexity and lack of clinical workflow integration for the patient-specific therapy.

Our goal in this study was to develop a generic musculoskeletal model of the knee which is easily adaptable to subject-specific situations and to evaluate the model on the basis of in-vivo kinematic measurements using Upright-MRI image data [3] (Fig 1 A).

Methods: The simulation model has been developed and adapted to a total number of 9 subject-specific cases in the multi-body simulation software AnyBody based on the StandingModel from the AnyBody Repository. The standard hinge joint was replaced with a new complex knee joint with 6DoF. The 3D bone geometries were obtained from an optimized MRI scan using expert's manual segmentation [3] and were then post-processed by mesh reduction and smoothing filters available in the mesh processing software MeshLab.

In this study, the anatomical locations of ligaments (ACL, PCL, MCL and LCL) and muscle attachments were determined based on literature data, since the model adaptation process was aimed to be valid for CT-data where no soft tissue information are available. For the same reason cartilage was approximated by a homogenous dilation of 3 mm for each bone and menisci were neglected.

For the subject-specific adaptation a general scaling, taking segment length, mass and fat into account, was used. The scaling was further modified to allow a detailed adaption of the subject-specific knee morphology including ligament and muscle attachments in the reference model.

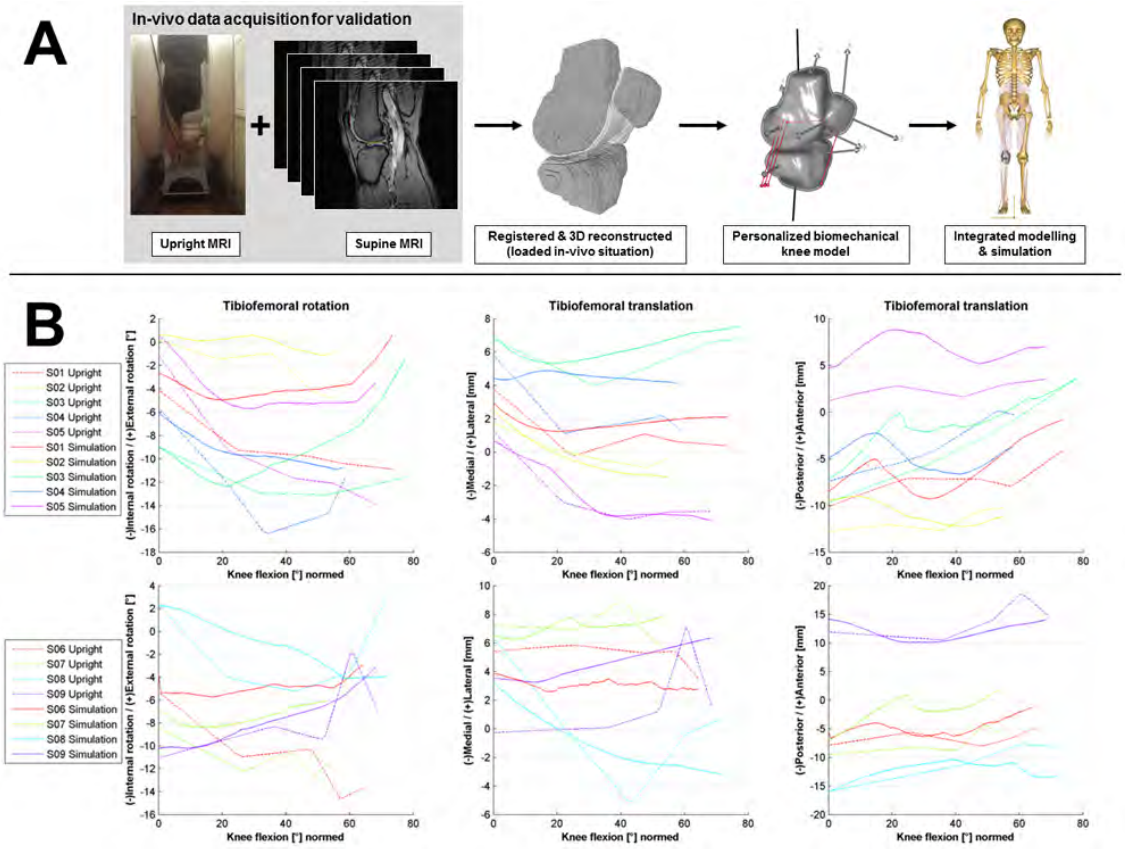
The boundary conditions were solely described by analytical methods and ground reaction forces have been predicted by adding muscle forces between the foot and environment. A single leg deep knee bend was simulated by kinematic

constraints, such as that the center of mass is positioned above the ankle joint. The contact forces in the knee joint were computed using the force dependent kinematic algorithm presented by Andersen et al. [2].

The simulation model was adapted to the 9 subjects, single leg deep knee bends were simulated and subject-specific kinematics were recorded according to the definition of Grood et al. [4]. The simulated kinematic results were then compared to their corresponding subject-specific in-vivo kinematic measurements data obtained by Upright-MRI under the same full-weight bearing condition in 5 static postures.

Results: We were able to simulate the whole group of subjects over the complete range of motion. The tibiofemoral kinematics of all 9 subjects could be simulated showing the overall trend correctly, whereas absolute values partially differ (Fig 1 B). Particularly, translations show a good agreement, e.g. the RMSE for medial/lateral translation was 0.49 for S05, whereas the rotations seem to be more sensitive to the model parameters, e.g. the RMSE for internal/external rotation was 7.19 for S06. The overall adaptation process takes about 15-30 min. per subject from the segmented data to the full personalized biomechanical model.

Figure:



Caption: A Experimental workflow for validation, B Predicted in-vivo kinematics vs. measured kinematics for 9 subjects

Conclusion: The presented simulation model is adaptable to an individual situation and seems to be suitable to predict, or at least approximate, subject-specific knee kinematics for e.g. investigation of the extensor mechanism, morphological analyses and optimization of the articulating geometries and surgical interventions. Principally, the trend of the kinematics

is captured, although absolute values partially differ. However, model optimization, sensitivity analyses of selected parameters and a semi-automation of the workflow are parts of our ongoing work.

AS-0223

EFFECT OF EXERCISE-INDUCED CHANGES OF THE INTRINSIC TRICEPS SURAE MUSCLE-TENDON UNIT PROPERTIES ON MAXIMAL WALKING VELOCITY IN THE ELDERLY

Gaspar Epro [1] [2,*]Andreas Mierau [3]Gert-Peter Brüggemann [1]Kiros Karamanidis [2]

[1]Institute of Biomechanics and Orthopaedics, [2]Institute of Movement and Sport Gerontology, [3]Institute of Movement and Neurosciences, German Sport University Cologne, Cologne, Germany

Introduction and Objectives: It has previously been reported that deterioration in contractile strength and tendon stiffness in the elderly is associated with altered motor task execution and reduced performance while walking [1,2], and that resistance training improves muscle function, resulting in more effective and safer gait characteristics in the older population [3]. In particular, triceps surae (TS) muscle-tendon unit (MTU) properties seem to be an important determinant for walk-to-run transition speed [4], emphasizing the relevant role intrinsic MTU properties play in gait performance. The objective of this empirical study was to examine the hypothesis that maximal walking velocity is related to TS MTU mechanical and morphological properties and their enhanced capacities would improve gait velocity in the elderly.
Methods: Thirty four older female adults (66±7 yrs.) took part in the study. Nineteen of them were recruited for the experimental group, who underwent a 14-week TS MTU physical exercise intervention which has been previously established to increase muscle strength and tendon stiffness [5]. The remaining 15 subjects formed the control group (no physical exercise intervention). The experimental group performed three times per week five sets of four repetitive (3·s loading, 3·s relaxation) isometric plantar flexion contractions in order to induce high cyclic strain magnitudes on the TS tendon and aponeurosis. Maximal walking velocity, defined as walking with a double support phase, was determined by using two force plates (60 x 40 cm, 1080 Hz; Kistler, Winterthur, CH) and a motion capture system (Vicon Motion Systems, Oxford, UK) with 12 infrared cameras operating at a frequency of 120 Hz. TS MTU properties were assessed using simultaneous dynamometry and ultrasonography (Esaote MyLab Five; Esaote Biomedica, Genoa, IT).
Results: A significant correlation was found between the TS MTU mechanical and morphological properties and maximal gait velocity ($0.40 < r < 0.64$; $P < 0.05$; $n = 34$). The experimental group showed higher TS contractile strength, tendon stiffness, and higher gastrocnemius medialis muscle thickness post- compared to pre-intervention ($P < 0.05$). However, calculated maximal gait velocity did not differ between pre and post-intervention measurements (2.39 ± 0.41 vs. 2.44 ± 0.45 $m \cdot s^{-1}$). Control subjects showed no statistically significant differences in maximal gait velocity or TS MTU mechanical and morphological properties.
Conclusion: This empirical study confirms previous forward simulation models [4] proposing that intrinsic TS MTU properties are significant determinants of gait performance. However, older adults may not be capable of fully utilizing improvements of the MTU capacities while walking at maximal velocities following a 14 week physical exercise intervention. Therefore, the benefits of a long term physical exercise intervention (1.5 years) will be discussed.

ROLE OF EACH LEG TOWARDS ANGULAR IMPULSE GENERATION DURING TURNING-WHILE-WALKING PERFORMED AT DIFFERENT SPEEDS BY OLDER ADULT FALLERS

Antonia Zaferiou [1,*] Laura Held [2] Witaya Mathiyakom [3]

[1]Biomedical Engineering, University of Southern California, [2]U.S. Department of Veterans Affairs, Los Angeles, [3]Department of Physical Therapy, California State University, Northridge, Northridge, United States

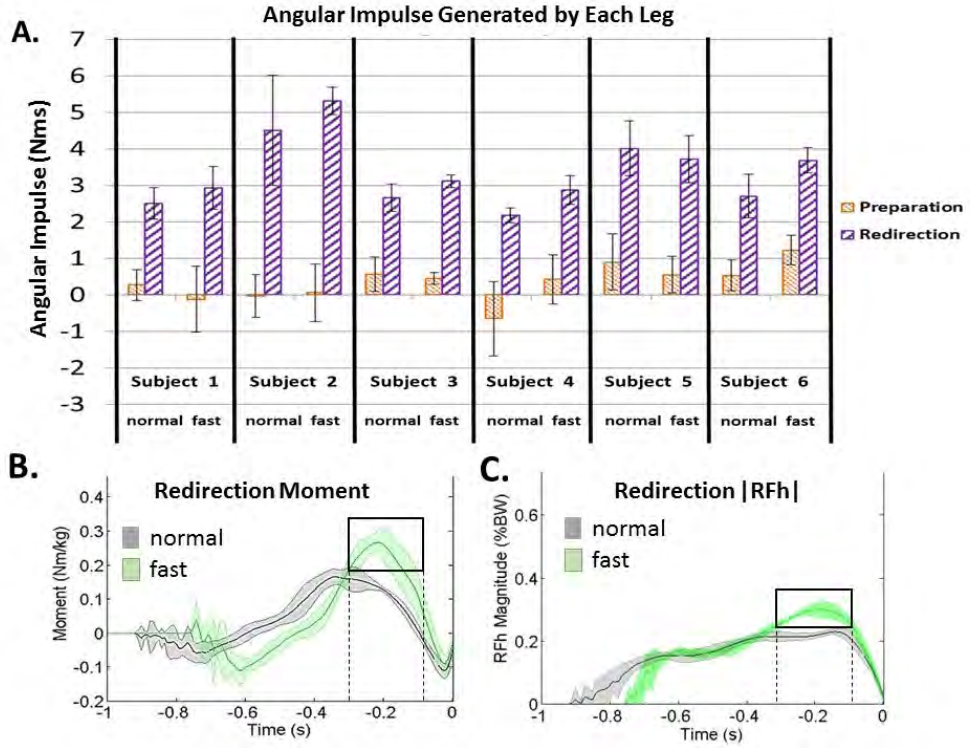
Introduction and Objectives: Turning-while-walking (TWW) is an essential functional activity [1]. During TWW, the horizontal trajectory of the total body center of mass (CM) is controlled relative to the base of support via resultant horizontal ground reaction forces (RFh) generated during foot contact [2]. The RFh generated by the lower extremity must be coordinated during preparation, redirection, and termination foot contacts such that the linear impulse and angular impulse (AI) requirements of the task are satisfied while maintaining balance of the CM over the base of support. Achieving these mechanical objectives during TWW can be challenging to older adult fallers, as indicated by the high incidence of falls and serious injuries sustained during TWW [3-5]. As turn speed increases, the mechanical demands required to generate both linear and angular impulse increases, which increases task difficulty, particularly for older adult fallers. An understanding of how older adult fallers generate angular impulse is currently limited, but necessary in order to improve performance of TWW in this population. The goal of this study was to identify how AI was generated during TWW. Specifically, we aimed to investigate the role of the lower extremity during preparation and redirection foot contacts in generating AI during TWW at normal and faster than normal speed. We expected that as the CM horizontal speed increased, AI generated during preparation and redirection ground contacts would increase and the redirection ground contact would generate more AI than will the preparation contact.

Methods: Six older adult fallers (ages: 65-80) participated in this study. These older adults were classified as transitionally frail [6] and had at least two falls over the period of 12 months prior to the study. At the time of data collection, they did not have any acute medical, musculoskeletal, and neurological conditions, including vestibulopathy, which would have affected TWW performance. These older adult fallers were asked to perform a series of experimental tasks of 90 degree redirections using self-selected (“normal”) and “faster than normal” (“fast”) speeds. Five successful trials of each task were collected. During the experimental tasks, ground reaction force (AMTI, 1200Hz) and kinematic data (Vicon, 120Hz) were captured simultaneously during preparation and redirection ground contacts. The moments applied about the CM were calculated, and used to determine angular impulse generated during each step. Between-task differences in mean angular impulse generated under each turn condition by each leg were compared using paired t-test.

Results: As expected, the majority of the AI was generated during the redirection step of TWW tasks performed at both normal and fast speed. When comparing between speeds, there was no significant difference in AI generated during the preparation step. However, during the redirection ground contact, AI was significantly greater during the fast trials compared to the normal speed (P=0.04). As a result, the horizontal CM velocity in the turn direction at the end of redirection ground contact was also greater for the fast TWW tasks compared to normal speed TWW. Additionally,

subject-specific mechanisms (e.g., RFh magnitude, direction, and/or moment arm modulation) were used to increase the peak moment applied by the redirection ground contact during fast trials.

Figure:



Caption: (A) Mean (SD) angular impulse generated by each subject during preparation and redirection ground contacts in each turn condition (normal vs. fast). (B) Mean (SD) moment applied by redirection ground contact for exemplar Subject 1 for each turn condition (normal vs. fast). (C) Mean (SD) redirection ground contact RFh magnitude for exemplar Subject 1 for each turn condition (normal vs. fast). The increase in mean peak moment during redirection ground contact of fast trials performed by Subject 1 (B) was mainly due to an increase of RFh magnitude (C).

Conclusion: The results of this study suggest differences in the role of each leg to generate angular impulse required for TWW performed by older adult fallers. The preparation leg contributed minimally to the AI required for the turn, while the redirection leg contributed significantly to the AI. These results also suggest that the termination ground contact must generate AI in opposition to that generated by the redirection ground contact in order to maintain the desired CM trajectory. However, further research is needed to prove this contention.

EFFECTS OF STRENGTHENING AND STRETCHING EXERCISES ON RUNNING BIOMECHANICS IN OLDER ADULTS: A RANDOMIZED CONTROLLED TRIAL.

Reginaldo Fukuchi [1,*] Darren Stefanyshyn [2] Lisa Stirling [2] Reed Ferber [2]

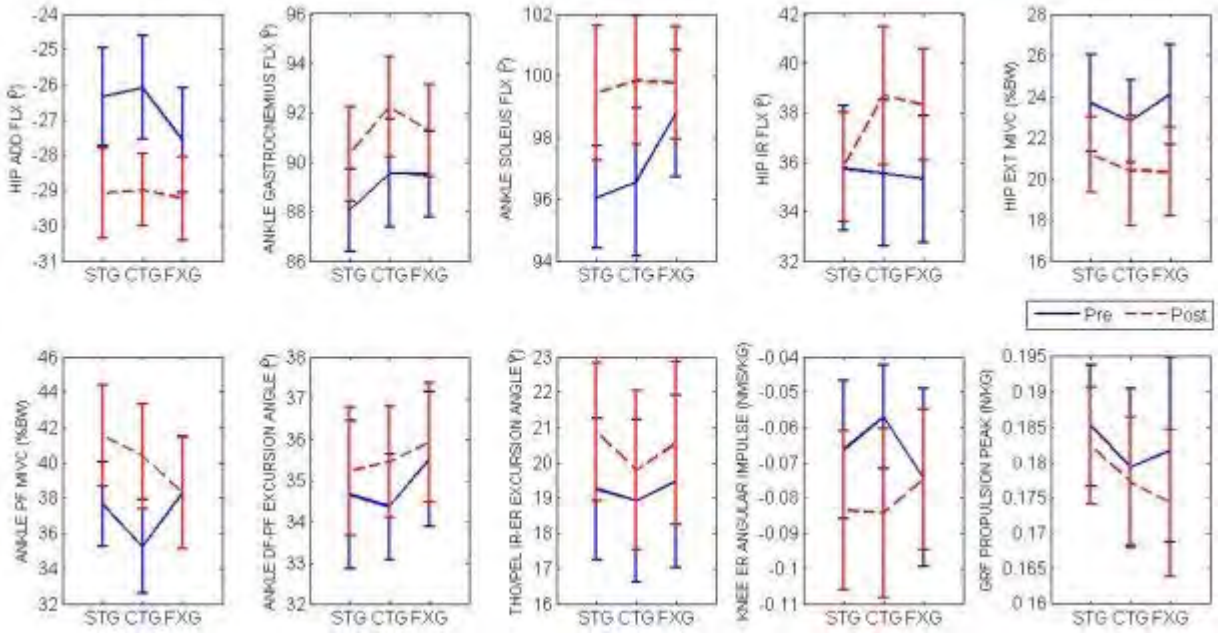
[1]Biomedical Engineering, Federal University of ABC, Santo André, Brazil, [2]Kinesiology, University of Calgary, Calgary, Canada

Introduction and Objectives: Increases in running participation have been followed by an increased injury rate among older adults[1]. Muscle weakness and loss of flexibility have been associated with age-related changes in gait[2]. Despite the fact that flexibility and strengthening exercises to address these decrements may mitigate the effects of ageing and prevent running-related injuries[3], few studies have investigated the inter-relationship between increases in flexibility and strength and concomitant changes in gait biomechanics. Therefore, the purpose of this study was to investigate the effects of an 8-week strengthening or flexibility protocols on gait mechanics in older runners.

Methods: For this randomized controlled trial, 105 older subjects (55-75yrs) were randomly assigned to one of the three groups: strengthening (STG), flexibility (FXG) or a control group (CTG). Subjects were assessed before and after an 8-week exercise protocol. Written informed consent was obtained from each participant prior to the initial data collection. Maximal isometric voluntary contraction (MIVC) measures were obtained, using a hand-held dynamometer (HHD), for the hip abductors, external rotators, and extensors; knee extensors, and ankle plantar-flexors. Flexibility (FLX) measures were obtained by assessing the joint range of motion (ROM), using a goniometer, of the following movements: hip adduction, hip internal and external rotation and ankle dorsiflexion. Gait kinematic and kinetic measures (BIO) were obtained using a motion analysis system while the subjects ran at 2.7m/s on an instrumented treadmill[4]. The effects of exercise on the dependent variables were evaluated by a general linear mixed model (GLMM; α=0.05) across group (STG, FXG, CTG) and time (pre-post).

Results: 93 subjects returned for their 8-week follow-up (retention rate of 88.7%). There was a significant time-effect for the majority of clinical variables, indicating that increased flexibility and muscle strength occurred following intervention. No group effect was observed for the gait or clinical variables (Table 1 and Fig.1). Few studies have investigated the effect of strength or flexibility training in older runners despite the fact that these exercises have been widely recommended to improve function and to prevent running-related injuries[5]. We speculate that the room for improvement in both flexibility and strength was limited since the older runners in the present study were already physically active. Additionally, the exercise program adopted in this study (volume, intensity, frequency, etc.) may not be sufficient to improve function in older active individuals. An increased ankle DF-PF excursion angle, Tho/Pel IR-ER excursion angle and knee ER impulse were observed following intervention but, similar to the clinical variables, these changes were irrespective of the type of exercises (Table 1 and Fig.1). We speculate that gait-related changes may be related to factors such as familiarization with testing procedures or other extraneous effects.

Figure:



Caption: Interaction plots showing mean and 95% confidence intervals for the variables before and after intervention.

Conclusion: The results of the present study suggests that an 8-week strengthening or flexibility training protocol results in clinical improvements for these measures but did not have an influence on discrete gait biomechanical variables.

REDUCED CYCLING SPEED ALONE DOESN'T EXPLAIN DIFFERENCES IN CYCLING KINEMATICS BETWEEN OLDER AND YOUNG CYCLISTS

Rosemary Dubbeldam [1,*] Chris Baten [1 2] Jaap Buurke [1 2] Hans Rietman [1 3]

[1]Roessingh Research and Development, [2]Faculty of Electrical Engineering, Mathematics and Computer Science , Department of Biomedical Signals and Systems, [3]Faculty of Engineering Technology, Department of Biomechanical Engineering, University of Twente, Enschede, Netherlands

Introduction and Objectives: The Dutch are a cycling nation: they get on their bikes as often as they get into their cars. Not only the young but also elderly make frequent use of their bicycles, among others for short trips to shops or friends and for longer recreational or sport trips. While cycling contributes to health and the quality of life, older cyclists have a high risk of sustaining a fall with their bicycle and sustaining a serious injury. About three-quarters of these falls are single-bicycle-accidents, accidents where no other road user is directly involved. In an ageing population where the daily kilometres cycled per elderly are increasing, it is expected that by 2020 the number of seriously injured elderly in single-accident bicycle crashes will increase to 1700 per year. Therefore, prevention of single-bicycle accidents is needed.
Multiple studies have analysed older cyclist single-accident situations and causes and have defined accident prototypes and confounding personal, infra-structural and other environmental factors. Among others, as we all know from daily observations, older cyclists cycle at low velocities and tend to sway across the roads. However, little is known about the effect of age on cycling kinematics and even less about the underlying personal accident mechanisms of older cyclists, which may play an important role in explaining the higher accident risk with increasing age. A better understanding of elderly cycling behaviour (kinematics) and accident mechanisms may in future lead to the development of safer bicycles and fall risk evaluation tools for clinicians. As a first step, this study aimed to analyse straight-forward cycling behaviour (kinematics) of older and younger adults in an ambulant setting and relate their cycling behaviour to their corresponding cognitive and physical abilities.

Methods: Fifteen young (18-40 years) and 33 elderly (65-82 years) cyclists, with and without a bicycle fall-history, participated in this study. Physical and cognitive assessments were performed and included: knee proprioception, Berg Balance Scale, handgrip strength, short-term memory and reaction time. Bicycle motion was recorded outdoors with two Inertial Measurement Units, one attached to the steer and one attached to the bicycle frame (Fig. 1). The cyclists were asked to mount the test bicycle, cycle straight for about 200 m and dismount. These tasks were performed during normal cycling, slow cycling and cycling while performing a dual-task. FUSION 3D Tools software was used to assess cycling variability by means of the standard deviation (SD) of the steer, roll and sway angle and angular velocity. The cycling velocity was calculated by integrating the longitudinal acceleration from the IMU accelerometer signal on the bicycle frame. First, differences in physical, cognitive and kinematic parameters between the groups of young and elderly cyclists were identified. Second, a multi-linear regression model was used to study the relationship between clinical and kinematic parameters (significance set at $p<0.05$).

Results: As expected, the older cyclists demonstrated lower scores on the short-term memory tests, Berg-balance score, handgrip strength, dual task performance and Go/No-go reaction time compared to the young cyclists ($p<0.05$). For the older participants, the mean cycling velocity (9 vs. 14 km/h) was lower and the SD of the sway (1.8 vs. 1.4 deg) and roll angle (0.88 vs. 0.72 deg) were higher compared to the younger cyclists.
The linear regression model included cycling velocity and the physical and cognitive factors that were significantly different between age groups. The predictive strength of this linear regression model varied for the studied kinematic parameters: R squared values were assessed for SD of steer angle (0.141), SD roll angle (0.318) and SD sway angle (0.295). Higher variation (SD) of the steer and sway angle were significantly related to lower cycling velocities but not to physical and cognitive abilities. On the contrary, higher variation (SD) of the roll angle was significantly related to worse performance on dual task performance, handgrip strength and short-term memory tests but not to cycling velocity.

Figure:

Caption: Figure 1. Cyclist on test bicycle with inertial measurement units attached

Conclusion: The results of this study suggest that reduced cycling velocity alone does not explain observed differences between young and older cyclist bicycle kinematics. Personal cyclist abilities such as handgrip strength, short-term memory and dual-task performance influence cycling kinematics and may be predicting factors in the fall-risk of elderly cyclists.

ARE THERE DIFFERENCES IN ELDERLY BETWEEN OBSTACLE CROSSING WITH THE PREFERRED AND WITH THE NON-PREFERRED LEG LEADING?

Eliane C. Guadagnin [1,*] Emmanuel S da Rocha [2] Maarten Bobbert [3] Jacques Duysens [4] Marco A Vaz [1] Felipe P Carpes [5]

[1]Federal University of Rio Grande do Sul, Porto Alegre, [2]Federal University of Santa Maria, Santa Maria, Brazil, [3]VU University Amsterdam, Amsterdam, Netherlands, [4]KU Leuven, Leuven, Belgium, [5]Federal University of Pampa, Uruguaiana, Brazil

Introduction and Objectives: Falls in the elderly are frequently associated with obstacle contacts during walking. Whether a person will cross an obstacle first with the preferred leg or with the non-preferred leg will vary in daily life, depending on the motor activity being developed and, in the case of crossing obstacles, depending on factors such as approach distance and space available. It might be more difficult for a person to cross an obstacle first with the non-preferred leg, and perhaps fallers will tend to fall because of obstacle contacts occurring when the non-preferred leg is leading. Only few studies have studied asymmetries in obstacle crossing (TOMAR; GUPTA, 2012; ROCHA et al., 2013). Here we compared performance of obstacle crossing in elderly with the preferred leg leading and with the non-preferred leg leading. As in daily life most people will typically be thinking of other things while walking, we had our participants performing simultaneously a cognitive task.

Methods: Volunteers participating in this study were elderly (n=20) aged 66 ± 4.4 years, body mass of 67.9 ± 14.2 kg and height of 1.54 ± 0.06 m, all able to walk independently. Participants walked barefoot at self-selected speed along an 8 m walkway and crossed a polystyrene obstacle (20 cm wide and with height defined as 20% of each subject's leg length), which was placed in the middle of the walkway, and it was always visible to the subjects. Bilateral kinematics was sampled at 200 Hz using Plugin Gait markers (Vicon Motion Systems, Oxford, UK). Kinematic data were low-pass filtered with a 4^{th} order Butterworth filter at a cut-off frequency of 8 Hz.

The following cognitive task was used: when experimenter said "red" or "blue", the participant had to reply "no" and "yes", respectively. When the experimenter mentioned any other color name, the participant had to simply repeat the color name. Trials were recorded until 10 trials were obtained for each leg. Crossings with different leading legs were elicited by having subjects initiate walking from a standing position with either the left or the right leg. Participants did not receive any instruction concerning which leg should cross the obstacle first. Leg preference was verified using the revised Waterloo footedness questionnaire (ELIAS et al., 1998).

Leading limb toe clearance, trailing limb toe clearance, leading limb heel clearance, trailing limb pre-obstacle distance, leading limb post-obstacle distance and gait speed were determined. Data normality was verified using the Shapiro-Wilk test. The legs were compared with paired t-test at a 0.05 significance level.

Results: Leading limb post-obstacle distance was statistically larger in the preferred than the non-preferred leg (Table 1). No differences were observed between preferred and non-preferred legs for leading limb toe clearance, trailing limb toe clearance, leading limb heel clearance, trailing limb pre-obstacle distance, and gait speed.

Asymmetry in the leading limb post-obstacle distance was found in elderly performing obstacle crossing during walking at preferred gait speed and while performing a dual task. A shorter post-obstacle distance has been reported as a possible cause for tripping (the heel coming down too close to the obstacle before landing (HEIJNEN et al., 2012)). Nevertheless, most of the other kinematic variables were not different between the legs, indicating that the obstacle used can be considered as a minor factor for the risk of falling increase. To test this potential increase it would be valuable to compare elderly with and without a falling history.

Conclusion: It is concluded that the use of the non-preferred leg as the leading limb for obstacle crossing during dual task performance on a walkway mildly increases the risk of falling.

Table:

	Preferred	Non-preferred
Leading limb toe clearance (cm)	12.2±2.4	12.1±2.4
Trailing limb toe clearance (cm)	11.3±4.1	11.6±4.1
Leading limb heel clearance (cm)	10.7±2.4	9.9±2.2
Trailing limb pre-obstacle distance (cm)	11.6±1.9	11.6±2.3
Leading limb post-obstacle distance (cm)	12.4±3.9	11.0±2.9*
Gait speed (m/s)	0.9±0.1	0.9±0.1

AS-0228

WALKING WITH A PLANTAR FLEXION ASSISTING ANKLE-FOOT EXOSKELETON IN AN OLDER POPULATION

Samuel Galle [1,*] Philippe Malcolm [1] Dirk De Clercq [1]

[1] Movement and Sport Sciences, Ghent University, Gent, Belgium

Introduction and Objectives: Walking is the most frequent way of locomotion in humans and the ability to walk has a strong influence on quality of life. With the contribution of biomechanists and physiologists in the field of robotics, assistive robotic legs (exoskeletons) that can be attached to the legs are developed to restore walking ability for subjects with reduced walking capacity. Walking capacity diminishes while getting older and when walking becomes difficult, people are dependent on walking frames, wheelchairs or mobility scooters. These devices are often unpractical and dissociate us from our natural way of interacting with our environment. Reduced walking speed in the elderly is related to reduced ankle power and therefore an ankle-foot exoskeletons that adds ankle power to the biological ankle joint seems a practical solution to improve their walking capacity. For such mobility assistance, reduction in human energy cost is the benchmark. On the other hand, the assisted walking has to remain a stable gait pattern. Previous research in 3 subjects [1] suggested that the elderly could walk with plantarflexion assistance which resulted in a reduction in metabolic cost but the number of subjects was insufficient to draw conclusions.

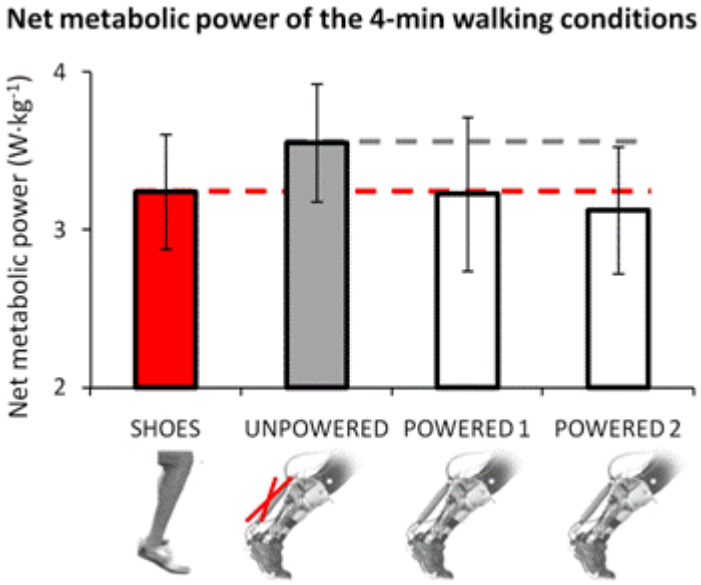
The objective of this study was to test if a healthy older population (age 65 or more) could walk after a short habituation with a simple pneumatically actuated ankle-foot exoskeleton with plantarflexion assistance [2], if this results in a reduced metabolic cost for powered exoskeleton walking compared to walking with normal shoes and if walking stability is influenced. This study must be seen as a necessary step towards the assistance of an older population with walking impairments.

Methods: Eight healthy subjects with no specific walking impairments and no experience with treadmill nor exoskeleton walking participated in the experiment. One subject was not able to walk with the device comfortably because of deviating walking kinematics, which resulted in reduced exoskeleton function. The seven remaining subjects (6 male and 1 female; age 69.3±3.5 years; body mass 73.1±6.9 kg; stature 170.4±6.2 cm; European shoe size 42.1±1.8) performed a 30 min habituation protocol on a first day. On a second day, subjects performed four 5-min walking intervals at 1.11 $m \cdot s^{-1}$ (normal shoes, unpowered exoskeleton and 2 times powered exoskeleton: Powered 1 and Powered 2). O_2 consumption and CO_2 production, subjects' perception and exoskeleton kinetics were measured for every condition on this second day.

Results: Subjects did not perceive walking on the treadmill with their own shoes significantly more difficult than overground walking and perceived exoskeleton walking during the second powered condition less difficult compared to unpowered exoskeleton walking. The net metabolic cost during walking with the powered exoskeleton was significantly reduced with 9.4±6.1% for the first powered condition and 12.0±6.9% in the second powered condition compared to unpowered walking (Fig.). This indicates that also an older population can benefit from plantarflexion assistance. However, no significant differences in net metabolic cost could be found between powered exoskeleton walking and walking with normal shoes, which is mainly due to the 9.8±8.0% increase in metabolic cost in the powered condition due to the weight and the hindrance of the unpowered exoskeleton. Recent improvements in exoskeleton design and function

have shown that this penalty could be reduced to 0 to 5%, which would result in a reduction in net metabolic cost for powered walking versus walking with normal shoes, also in an older population.

Figure:



Caption: Net metabolic power for walking with normal shoes (SHOES), walking with the exoskeleton without actuation of the pneumatic muscles (UNPOWERED), a first condition (POWERED 1) and a second condition with assistance of the pneumatic muscles (POWERED 2).

Conclusion: Our findings support the introduction of (ankle-foot) exoskeletons in the elderly as we found a reduction of more than 12% for powered exoskeleton walking versus unpowered exoskeleton walking. However, not all subjects were able to walk with our standard exoskeleton with a fixed assistance algorithm and further data analysis needs to learn us how walking stability is influenced. Also, regardless of the prior habituation session there seemed to be a habituation effect during the data collection as both the reduction in metabolic cost and the perceived difficulty further reduced from the first to the second powered condition. This suggests that a more individual approach for actuation optimization and a longer habituation, together with improved exoskeleton design and hardware, could lead to reductions in metabolic cost for powered exoskeleton walking versus normal walking in the elderly and could ultimately lead to exoskeletons that can assist elderly (with walking impairments) during daily life.

AS-0229

ARE THE FEET AS LOCALLY STABLE AS THE CENTER OF MASS DURING WALKING?

Claude Pothrat [1,*] Marvin Dufrenne [1] Elke Viehweger [2] Eric Berton [1] Guillaume Rao [1]

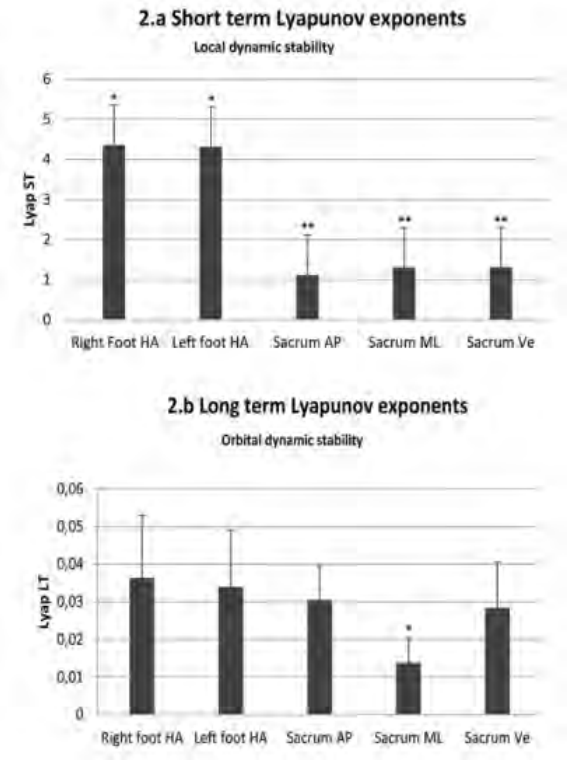
[1]Institute of Movement Sciences, Aix Marseille Université, MARSEILLE cedex 09, [2]Pediatric orthopedic department, APHM, La Timone Hospital, 13005 Marseille, France

Introduction and Objectives: The goal of any locomotion task is to move the center of mass from one point to another in space. An important shortcoming of traditional gait analyses methods is that they do not consider the cyclical nature of gait. Bipedal walking is known to be naturally unstable due to micro-perturbations such as internal neuro-muscular noise, or external changes of the environment. Characterizing gait dynamic stability is essential for a functional approach including the comprehension of motor control adjustments that avoid falling. Non-linear time series analyses have been widely used to quantify local and orbital dynamic stability of locomotor tasks[1]. Studies have been conducted on the influence of various parameters on stability such as speed, footwear, type of support, pathologies, that affect the Center of Mass (CoM) stability. It is however unclear how the limbs stability is controlled relatively to the CoM stability. Look et al's result suggest during running that the lower local dynamic stability of the knee is compensated in order to maintain a better stability at the CoM. The present study aimed at investigating on the dynamic stability of gait, both at the foot and at the CoM levels. We hypothesized that, as the foot segment is the only contact with the ground, the local dynamic stability will be low compared to the CoM .

Methods: 6 men and 6 women (aged 27±3.5, height: 174±7 cm, weight: 68±10 Kg) participated in the study. Participants were asked to walk on a treadmill during 3 minutes. Walking speed was normalized using the Froude number. Participants were equipped with retro-reflective markers on both feet following Graf's protocole. The finite helical angle has been calculated for both feet between the rear- and front-foot segments, in order to get the intrinsic foot kinematics[2]. A 3D accelerometer was placed on the sacrum. 60 gait cycles were extracted from the recording, and the dynamical responses to perturbations were investigated in terms of short- and long-term Lyapunov exponents. State spaces were constructed using the delay coordinate embedding method, for each time series. The number of dimensions was calculated using a global false nearest neighbor analysis and the time delay was estimated with the first minimum of the average mutual information function. Short term (λ_{ST}) and long term (λ_{LT}) maximum Lyapunov exponent were calculated and compared between for time series data (foot Helical angle (HA) and 3D sacrum acceleration). Repeated measures ANOVA have been performed to compare foot and sacrum short- and long-term stabilities, and a Newman-Keuls post hoc test was used whenever necessary ($p<0.05$).

Results: Increasing coefficients meant a loss of dynamic stability. λ_{ST} of the HA was 4.33±0.25 on average for right and left feet. The coefficients for the acceleration of the sacrum reached 1.1±0.09 for anteroposterior, 1.3±0.15 for the mediolateral and 1.3±0.14 for the vertical directions. No significant difference was observed between the time series for the long-term coefficient except for the mediolateral acceleration of the sacrum, lower than all the other ones (Fig 2.b).

Figure:



Caption: 2.a Short term Lyapunov coefficients. HA stands for helical angle, AP (AnteroPosterior), ML(MedioLateral), Ve (Vertical). 2.b shows the long term lyapunov coefficients for the same time series data. Different numbers of * means results are significantly different.

Conclusion: No difference emerged in λ_{ST} and λ_{LT} between the two feet for all the time series. λ_{ST} on the time series data of the feet were significantly higher than for the sacrum, revealing a lower stability for this segment relative to the CoM. On the contrary, no difference emerged on the long-term coefficient, with feet as stable as the sacrum. If the feet obviously handle a lot of stress during walking, the motor control system seems to be able to dissipate the short-term perturbation to remain stable over the long term. Moreover adaptations seem to be established along the kinematic chain to keep the CoM much more stable than the feet segments.

Results on the sacrum long term stability showed a significantly smaller lyapuvov coefficient for mediolateral acceleration. Considering the redundancy of the human body kinematic chain, and the number of degrees of freedom to control, the motor control system is likely to stiffen some movement in order to allow the performance of walking task. In our case, the mediolateral displacement of the CoM seems to be more controlled in terms of orbital stability. In order to keep the dynamic stability as elevated as possible at the CoM level, the motor control system seems to make limbs handle most of the short term perturbations while the system remains orbitally stable at both the CoM and limbs levels.

CHANGES IN COMFORT AND HEEL CUSHIONING PERFORMANCE OF BASKETBALL SHOES WITH INCREASING SHOE USAGE TIME

Wing Kai Lam [1,*] Guoqing Wu [1 2] Hui Liu [2] Jason Tak-Man Cheung [1]

[1]Li Ning Sports Science Research Center, Li Ning (China) Sports Goods Company, [2]Department of Kinesiology, Beijing Sport University, Beijing, China

Introduction and Objectives: Basketball is one of the most popular sports in the world. Players perform an average of 70 jumps and experience up to nine times of vertical impact forces of one's body weight [1]. Impact attenuation is one of the most key functions of the basketball shoes. Previous studies demonstrated that running shoe degradation was associated with reduced cushioning performance [2,3], such information on basketball functionality (cushioning and perception) is unavailable. This study aimed to investigate the cushioning and perception performance of basketball shoes across different controlled wearing time.

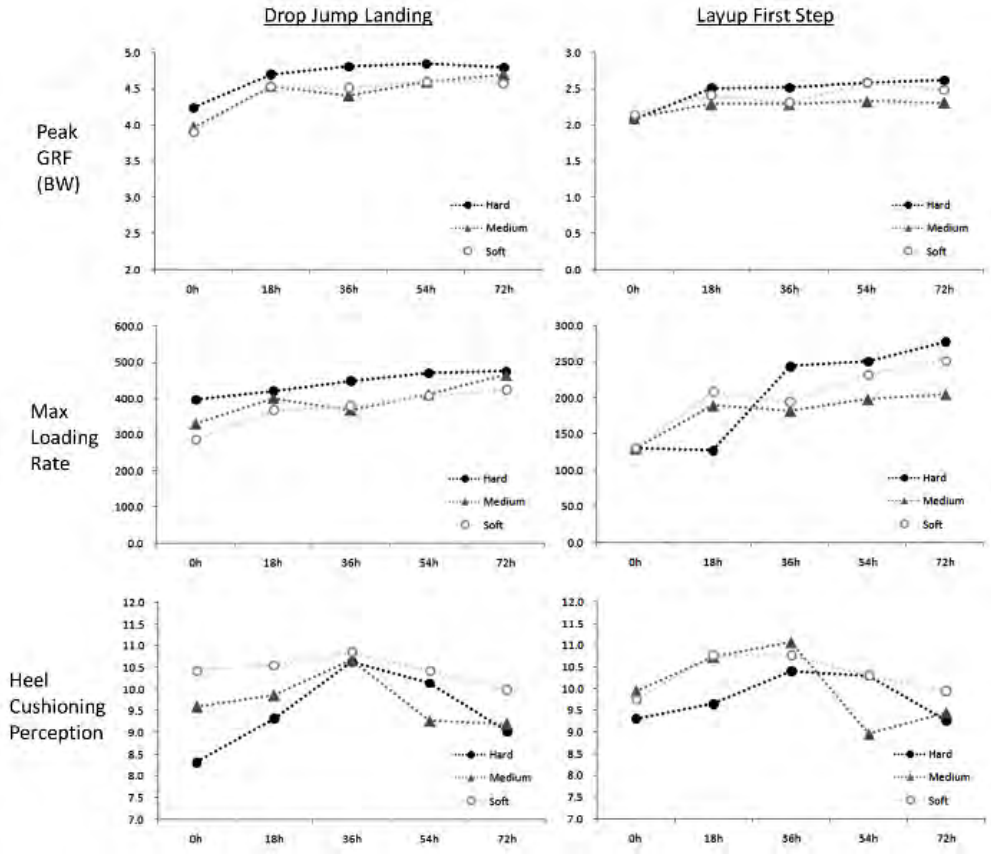
Methods: Fifteen male university basketball players (age: 20.9±1.2 yrs, height: 178±3.0 cm, weight: 73.4±7.6 kg) performed five trials of drop jump landing and layup maneuvers in each of the three identical test shoes (Hard, Medium, Soft) at 0 and 18, 36, 54, and 72 hours of court training wearing time. The shoes only differed in midsole hardness at the heel region. Mechanical impact performance (peak acceleration) was measured with an impact tester (Exeter Research V2.6, USA) at each time condition (Table 1). The shoe usage condition was standardized by asking three standard shoe wearers, who were similar in age, size, weight, and playing position, to use the shoes in the same typical training sessions that included footwork, fast break, and competitive game training at the university. All shoes were randomly presented in each of the time sessions across participants.

A wooden top 900x900 force plate (AMTI, USA) was used to measure the ground reaction forces (GRF) during landing impacts for each of the two maneuvers. Perception of heel cushioning was assessed immediately after execution of movements using a Visual Analog Scale (VAS) from 0 to150 mm. The second impact peak of drop jump and the first impact peak of layup were selected to evaluate heel cushioning performance (peak vertical GRF and the maximum loading rate of vertical GRF) [4]. All variables were analyzed using a Shoe x Time (3 x 5) ANOVA with repeated measures. The significant level was set at $p < .05$.

Results: In drop jump landing, Shoe and Time effects were found for peak GRF, maximum loading rate, and heel cushioning perception. Higher peak vertical GRF and maximum loading rate with poorer perception were found for Hard shoe compared to softer shoes ($p < .05$). Meanwhile, greater peak GRF and loading rate were found for latter time conditions than the initial time condition. Players perceived better heel cushioning at 36h than 0h, 54h, and 72h conditions ($p < .05$).

For the first step of layup, Shoe and Time effects were found for peak vertical GRF and maximum loading rate while only Time effect was found for perception rating. Smaller peak vertical GRF and loading rate were found for Medium shoe compared to Hard and Soft shoe conditions ($p < .05$); Greater peak impact forces were found at 54h and 72h ($p < .05$). Better heel cushioning perception rating was found for 36h compared to 0h and 72h conditions ($p < .05$).

Figure:



Caption: Figure 1. Peak vertical GRF, maximum loading rate of peak vertical GRF, and heel cushioning perception scores for drop jump landing and layup first step landing.

Conclusion: Increased shoe usage time would play a role in shoe comfort and cushioning performance. Hard shoe demonstrated inferior perceived and biomechanical cushioning performance than Medium and Soft shoes. Interestingly, superior shoe perception was found for the 36h condition in both tested maneuvers, suggesting that the shoe that worn after 36 hours might enable an optimal break in period for better perceived shoe fit and comfort for players. Due to the possible changes in mechanical properties and perceived comfort of footwear with varying usage time, a standard shoe accommodation period and footwear properties evaluation protocols should be implemented in footwear research especially for large scale and longitudinal studies, in which shoe usage time variation can be significant.

Table:

	0h	18h	36h	54h	72h
Hard (Asker 62C)	10.89	11.04	11.93	11.83	12.00
Medium (Asker 52C)	10.02	10.44	10.57	11.20	11.17
Soft (Asker 47C)	9.24	10.86	10.32	10.42	11.19

BAREFOOT VS. SHOD: A COMPARISON OF LOWER LIMB MOTION DURING RUNNING

Ben Langley [1,*] Mary Cramp [2] Stewart Morrison [1]

[1]School of Health, Sport and Bioscience, University of East London, London, [2]Centre of Health and Clinical Research, University of the West of England, Bristol, United Kingdom

Introduction and Objectives: There is controversy regarding the association between running footwear and footwear-related injury [1]. In response to this, assessment of barefoot running patterns has emerged as a trend within the biomechanics literature and fuelled the debate around the impact of footwear on running biomechanics. Recent studies [1,2] have revealed significant differences between shod and barefoot running in sagittal plane hip, knee and ankle joint motion at discrete time points within the gait cycle. However, analysis of discrete events offers limited insight into the kinematic differences between barefoot and shod running patterns and relies upon the subjective selection of key variables within the waveform. Therefore, the aim of this study was to further examine differences in barefoot and shod lower limb kinematics during running using trend symmetry (TS) analysis.

Methods: Fifteen males (27 ± 5years, 1.77 ± 0.04m, 80 ± 10kg) ran at a self-selected pace (2.8 ± 0.5m.s-1) on a treadmill in barefoot and shod conditions (standardized ASICS running shoes). Kinematic data were collected using an eight camera VICON MX motion analysis system, sampling at 200Hz. Hip, knee and ankle angles were calculated using the Plug in Gait model [3]. TS analysis [4] was used to compare kinematic curves between the two conditions. TS values were calculated for each subject and averaged across all subjects. Within the TS analysis, the range offset (RO) and range amplitude ratio (RAR) were calculated. Additionally, joint angles upon initial contact (IC) and stance phase range of motion (ROM) were compared between conditions using paired t-tests and Wilcoxon matched pairs analysis.

Results: TS, RO and RAR values are reported for each joint in Table 1. TS analysis revealed highly symmetrical (TS > 0.95) kinematic patterns between barefoot and shod conditions at the hip, knee and ankle in the sagittal plane, hip and ankle in the frontal plane and the knee and ankle in the transverse plane. Knee joint motion in the frontal plane was the least symmetrical (TS = 0.87). The RO revealed small mean differences between conditions (RO < 4°). RAR scores highlight greater ranges of motion in the shod condition for all joints, apart from sagittal plane ankle joint movement. Significant ($p < 0.05$) differences between conditions upon IC were recorded at the ankle in all three planes. Sagittal plane knee, and transverse plane hip, knee and ankle joint motion were significantly ($p < 0.05$) greater in the shod condition. Sagittal plane ankle joint motion was significantly ($p < 0.05$) greater in the barefoot condition.

Conclusion: The aim of this study was to further examine differences in barefoot and shod lower limb kinematics during running using TS analysis. When compared over the entire kinematic waveform, barefoot and shod running patterns are generally highly symmetrical, with small mean differences (RO) between conditions. The highly symmetrical motion patterns between conditions may suggest that kinematic adaptations to barefoot running have less of an influence upon running patterns than previously suggested based upon analysis of discrete variables. Despite highly symmetrical movement patterns, the key adaptation to running barefoot appears to be an increase in ankle joint plantar flexion upon IC, which demonstrates a move towards mid- to fore-foot striking patterns within this condition. It is speculated that the

differences in joint ROM between conditions reported in this study are a direct result of the change in foot striking patterns. Previous research [5] has suggested that the changes in joint ROM between foot striking patterns, as reported between conditions within the current study, maybe indicative of changes in the shock attenuation mechanisms as a result of different loading patterns.

Table:

		TS (unitless)	RO (°)	RAR (unitless)
Hip	Sagittal	1.00 (0.00)	-1.00 (3.40)	0.98 (0.08)
	Frontal	0.98 (0.02)	-0.24 (1.79)	0.89 (0.24)
	Transverse	0.89 (0.11)	-0.74 (8.33)	0.85 (0.24)
Knee	Sagittal	0.98 (0.02)	-0.34 (3.81)	0.88 (0.14)
	Frontal	0.87 (0.14)	-0.41 (4.66)	0.75 (0.42)
	Transverse	0.98 (0.02)	2.29 (7.63)	0.83 (0.22)
Ankle	Sagittal	0.98 (0.02)	0.08 (4.80)	1.09 (0.17)
	Frontal	0.98 (0.02)	0.56 (0.94)	0.91 (0.17)
	Transverse	0.98 (0.02)	-3.29 (7.25)	0.88 (0.19)

NOTE: Positive range offset and range amplitude ratios above 1 denote greater motion in the barefoot condition

NORM DATA FOR BENDING AND TORSIONAL LOADS OF THE FOOT IN SHOES INCLUDING THE EFFECT OF GENDER

Annette Kerkhoff [1,*] Klaus Peikenkamp [1]

[1]Laboratory of Biomechanics, Physical Engineering, University of Applied Sciences, Münster, Germany

Introduction and Objectives: The measurement and estimation of foot loading is of great interest, especially in case of diabetes mellitus. The weight bearing of the foot has been widely measured in several studies with the help of pressure distribution systems [1]. One problem of pressure measurement is that it only measures the vertical component of the force acting on the foot. In daily life, the foot is protected and supported by shoes. Insole-Systems are used to receive information about the interaction between foot and shoe. A new system: betois (bending torsional insole system) which measures three dimensional deformations was developed. It measures bending and torsional moments between foot and shoe proximal to the Metatarsophalangeal Joint (MTP) I and V and distal to the processus calcaneus (H) with a coefficient of determination of $R^2 > 0.99$ and a linearity near 1. These moments seem to be important variables in the detection of stresses acting on the foot. Before pathological moments can be determined, data from healthy subjects must be available and the effect of gender has to be investigated.

Methods: Betois measures bending (Mb) and torsional (Mt) moments using strain gauges proximal to the caput metatarsal I and V and distal to the processus calcaneus. 53 healthy subjects (38,7y ± 11,7y) participated in this study walking at self-selected speed with the same shoe (Saucony Hattori LC) on a treadmill. After a familiarization period, data were collected with a sampling frequency of 125 Hz over one minute of walk. For data analysis, data were low-pass filtered (Butterworth, 10Hz, 2. order). Heel strike was determined using the sensor beneath the heel. Afterwards, gait cycle curves were normalized to 100 % of gait cycle (gc) (101 data points) and the mean of 30 steps computed. Mean curves and 95 % confidence bands were calculated using the bootstrap-method. Positive values represent dorsalextension and negative plantarflexion moments. In case of torsional moments positive values describe eversion and negative inversion moments. To examine the difference between the gender groups the confidence bands for the difference of the mean (CBDM) were established [2].

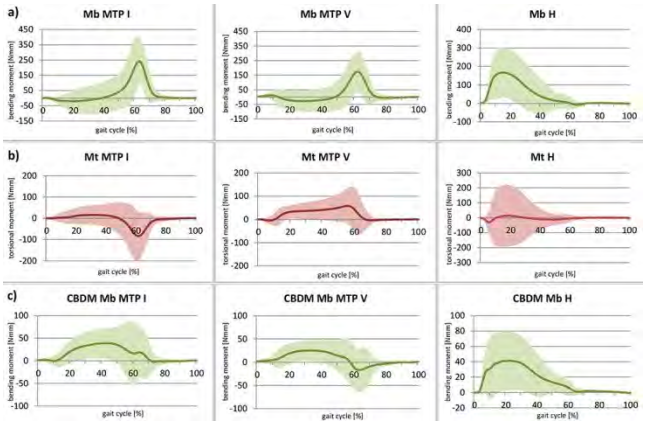
Results: For MTP I and V alternating bending moments were measured. At the beginning of gc a slight plantarflexion moment occurs with its maximum of -21Nmm at 21 % of gc for MTP I and –27Nmm at 28% of gc at MTP V. At terminal stance the moments act in direction of dorsalextension. MTP I reaches its maximum at 63% gc with 243Nmm. Simultaneously, MTP V reaches its maximum with 174Nmm (figure a).

The torsional moments are smaller than bending moments. At loading response a slight eversion moment occurs until 50% of gc at MTP I. Afterwards an inversion moment occurs with its maximum of 82Nmm at 62% gc. At MTP V an inversion moment is measured with its maximum of 58Nmm at 56% gc (figure b).

For the heel a sharp rising dorsalextension moment occurs with its maximum of 166Nmm at 14% gc. Then it flattens slowly until zero crossing at 61 % gc (figure a). The mean of the torsional moment is near zero with a wide confidence band (figure b).

Comparing gender groups, bending moments at MTP I and V were significantly different at mid stance with a maximum difference of 38Nmm (43% gc) at MTP I and 48Nmm (38% gc) at MTP V (figure c). There is also a slight difference for torsional moments at MTP V during loading response. Looking at the gender difference for the bending moment at the heel, significant differences occur from 17 % until 32 % gc, with men tend to have higher bending moments (max. 80Nmm, figure c). For the torsional moments significant differences can be measured from 8 % until 39 % gc (max. 83Nmm). Men tend to have higher eversion moments.

Figure:



Conclusion: In this study norm data for bending and torsional loads were collected. Due to the large number of subjects and the large age range, the norm data created are representative of the loads on healthy feet. An alternating bending moment could be measured at MTP I and V. This alternating moment can be related to the deceleration before the mid-stance and push-off after mid-stance. The data show clearly a higher variability for torsional stresses compared to bending, and further investigation is needed to detect the reason for this variability. The norm curves can be used for comparing different groups of subjects, such as Diabetics with neuropathy. The examination of gender has shown that it has to be considered when comparing data. This result confirms the findings of other studies [3]. The significantly different bending moments in the middle and late stance phase indicate a gender-specific performance of the stance phase. Furthermore, the influence of other factors like age, walking speed, bodyweight or step length has to be determined.

LOWER LIMB BIOMECHANICS DURING THE FORWARD LUNGE: THE INFLUENCE OF A SHOE WITH IRREGULAR DEFORMATIONS OF THE MIDSOLE

Charlotte Apps [1,*] Thorsten Sterzing [2] Thomas O'Brien [1 3] Jason Cheung [2] Mark Lake [1]

[1]School of Sport and Exercise Sciences, Liverpool John Moores University, LIVERPOOL, United Kingdom, [2]Sports Science Research Center, Li Ning (China) Sports Goods Co Ltd, Beijing, China, [3]School of Sport, Health and Exercise Sciences, Bangor University, Bangor, United Kingdom

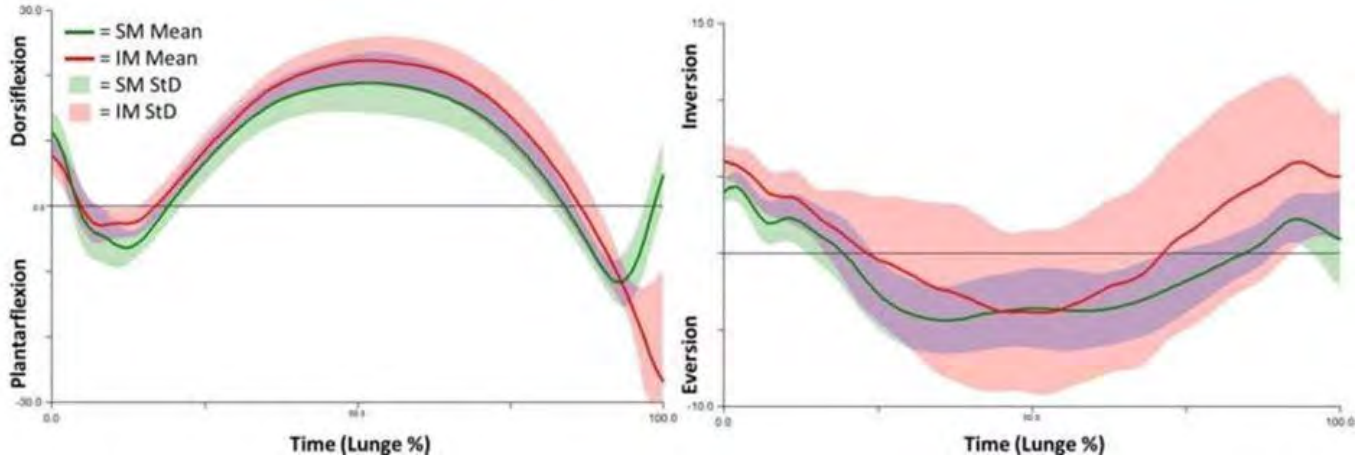
Introduction and Objectives: The concept of motor variability has established the importance of having many motion pathways to adapt to different constraints. Constraints used as training devices to enhance variability tend to have the same dimension, and risk becoming predictable by causing similar perturbations [1]. Unstable footwear, for example, cause initial increases in movement variability that reduces with further use [2, 3]. The creation of a randomly perturbing shoe sole can be likened to moving across uneven ground, where continuous unanticipated perturbations are likely to provide an improved training stimulus [4]. Consequently, a training shoe was developed to enhance variability by causing irregular and unpredictable midsole deformations. The purpose of this study was to examine the acute effects of this shoe on the variability of lower limb biomechanics during a typical gym movement task, the forward lunge.

Methods: Seventeen young, female gym class participants completed two sets of ten right leg forward lunges in a shoe with a stable midsole (SM) and with an irregular midsole (IM). Lunge frequency (20 bpm) was controlled by a drum beat. The IM was created by attaching independent highly flexible rubber bags (sidewalls 1.5 mm) to the shoe upper at the rearfoot, midfoot and forefoot. Small ball bearings (Ø:12 mm) and cube shapes (Ø:15mm, hardness: 85A Shore, TPU material) were placed inside the bags and allowed to move independently. SM was cut to the same medio-lateral shape as the IM bags and weights were attached to match the IM sole weight with the same shoe upper.

Right lower limb joint and segment angles and velocities at touchdown and maximum values (300 Hz, Vicon Peak, United Kingdom) as well as ground reaction forces (GRF) (900Hz, AMTI, United States) were synchronized and measured. Perception of overall lunge movement variability and shoe stability were assessed (9-point Likert Scale). A paired t-test revealed no differences between the first and second set of lunges in the same midsole condition, so both sets were collapsed together. Variables were compared between IM and SM by paired t-tests ($p<.05$).

Results: Participants perceived lunges in IM as more unstable and variable. In IM, sagittal plane kinematics revealed participants adopted a flatter shoe-surface touchdown angle, less ankle dorsiflexion at touchdown and higher maximum ankle dorsiflexion (Figure 1), and reduced maximum foot-slap and knee joint flexion velocities during loading. In the frontal plane, there was a more lateral foot shoe-surface angle, more ankle inversion at touchdown, a smaller maximum ankle eversion angle and a larger frontal ankle range of motion in IM. Variability was generally higher in IM and particularly in the frontal plane of the foot (51%) and ankle (55%) maximum angles and ankle range of motion (41%) (Figure 1). Resultant landing foot velocities were similar, but the trajectory of the foot was modified such that the vertical speed was 13% greater and anterio-posterior (AP) speed reduced 30% in IM. GRF results showed 13% larger and 46% more variable vertical loading rates and a 13% reduced AP GRF integral in IM.

Figure:



Caption: Figure 1: Mean and standard deviation (StD) of sagittal (left) and frontal (right) ankle angles during 2 sets of forward lunges in SM (green) and IM (red) of a typical subject. Time is normalised from touchdown until toe-off.

Conclusion: The irregular shoe midsole was a clear constraint to participants when performing forward lunges causing acute biomechanical and variability alterations. Foot velocities and sagittal joint angles at touchdown, and joint velocities during stance indicated a more cautious approach with IM shoe to reduce the AP GRF integral. Increased variability of initial vertical impact loading, and frontal shoe-surface and ankle angles indicates participants were unable to control these parameters. Therefore, the irregularly deforming midsole succeeded in causing increased variability of frontal plane foot and ankle movements, revealing potential to induce increased and sustained movement variability. Future work should confirm whether IM is able to maintain movement variability in the long term, through unpredictability, and explore potential lower limb training effects.

AS-0235

PROTECTIVE CAPACITIES OF ICE HOCKEY HELMETS FOR DIFFERENT MECHANISMS OF HEAD INJURY

J. Michio M. Clark [1,*]Andrew Post [1]T. Blaine Hoshizaki [1]Michael D. Gilchrist [2]

[1]Human Kinetics, University of Ottawa, Ottawa, Canada, [2]Mechanical and Materials Engineering, University College Dublin, Dublin, Ireland

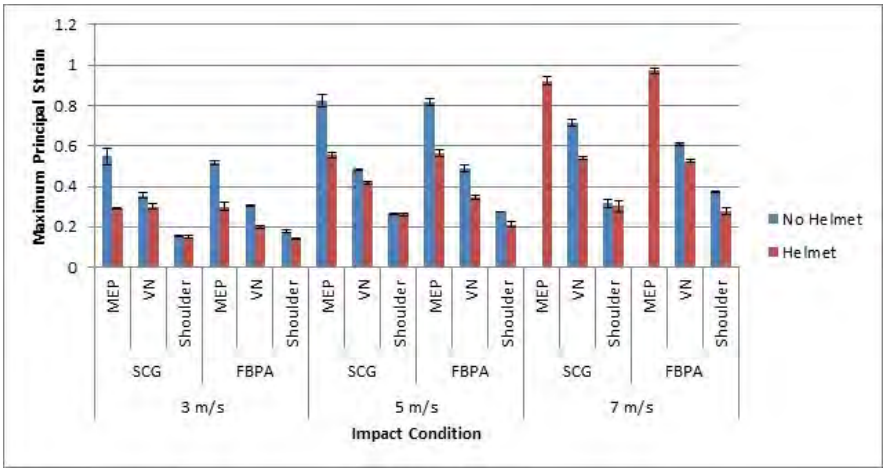
Introduction and Objectives: Mild traumatic brain injury (mTBI) is common in ice hockey and can lead to long term disability. The use of helmets has reduced the incidence of traumatic brain injuries (TBI), however the incidence of concussion has remained unaffected.[1] Current ice hockey helmet certification standards were primarily designed to mitigate the risk of TBIs. The ice hockey helmet standard employs a monorail drop device to simulate a fall to the ice. However, in ice hockey, the risk of mTBI is primarily associated with collisions and not with falls.[2] The impact characteristics of a collision are different than those of a fall. As a result, the protective characteristics of current ice hockey helmets may not adequately protect against the conditions of impact that commonly lead to mTBI. The purpose of this study is to measure the protective capacity of ice hockey helmets for different mechanisms of mTBI in ice hockey

Methods: A helmeted (ice hockey helmet) and unhelmeted 50% instrumented Hybrid III headform were impacted at two sites (Table 1) and three velocities of 3, 5 and 7m/s under conditions that represented three common mechanisms of injury in ice hockey. Falls to the ice were simulated using a monorail drop rig with a MEP anvil to represent ice. Collisions were simulated using a pneumatic linear impactor with two different strikers. A vinyl nitrile (VN) striker was used to represent a collision with a stiff elbow, and a more compliant shoulder pad striker was used to simulate shoulder-to-head impacts.[3] The impact mass was 13.1kg.[3] Three trials were conducted for each condition with the resulting accelerations used as input for the University College Dublin Brain Trauma Model (UCDBTM). Peak resultant linear and rotational acceleration of the headform was measured and maximum principle strain (MPS) in the cerebrum was calculated using the UCDBTM.

Results: The protective capacities of ice hockey helmets to reduce MPS for different mechanisms of head injury are presented in Figure 1. Comparison between mechanism of injury for linear and rotational acceleration and MPS revealed significant differences for all conditions ($p<0.05$), except for MPS when comparing falls and elbow collisions at site 1 when impacted at 3 m/s. Comparison of helmeted and unhelmeted impacts showed significant differences in linear and rotational acceleration for all conditions ($p<0.05$) with the exception of rotational acceleration and MPS of shoulder impacts at site 2 at all velocities.

Overall, the ice hockey helmet was successful in reducing the risk of brain injury from TBI magnitudes to where mTBI would be a likely result, except for velocities of impact at 7m/s.[3,4] At 7m/s the fall and elbow condition both resulted in magnitudes of response where there was a high risk of TBI. When examining the mechanisms of injury in reference to the literature,[3,4] helmets were effective at reducing the risk for both mTBI and TBI when determined by acceleration measures for falls and elbow collisions, but not for shoulder collisions. When MPS was used to determine risk, all mechanisms of injury represented a significant risk of mTBI for all velocity conditions, except for the shoulder at 3 m/s.

Figure:



Caption: Figure 1. The protective capacity of an ice hockey for three mechanisms of head injury on maximum principle strain.

Conclusion: This study examined the protective capacities of ice hockey helmets for different mechanisms of head injury. This result demonstrates the limitations of protective capacity of ice hockey helmets across mechanisms of injury commonly occurring in ice hockey. These results suggest that to influence the incidence of mTBI in ice hockey, helmet designs and current ice hockey helmet standards need to be improved to better reflect the nature of risk within the sport.

Table:

	Location on headfrom	Impact angle

AS-0236

THE RELATIONSHIP BETWEEN HEAD ACCELERATION AND BRAIN TISSUE RESPONSE VARIABLES FOR THREE COMMON IMPACTS IN AMERICAN FOOTBALL

R. Anna Oeur [1,*] Katrina Zanetti [1] Blaine Hoshizaki [1] Michael Gilchrist [1 2]

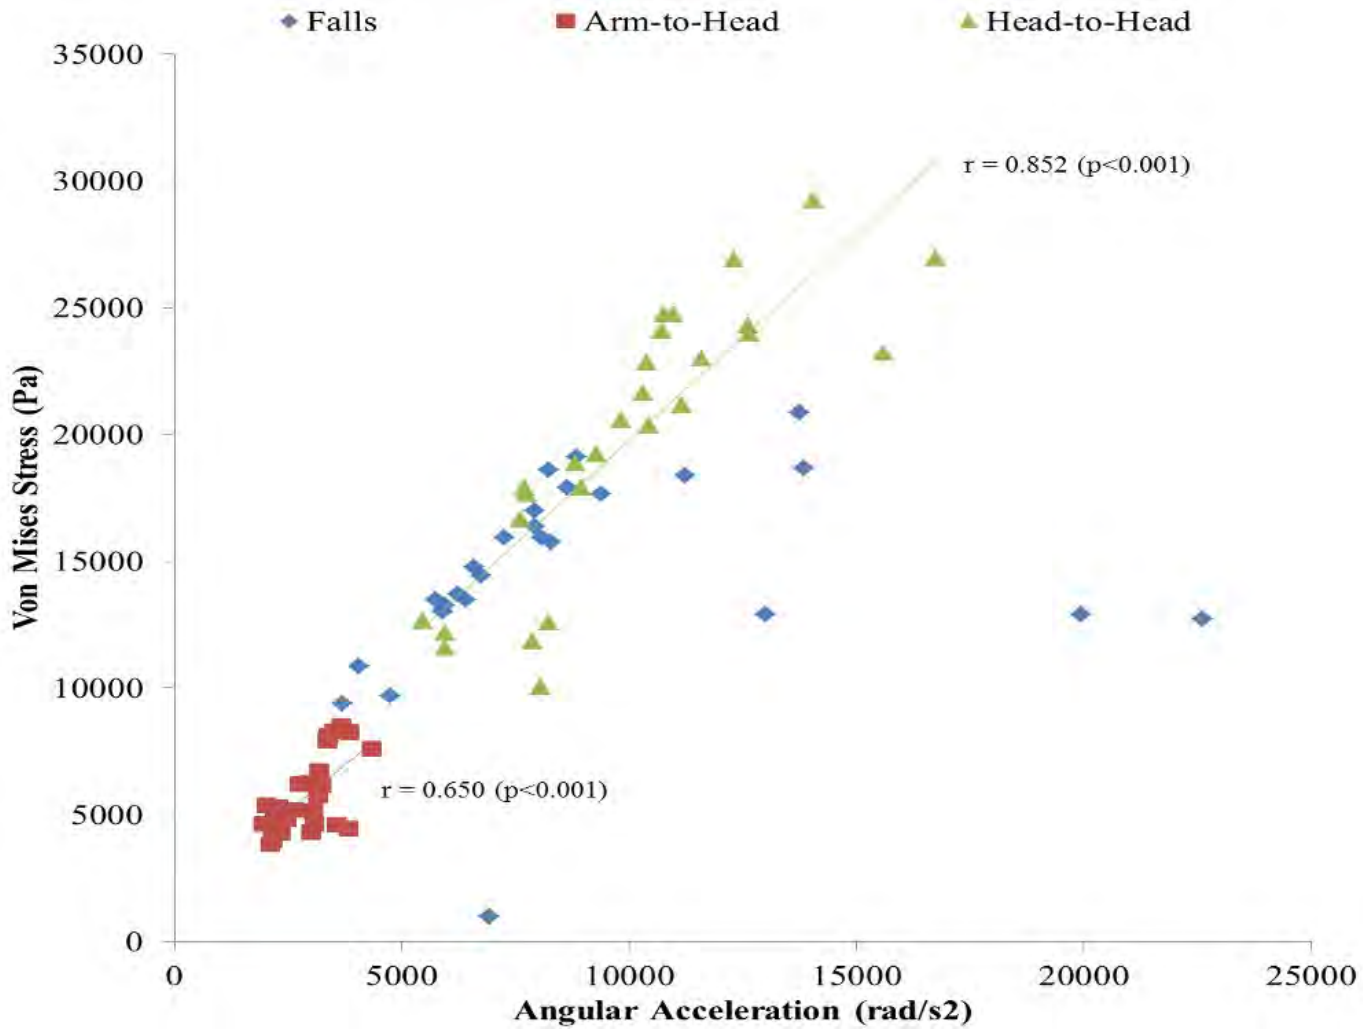
[1]Human Kinetics, University of Ottawa, Ottawa, Canada, [2]Mechanical and Materials Engineering, University College Dublin, Dublin, Ireland

Introduction and Objectives: Head impacts are the main cause of concussion for American football players for all levels of play [1]. The most common types of head impacts include head collisions, forearm strikes, and falls to the ground [2]. Head injury risk is measured using linear and angular head acceleration, however, resultant brain stresses and strains from finite element analysis have been proposed to be more appropriate in quantifying injury to the tissue [3]. Epidemiological research demonstrates that the nature of the accident event influences the type of concussive deficits observed in patients. A higher percentage suffered deficits from falling objects and assaults, as compared to sport impacts and motor vehicle accidents [4]. How an impact accelerates the head and injures the brain has been shown to influence the outcome type and severity [5]. The degree to which head acceleration is related to brain tissue response variables has yet to be understood for different conditions occurring in American football. An understanding of these relationships will provide information as to how concussion risk occurs. The objective of this study was to determine the correlation between peak resultant linear and angular accelerations with maximum principal strain (MPS), von Mises stress (VMS), and strain rate for three impacts in American football.

Methods: Head to head impacts were conducted at 11 m/s using a linear impactor, falls to the ground at 6 m/s using a monorail drop rig, and forearm strikes to the head at 5.5 m/s by a pendulum system. Impacts were performed at centric and non-centric sites with head dynamic response collected using a helmeted Hybrid III headform [6]. Accelerations were input into the University College Dublin Brain Trauma Model to obtain peak values of MPS, VMS, and strain rate in the cerebrum [7]. Pearson product-moment correlation coefficients (r) were calculated for each peak resultant linear and angular acceleration with peak MPS, VMS, and strain rate.

Results: Table 1 presents correlations between peak head acceleration and brain tissue results. Forearm strikes resulted in only angular acceleration having moderately high relationships with MPS and VMS. Falls showed moderately low correlations between both types of head acceleration for VMS and strain rate. All correlations for head to head impacts were found to be significant, with VMS having the strongest relationships with linear and angular acceleration. Figure 1 is an example of a chart depicting the relationship between VMS and angular acceleration. By breaking down the relationships by centric and non-centric sites, the correlation between VMS and linear (r=0.928) and angular (r=0.869) was improved for head to head impacts (p=<0.001). Similarly, angular acceleration and MPS had a stronger relationship for head to head impacts when only examining non-centric sites (r=0.910, p=0.001).

Figure:



Caption: Example data chart depicting the relationship between VMS and angular acceleration

Conclusion: Strength of correlations between head acceleration and brain response is specific to impact type. Head collisions had the strongest relationships, whereas forearm strikes and falls had generally weaker and more variable correlations. The high velocity nature of head to head impacts likely caused a coupling of the head and brain responses resulting in a spread of data that was more strongly and linearly related (Figure 1). Despite falls resulting in a near complete transfer of energy to the head and brain, where one would expect coupling, there was more variability in the data for these types of impacts, which lead to weaker relationships. Arm strikes were the least severe impacts, where the responses tend to cluster. These findings support the notion that injury risk is related to how impact occurs and demonstrates the limitation of using head acceleration to characterize concussion risk across all types of impacts occurring in American football.

Table:

Head Dynamic Response	**Brain Tissue Variable**	**Falls**	**Forarm-To-Head**	**Head-To-Head**
Linear Acceleration (g)	MPS			r = 0.477
				p = 0.012
	VMS	r = 0.420		**r = 0.858**
		p = 0.029		***p = <0.001***
	Strain Rate	r = 0.495		r = 0.425
		p = 0.009		*p = 0.027*
Angular Acceleration (rad/s^2)	MPS		r = 0.705	r = 0.690
			p = <0.001	*p = <0.001*
	VMS		r = 0.650	**r = 0.852**
			p = <0.001	***p = <0.001***
	Strain Rate	r = 0.667		r = 0.647
		p = <0.001		*p = <0.001*

UNDERSTANDING HIGH FORCE TRANSMISSION ON TRAUMA IN THE GLENOHUMERAL JOINT

David J. Hughes [1,*] Farhad Nabhani [1]

[1]School of Science and Engineering, Teesside University, Middlesbrough, United Kingdom

Introduction and Objectives: Understanding the transmission of forces through joints is crucial to all aspects to fracture prevention and repair. Until recently however, the accurate measurement of transmitted forces in the Glenohumeral joint has been difficult to calculate and define. Now, forces and moments are measured in-vivo using telemeterised shoulder implants. This method however, limits testing during high forces leading to trauma or fracture repair failure. For this reason ex-vivo testing which maintains the in-vivo loading conditions is needed to understand the non-linear dynamics of high force transmission into joints.

Methods: The Teesside Shoulder Rig is used to generate in-vivo loadings in 6 degrees of freedom simulating the supraspinatus, subscapularis, infraspinatus/teres minor, long head biceps and anterior, middle, and posterior deltoid muscles. Transferred forces and translational movement of the Proximal Humeral head are measured during a series of multi component, high impact load cases.

Results: The study shows the value of simulating and tracking force transfer through the Glenohumeral joint. During automotive rear impact loading simulations two clear forces are seen through the head, a shearing force through the coronal plane showing maximum forces of 970.5N and a compressive force into the Glenoid Fossa. Translation to the point of joint dislocation is achieved and individual muscular reaction forces measured. The joint is laterally impacted with up to 200% body weight forces showing clear force transfer into the Glenoid fossa but identifying the damping effect of the Glenoid capsule and force transfer into the coronal and sagittal planes. Stresses are calculated through the humeral head showing maximum transferred stresses of 345.4KN/m^2 when laterally loaded.

Conclusion: The testing provides accurate and measurable results for high impact loadings in the Glenohumeral joint. Clear patterns are observed which illustrate the body's remarkable ability to distribute forces and reduce stress generation in joints through muscular management. A greater understanding of the complex force transfer patterns of the Glenohumeral joint will enable improved high impact simulation, injury prevention and protective design approaches.

HOW DO GROUND REACTION IMPACT FORCES RESPOND TO CHANGES IN SUBMAXIMAL GAIT SPEED?

Emmanuel S. Da Rocha [1,*] Ana de David [2] Darren Stefanyshyn [3] Felipe Carpes [4]

[1]Applied Neuromechanics Research Group, Federal University of Santa Maria, Santa Maria, [2]University of Brasília, Brasília, Brazil, [3]Human Performance Lab, University of Calgary, Calgary, Canada, [4]Applied Neuromechanics Research Group, Federal University of Pampa, Uruguaiana, Brazil

Introduction and Objectives: Ground reaction force (GRF) magnitude, especially the vertical component, is widely described as proportional to locomotion speed. Although this general affirmation is true when high running speeds are considered, GRF patterns during submaximal speeds are not clearly described in the literature. As walking, fast walking and submaximal running speeds are often observed among recreational runners, in which high levels of lower extremity injuries are also described as related to impact, we wanted to know what happens with the GRF peak at heel strike when subjects are walking or running at different sub-maximal speeds. Therefore, the aim of this study was to compare the impact peak during comfortable walking, self-selected fast walking, slow running and running in male recreational runners.

Methods: Eleven recreational male runners (age 21.2 ± 1.8 years; height 1.77 ± 0.60 m; body mass 74.8 ± 5.6 kg) participated in this study. They were all rearfoot strikers, which was determined by visual inspection of their gait kinematics, training regularly without recent history of lower extremity injuries, and signed an informed consent form approved by the local ethics committee before the start of testing. All participants had recreational running experience (at least three times per week) in the last six months before the experiments.

Participants were evaluated while walking and running overground at different speeds using control running shoes (Adizero Tempo 5 M, Adidas Int.) in a single session in the laboratory. The trials started after measurement of body mass and height. Kinetic data were acquired at four different conditions as follows: (a) comfortable walking at self-selected pacing (1.61±0.11 m/s), (b) fast walking at the maximal possible walking speed (2.09±0.14 m/s), (c) slow running at a speed corresponding to 30% slower than running (2.90±0.09 m/s) and (d) running at 4.07±0.12 m/s.

The speed was measured using photoelectric cells 2 m apart (Banner Engineering Corp., Minneapolis, MN, USA) and placed just before and after the force plate. Ground reaction forces were sampled at 1200 Hz using a 3D force platform (Kistler 135 AG, Winterthur, Switzerland) in a 30-m walkway with data being acquired in the middle of the trial.

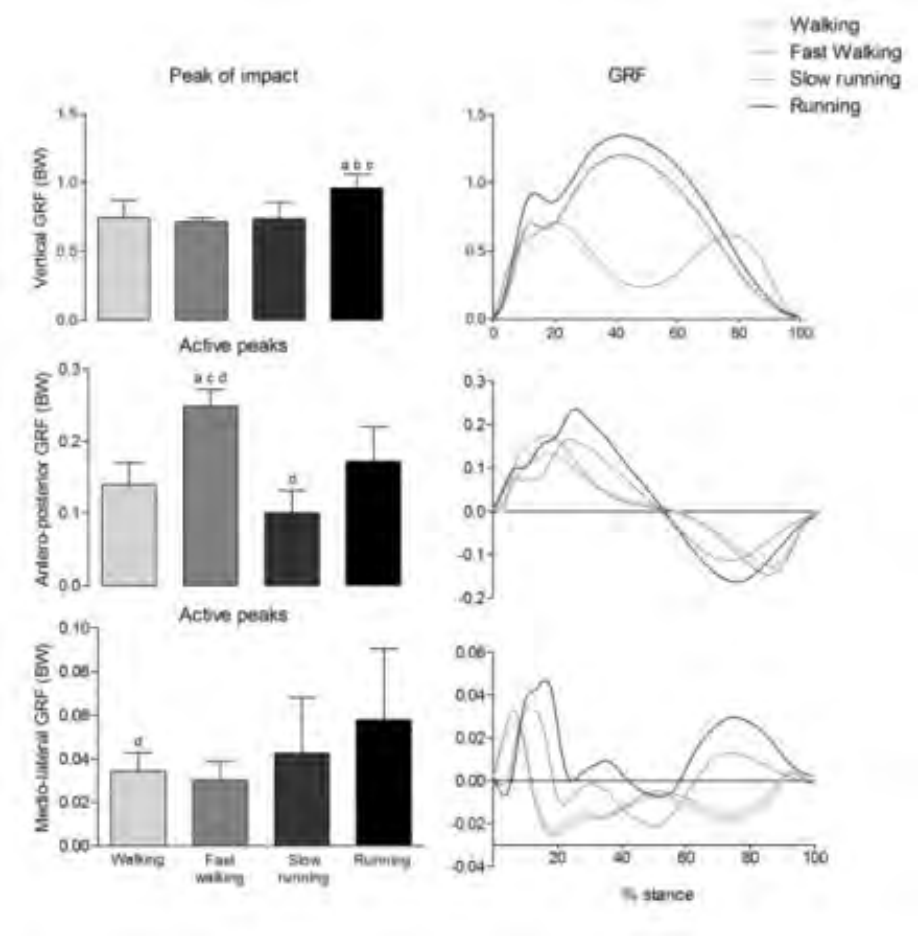
Data were filtered using a forth-order Butterworth low-pass filter (50 Hz cut-off). All walking and running waveforms were normalized to 100% stance phase. Kinetic data were normalized by body mass of each subject. Data were grouped and means and standard deviations were calculated. The peak forces at foot strike were identified for each subject.

Data normality was verified using a Shapiro-Wilk's test. An one-way analysis of variance with Tukey post-hoc when suitable was performed to determine the effect of speed on GRF. All tests were performed with SPSS 20.0 considering a significance level of 0.05.

Results: An effect of speed for the peak impact GRF was observed ($F=11.65$; $p<0.001$). Post-hoc analysis showed that the vertical GRF impact measured during running was higher than comfortable walking ($P<0.01$), fast walking ($P<0.01$) and slow running ($P<0.01$). Peak magnitudes of horizontal GRF were lower than observed for the vertical component.

However, effects of speed were also observed for both anteroposterior (F=34.51; p<0.001) and mediolateral (F=3.18; p=0.034) components. Anteroposterior GRF was higher during fast walking (P<0.01). For the mediolateral component, we observed differences between walking and running (P<0.01). Figure 1 shows the mean peaks for each GRF component and the average waveform for each component during stance phase. Horizontal forces did not follow a similar pattern and showed very low magnitudes when compared to the vertical component.

Figure:



Caption: Figure 1. In the left column the average peak values for impact force, normalized to body weight, for each ground reaction force component. In the right column, waveforms representing the average pattern for each force component and each speed. Note: a – different from comfortable walking (P<0.01); b – different from fast walking (P<0.01); c – different from slow running (P<0.01); d –different from running (P<0.01). BW: body weight.

Conclusion: Walking or running at speeds lower than 4.07±0.12 m/s elicited similar peak impact forces among recreational runners evaluated in our study. Horizontal forces did not follow a consistent pattern in response to changes in gait speed.

EVALUATING THE PROTECTIVE CAPACITY OF BASEBALL HELMETS TO CONCUSSIVE IMPACTS

Clara Karton [1,*] Andrew Post [1] T Blaine Hoshizaki [1] Micheal Gilchrist [2] Julian Bailes [3]

[1]University of Ottawa, Ottawa, Canada, [2]University College Dublin, Dublin, Ireland, [3]University of Chicago, Evanston, United States

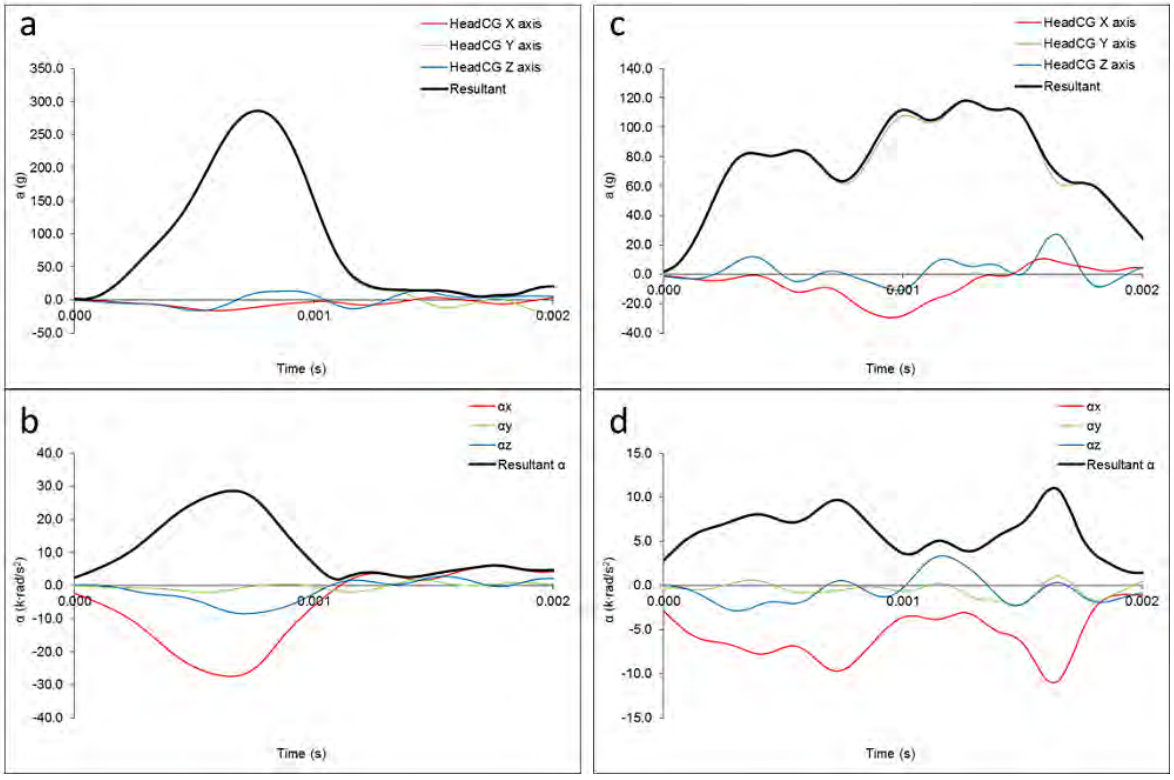
Introduction and Objectives: Baseball is a widely participated sport, particularly in the United States in which approximately 19 million people of all ages engage each year[1]. The most prevalent and severe head injury mechanism in baseball is ball to head impacts, typically involving the batter hit by a pitch[2]. Although helmets worn by the batter protect the athlete against catastrophic injury, concussions are still being reported. The purpose of this study was to examine the protective capacity of baseball helmets from ball impacts and develop a methodology that could be used to evaluate their performance against a common cause of concussion.

Methods: The impacts were performed using a pneumatic ball launcher and an instrumented Hybrid III headform outfitted with a baseball batter helmet. The ball was launched at 35.7m/s (80mph) which was measured with a laser timegate. A video review of ball to head impacts resulting in concussion within Major League Baseball was conducted and four impact sites were chosen as commonly impacted sites. An additional three impact sites were chosen based on current standard methods, for a total of seven projectile impact sites. Four helmet models were evaluated in this research, with a new helmet used for each of three impact trials per site. The results of each impact were recorded in linear and rotational acceleration. These acceleration loading curves were then used as input for the University College Brain Trauma Model to determine the peak maximum principal strain in the brain for each impact. This variable was used as it has been found in the past to have the highest correlation with risk of concussive injury.

Results: Results for head dynamic response and brain tissue strain for the four common concussion impact sites for helmet models A-D are presented (Table 1). Statistical analyses found significant main effects between both impact site and helmet model. Impact site comparison showed significant differences, but not between all sites, which is likely a result of the high standard deviations caused by collapsing all helmet results. Helmet model analysis revealed that rotational acceleration had more significant differences than any other metric.

The magnitudes found for all sites would be in ranges that would suggest a high likelihood of concussion[3]. This could be explained by the fact that there was little difference between helmet energy absorbing liners. Interestingly helmet D, which had a very hard composite shell, produced the lowest magnitudes for 5 of the 7 impacts (sites 1- 5). Suggesting that for this type of projectile impact, having a hard shell to help distribute the forces would be desirable. This hard shell led to a lengthening the duration of the impact which engaged more foam and reduce the magnitudes of the impact, reducing risk of injury (figure 1).

Figure:



Caption: Figure 1. Comparison of the acceleration loading curves for helmet C (a and b) and D (c and d).

Conclusion: The methodology proposed used a series of impact sites that were successful in distinguishing differences in design characteristics between helmet models in dynamic and brain tissue response. In addition, at 80 mph, these sites showed a consistent high level of risk regardless of the helmet worn, indicating limited protection by these helmets for concussive impacts. The mechanism of concussion shown by this research are baseball impacts that result in very brief (2ms or less) acceleration loading curves. These curves are distinct from other sports, suggesting the understanding of concussion and development of protective helmet technologies must be specific to baseball.

Table:

		Peak acceleration			Maximum principal strain
Impact site	Helmet model	Linear (g)	Rotational (krad/s^2)		Cerebrum
4	A	192.0 (35.3)	22.9 (3.2)		0.336 (0.03)

A COMPARISON OF STRESS DISTRIBUTION IN THE HEALTHY AND OSTEOARTHRITIS-AFFECTED EQUINE THIRD METACARPAL UNDER IMPACT LOADING USING FINITE ELEMENT ANALYSIS

Cristin Mccarty [1,*] Jeffrey J. Thomason [1] Karen Gordon [2] Timothy A. Burkhart [3] David W. Holdsworth [4] Jaques S. Milner [5]

[1]Biomedical Science, [2]Biomedical Engineering, University of Guelph, Guelph, [3]Mechanical and Materials Engineering, [4]Surgery and Robarts Research Institute, [5]Robarts Research Institute, Western University, London, Canada

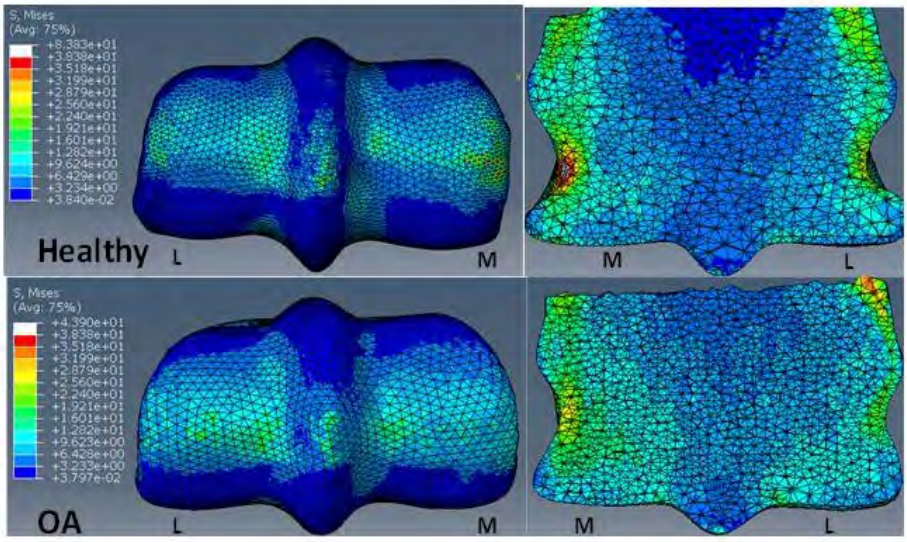
Introduction and Objectives: The metacarpophalangeal (MCP) joint of horses is a valuable, large-animal model for studying bone disease of mechanical origin. Osteoarthritis (OA) in the MCP joint is common among racehorses [1] and is associated with a change in the micro-architecture of the subchondral bone and overall joint geometry [2]. Exercise-induced bone remodeling in the distal articular condyle of the third metacarpal (MC3) can cause subchondral bone sclerosis and damage to the articular cartilage. This damage weakens the joint integrity and can lead to catastrophic condylar failure that ultimately results in early retirement or euthanasia of young horses [1]. The underlying bone structure within the MCP joint is representative of the mechanical loading history (dependent on magnitude, rate and repetitiveness) sustained during high-speed racing and training [3]. Contact stress during midstance (i.e., at full joint extension) has been shown to be associated with site-specific changes within the distal end of MC3 [3]. Force magnitudes are considerably lower at impact (~2-10% of the peak at midstance), but it is known that repetitive impact can be involved in the etiology of osteoarthritis [4]. Accelerations of high magnitude and high frequency have also been shown to elicit bone changes and contribute to damage within a joint [4]. Repetitive loading under high-speed locomotion occurs 100-150 times per minute during racing and training, and imposes large stresses on the MCP joint. Characterization of stresses associated with the loading conditions at all stages of the stance is essential in understanding the biomechanical causes associated with the changes in bone tissue. Given the complexities that are associated with measuring the joint forces and contact areas *in vivo*, computational models, specifically finite element models, are practical alternatives. Finite element modeling (FEM) provides a non-destructive method for predicting the stresses and strains in structures that have complex geometries, specific material properties and that are subjected to complex loading patterns. Finite element modelling has been used within equine research to examine the stress distribution at midstance in the hoof [5], proximal phalanx [6], third metacarpal [6]and entire distal forelimb [7]. While these studies have provided valuable data including the stress distribution within the MCP joint under quasi-static loading associated with midstance, there is no equine FEM that examines the effect of impact loading. Therefore, the purpose of this study was to create two subject-specific, three-dimensional, finite-element models of the equine MCP joint (one with advanced OA and one healthy) and compare the stress distribution patterns under impact loading in each model.

Methods: Two right MCP joints (third metacarpal and proximal phalanx) were scanned using micro-computed tomography (μCT). Images were segmented, and meshed using modified 10-node quadratic tetrahedral elements. Bone material properties were assigned based on the bone density. An impact velocity of 3.55 m/s was applied to each model and contact pressures and stress distribution were calculated for each. In a separate iteration, the third metacarpal was loaded statically. A sampling grid of 160 equidistant points was superimposed over selected slices, and average peak

stresses were calculated for 6 anatomical regions. Within-region maximal peak and average von Mises stresses were compared between healthy and OA bones in both midstance and impact loading.

Results: Average impact stresses across all regions, in both locations (palmar and dorsal) were greater in the OA model (Figure 1). Highest impact stresses were located in the dorsal medial condyle in the healthy (12.8 MPa) and OA (14.1MPa) models, and were lowest in the palmar medial and lateral parasagittal grooves in the healthy (5.94 MPa) and OA (7.07 MPa) models. The healthy static model had higher peak (up to 49.7% greater) and average (up to 38.6% greater) stresses in both locations and across all regions compared to the OA static model.

Figure:



Caption: Figure 1: Comparison of von Mises (MPa) surface stress (left) and a lateromedial slice of von Mises stress (right) between healthy and OA models under impact loading. M: Medial, L: Lateral

Conclusion: Impact loading creates stresses similar to those found during midstance and both loading conditions are likely to contribute to the repetitive stress that overtime lead to OA within the MCP joint. Both impact and static loading should be considered for future studies involving joint mechanics in the context of injury causation.

FACILITATED SOLEUS H-REFLEX AND NORMAL GAIT VARIABILITY DURING WALKING IN PEOPLE WITH KNEE OSTEOARTHRITIS

Tine Alkjaer [1,*]Helle Dalsgaard [1]Peter C. Raffalt [1]Erik B. Simonsen [1]Nicolas C. Petersen [2]Henning Bliddal [3]Marius Henriksen [3]

[1]Department of Neuroscience and Pharmacology, [2]Department of Neuroscience and Pharmacology & Department of Nutrition and Exercise, University of Copenhagen, Copenhagen N, [3]Clinical Motor Function Laboratory, The Parker Institute, Department of Rheumatology, Copenhagen University Hospitals, Frederiksberg, Denmark

Introduction and Objectives: Osteoarthritis (OA) of the knee is very common [1] and associated with significant pain and mobility limitations. Walking is a fundamental movement, which enables humans to ambulate independently and walking disability has been independently associated with higher all-cause mortality in people with knee OA [2]. Adequate function of the knee joint is critical for normal walking performance and may be impaired by knee OA. Numerous studies have compared neuromuscular and biomechanical aspects of walking in people with knee OA with those of healthy controls suggesting different muscle activation, kinematic and/or kinetic patterns. These differences in neuromuscular and biomechanical aspects of walking could link to differences in basic movement control strategies that can be determined from basic neuromechanical assessments, such as the soleus (SO) Hoffmann (H)-reflex [3] and altered gait pattern variability [4]. Thus, in the present study we assessed the SO H-reflex modulation during walking and gait variability in patients with knee OA and in healthy controls. The purpose was to test the hypothesis that the excitability of the SO H-reflex would be facilitated and that the gait pattern regularity would be increased in patients with knee OA compared with healthy age-matched subjects.

Methods: We included patients with a clinical diagnosis of knee OA (radiographically verified) from the OA outpatient clinic at Copenhagen University Hospital Bispebjerg and Frederiksberg. Healthy age-matched volunteers were recruited among colleagues and relatives of employees at the University of Copenhagen. The experiment consisted of two parts: 1) Assessment of soleus (SO) H-reflex modulation during walking and 2) assessment of the temporal structure of kinematic gait pattern (i.e. regularity) and muscle activities during walking. The SO Hoffmann (H)-reflex modulation was assessed during treadmill walking due to the method described in [3]. In separate trials the kinematic gait variability was assessed from goniometry of the ankle and knee joints. The regularity of the kinematic gait pattern was assessed by sample entropy. In addition, muscle activities of ankle and knee joint muscles were recorded. The subjects were asked to walk continuously for 6 min on the treadmill at 3.5 km/h, while the muscle activity and goniometer signals were recorded. The sampling was triggered by a footswitch placed under the heel.

Results: Fifteen OA patients (females) met the inclusion criteria and were invited to participate in the study. Eleven OA patients accepted the invitation while four patients were unable to participate for logistical reasons. Eleven healthy age-matched female subjects were recruited as controls. The SO H-reflex excitability was significantly increased in the knee OA group around heel strike when compared with the controls (Fig. 1). The mean group difference in the H-reflex in the

initial part of the stance phase (control – knee OA) was -6.6 %Mmax (95% CI: -10.4 to -2.7, p=0.041). No statistically significant mean group differences were observed in the kinematic gait pattern regularity or muscle activity.

Figure:

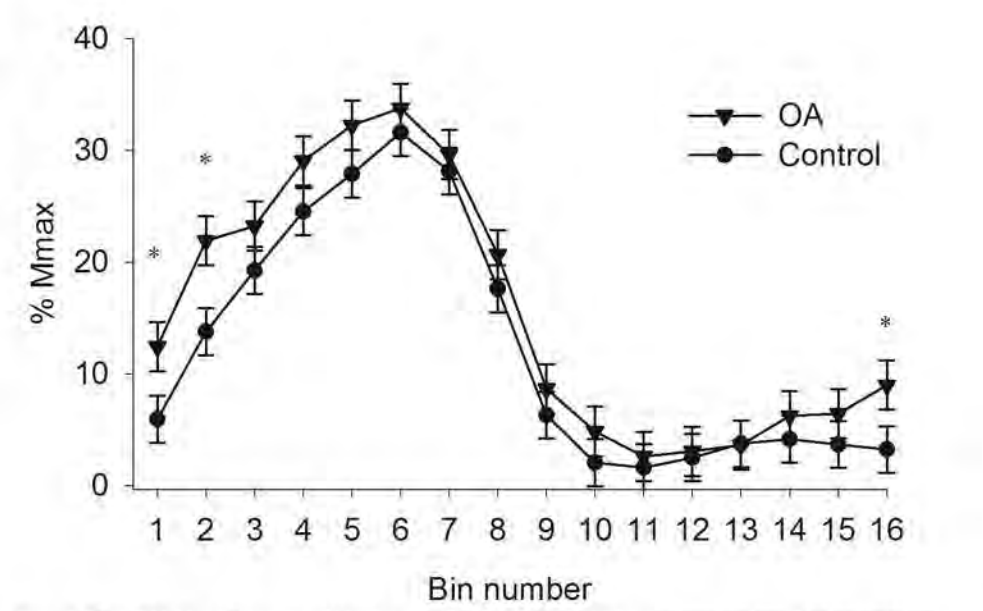

Fig. 1 The SO H-reflex modulation over the gait cycle averaged in 16 bins (stance phase bin 1-10 and swing phase bin 11-16) of the OA (filled triangles) and control groups (filled circles). Error bars are ±SE. Asterisks indicate statistical significant differences between the groups at $p<0.05$.

Conclusion: We suggest that these results reflect that the OA group walked according to a neural strategy favoring protection against loading induced pain in the loading acceptance phase of the gait cycle. This indicates that the OA group increased the excitability of the plantarflexor stretch reflex as a preparatory mechanism to avoid sudden pain induced quadriceps inhibition during walking that may result in episodes of “giving way“ of the knee joint which are common in knee OA.

EMG

AS-0243

SUBJECT-SPECIFIC INTRINSIC AND EXTRINSIC THUMB MUSCLE ACTIVITY DURING FUNCTIONAL TASKS OF DAILY LIFE

Faes Kerkhof [1,*] Gertjan Deleu [1] Priscilla D'Agostino [1] Evie Vereecke [1]

[1] Development and Regeneration @ Kulak, Leuven University, Kortrijk, Belgium

Introduction and Objectives: The trapeziometacarpal (TMC) joint is subjected to severe compressive forces during manual tasks which are for a large part due to muscle contraction. Furthermore, muscles surrounding the TMC joint are important stabilizers of this highly mobile, and intrinsically unstable, joint. On the other hand, joint instability and high compressive forces have been linked to the onset of osteoarthritis (OA), suggesting that the muscles surrounding the TMC joint play an important role in the development of TMC OA. The aim of this study is to explore if specific muscle activation patterns can be found during a lateral key pinch, power grasp and jar twist task to eventually relate those to joint loading.

Methods: Isometric forces and fine-wire electromyographic (fEMG) activity produced by 4 intrinsic thumb muscles (m. abductor pollicis brevis, m. adductor pollicis, m. flexor pollicis brevis, m. opponens pollicis) and 4 extrinsic thumb muscles (m. extensor pollicis brevis, m. extensor pollicis longus, m. abductor pollicis longus, m. flexor pollicis longus) were measured in 11 healthy female volunteers. Muscle activity was captured using an 8 channel Delsys wireless system. Pairs of disposable hooked wire electrodes were inserted by a certified hand surgeon using an ultrasound guided technique. Isometric force data were collected using a load cell embedded in a custom-made polycarbonate jig. The participants performed isometric contractions for 5 seconds during a key pinch, a power grasp and a jar twist task. They were instructed to perform two maximal isometric contractions and one contraction at 80% of their maximal force per task. The tasks were executed with and without EMG recording to verify if electrode placement influenced force production.

The raw EMG signals were filtered (10 Hz, high pass 2nd order Butterworth) and the full wave was rectified using EMGworks 4.0 analysis software. Normalization was achieved by using the highest EMG amplitude per muscle and per subject.

A Wilcoxon signed-rank test was used to statistically test the difference between the normalized intrinsic and extrinsic muscle activity. A paired t-test was applied to compare the generated force pre- versus post-electrode insertion.

Results: A high interindividual variability in muscle activity was seen in all three tasks. In both the maximum effort as well as the 80% effort, no significant differences in activation between intrinsic and extrinsic muscles were found in the pinch or grasp task ($p>=0.05$). However, the maximal effort jar twist task resulted in a significantly higher activation of the intrinsic compared to the extrinsic muscles ($p=0.003$).

Insertion of the fEMG electrodes appeared to significantly decrease the external force production in all tasks during both maximum and 80% effort contractions (table 1).

Conclusion: The thumb muscles display a high interindividual variability in muscle activity during functional tasks of daily life, such as pinch, grasp and jar twist. The results of this study suggest that to produce a substantial amount of force, a well-integrated, but subject-specific, co-contraction between the intrinsic and extrinsic thumb muscles is necessary. Despite the variability, these findings can be used as input for an EMG-driven musculoskeletal model. Further research

will focus on how differences in muscle activation patterns influence joint loading and if this could contribute to the onset of trapeziometacarpal joint osteoarthritis.

Table:

Effort	Task	Force Before (N)	Force After (N)	p-value
Maximum	Grasp	119.04±26.38	97.13±23.67	$p<0.001^1$
	Pinch	100.96±27.45	75.85±17.34	$p<0.001^1$
	Jar twist	148.97±45.14	112.24±43.65	$p<0.05^1$
80%	Grasp	82.95±20.24	73.04+18.29	$p<0.05^1$

MOVEMENT CONTROL DURING ACTIVE SPINAL RANGE OF MOTION IS ACHIEVED BY A DIFFERENTIAL USE OF ECCENTRIC AND CONCENTRIC MUSCLE ACTIVITY

Stephanie Valentin [1,*]Theresia Licka [1]

[1]Movement Science Group, Equine Clinic, University of Veterinary Medicine Vienna, Vienna, Austria

Introduction and Objectives: Neuromuscular control of the rectus abdominis (RA), obliquus internus (OI), obliquus externus (OE), and erector spinae (ES) muscles has been widely investigated during a range of conditions such as perturbations [1], stability exercises [2], gait [3] and other functional exercises [4] using electromyography (EMG). However, little attention has been paid to activity of these muscles during spinal range of motion exercises, in particular in a 4-point kneeling posture (4P), even though this posture is often adopted for low back pain exercises. The aim of this study was to investigate the concentric and eccentric activity of trunk muscles during active spinal range of motion exercises in young and mature healthy adults in two postures.

Methods: Twenty-four healthy participants (12 young, aged 18-25 years; 12 mature, aged 45-60 years) were included. Reflective markers were attached over the spinous process of the 11th thoracic vertebra (T11), the head, the left and right styloid processes, and lateral femoral condyles. Three-dimensional kinematic data were collected using 10 high speed cameras (Eagle Digital Real Time System, Motion Analysis Corp., 120Hz). Surface EMG electrodes (Delsys Trigno, 1200Hz) were attached over the left and right ES, RA, OE, and OI after skin preparation. Data were collected during three repetitions of 10s of flexion and extension movements in U and 4P. Participants were instructed to perform each movement to their end range and return to the starting posture in one fluent movement. Raw EMG data were resampled, rectified, zero-mean offset, and a 4^{th} order low pass Butterworth filter applied. Processed EMG data from 0.5s before movement onset and 0.5s after movement cessation (both based on vertical T11 movement) were included for analysis. EMG data were normalised to the maximally observed muscle activity from any trial and movement for each muscle, and the maximum and 1^{st}, 2^{nd}, and 3^{rd} quartiles (Q1, Q2, Q3) calculated for the concentric and eccentric phase of muscle activity. Due to non-normally distributed data, differences between concentric and eccentric activity were compared for Q1, Q2 and Q3 in the young and mature groups separately using a Wilcoxon Rank test.

Results: Significant differences were found for every muscle and quartile, although this was dependant on age group, posture adopted and movement direction. Where significant differences occurred in 4P, concentric activity was greater than eccentric activity for flexion and extension in both the young group (flexion: RA left Q1, all abdominal muscles Q2 and Q3; extension: ES Q2 and Q3, RA and OE left Q1 and Q2, OI all quartiles; all $p<0.05$) and mature group (flexion: ES left all quartiles, ES right Q1, all abdominals Q3, RA right and OI left Q2, extension: ES Q2 and Q3, OI and OE Q1 and Q2, OI right Q3; all $p<0.05$). However, for both age groups in U during flexion, concentric activity was significantly greater than eccentric activity for ES in all quartiles, but eccentric activity was significantly greater than concentric activity in the abdominal muscles (young group: OE left Q1, OI right all quartiles; mature group: OE left Q1 and Q2, OE right Q2 and Q3, OI left all quartiles; all $p<0.05$). The opposite was found for extension, where eccentric activity was significantly greater than concentric activity for ES but only in the young group (all quartiles; $p<0.05$), and concentric activity was

significantly greater than eccentric activity in the abdominal muscles (young group: OE left Q3, OI Q1 and Q3; mature group: RA Q3, OE and OI left Q1, OE right and OI Q3; all $p<0.05$).

Conclusion: Muscle activity is generally larger during concentric than during eccentric muscle use [5]. However, the overall findings from this study would indicate that antagonist muscle activity is usually greater during the concentric phase and agonist muscle activity is greater during the eccentric phase during active range of motion exercises in U. This is in contrast with 4P, where concentric muscle activity was greater than eccentric activity in both agonists and antagonists. These findings were identified in both age groups. Probably the effect of gravity in U reduces the need for concentric activity during active range of motion exercises and the eccentric activity, which provides control and deceleration during approach of the neutral posture, plays a more important role. The results of this study may be of relevance when selecting range of motion exercises in a low back pain rehabilitation setting.

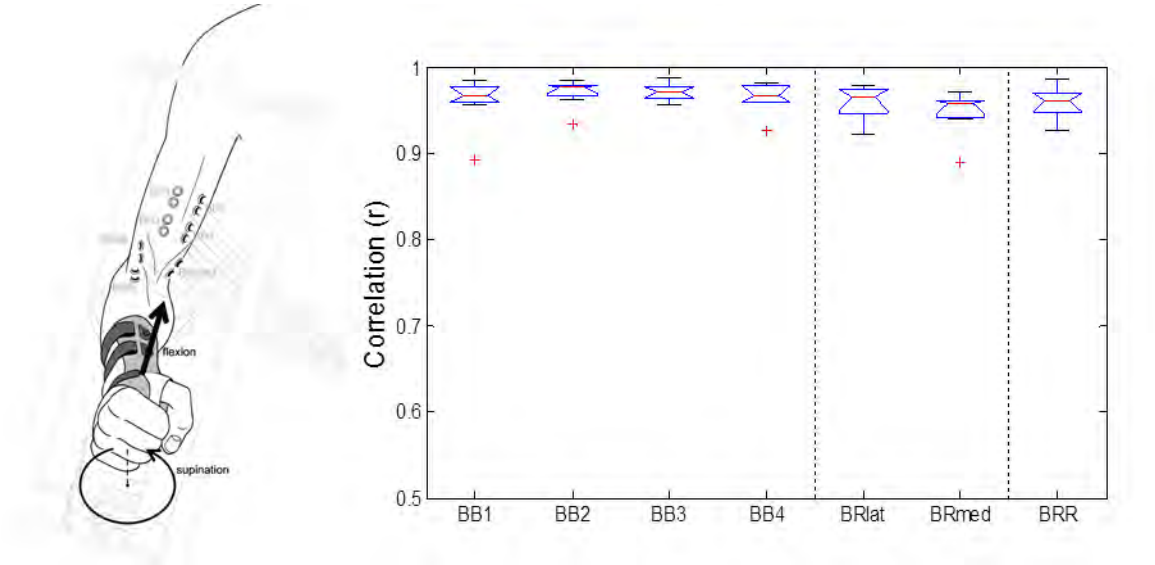
THE ASSESSMENT OF BRACHIALIS MUSCLE ACTIVATION WITH SURFACE ELECTROMYOGRAPHY

Didier Staudenmann [1,*] Wolfgang Taube [1]

[1]Movement and Sport Science, Department of Medicine, University of Fribourg, Fribourg, Switzerland

Introduction and Objectives: The brachialis muscle (BR) represents an important elbow flexor and its activity has so far mainly been measured with intramuscular electromyography (EMG). In contrast to the biceps brachii (BB) that inserts into the radius (biceps tubercle) and is thus active during elbow flexion and forearm supination, the BR inserts into the ulna and therefore exclusively contributes to flexion force. Consequently, pure elbow flexion should result in activity in both BB and BR whereas elbow flexion with superimposed forearm supination (flexion+supination) should preferentially activate the BB – provided that recordings in BR are not contaminated by the neighboring BB muscle. Thus, the aim of this study was to examine whether the activity of the BR can be assessed with surface EMG without interference from the BB.
Methods: With eight subjects we measured surface EMG of the arm flexor synergists BR, BB, and brachioradialis (BRR) during two isometric voluntary contraction types (see Figure): 1) pure elbow flexion and 2) flexion+supination. The correlation coefficients between EMG amplitudes and flexion force (supination torque) were determined.
Results: During pure flexion the activities of all synergists were similarly correlated with the flexion force (r=0.96±0.02; p=0.075, see Figure). During flexion+supination the activity of the BR was significantly distinct from the activity of the BB (p<0.01), with a 14% higher correlation for the BR with the flexion force and a 40–64% lower correlation with the supination torque. The BB predicted supination torque substantially better than the BR and BRR (r=0.93±0.02; p<0.01).
Figure:



Conclusion: The muscles generating an elbow flexion are the BB, BR and BRR, with a major contribution from the BR. However, it was not clear so far, whether it is possible to record activity of the BB with surface EMG without interference from BR. The current results indicate a clear distinction between BB and BR as activity in these synergistic muscles was similarly well correlated to flexion force in the first contraction type (pure flexion) but different for the second contraction

type (flexion+supination). It can therefore be concluded that the activity of the BR can be assessed with surface EMG without substantial interference from the BB.

Caption: Figure: Left: Position of the right arm during isometric elbow flexion (forearm supination) with electrode over biceps brachii (BB), brachialis (BR) and brachioradialis (BRR). Right: correlation between EMG amplitude and elbow flexion for the different muscle sites.

THE EFFECT OF FEAR OF FALLING AND VESTIBULAR SENSORY FEEDBACK ON POSTURAL CONTROL KINEMATICS

Jonathan de Melker Worms [1,*] John Stins [2] Peter Beek [2] Ian Loram [1]

[1]Faculty of Science and Engineering, School of Healthcare Science, Manchester Metropolitan University, Manchester, United Kingdom, [2]MOVE Research Institute Amsterdam, Faculty of Human Movement Sciences, VU University Amsterdam, Amsterdam, Netherlands

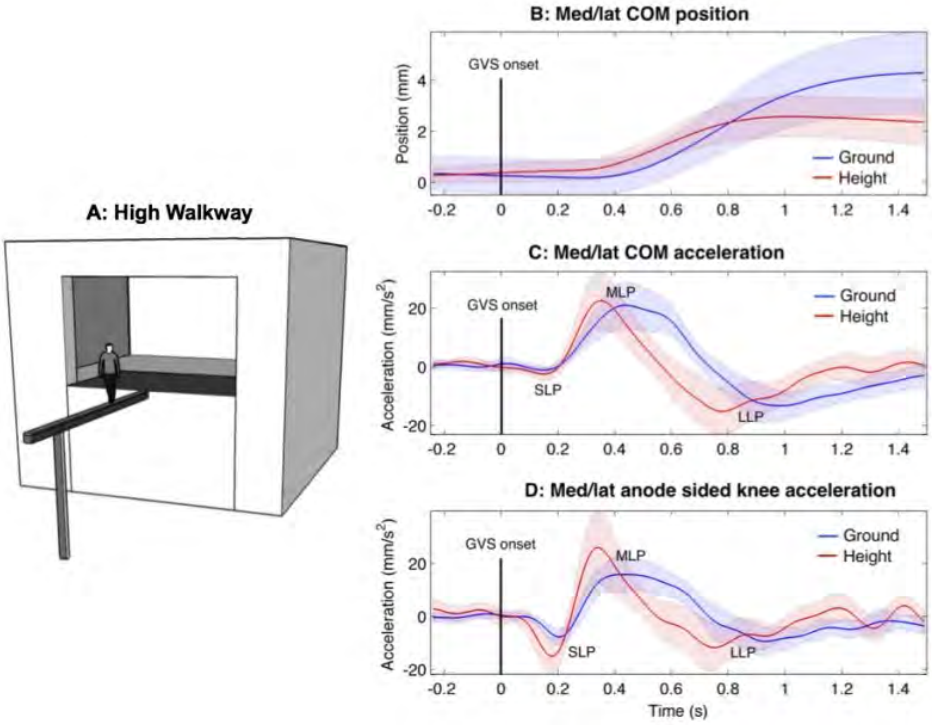
Introduction and Objectives: In the elderly, fear of falling is associated with an increased risk of falling. In this study we focus on direct effects of fear of falling and vestibular sensory feedback on full body postural control. Using galvanic vestibular stimulation (GVS) sensory information from the vestibular nerve is modified, causing increased body sway [1]. The literature shows inconsistent effects of fear of falling and vestibular sensory feedback on postural control. Using kinematic data Osler et al. [1] inferred that induced body sway within 800 ms after GVS onset is unaffected by fear of falling, by comparing subjects standing at height and at ground level. Conversely, using a continuous stochastic GVS signal (SVS) and recording ground reaction force (GRF) data, Horslen et al. [2] found increased SVS-GRF coupling at height compared to ground at 2 time points in the early time domain. The time points were termed short latency peak (SLP) at ~150 ms and medium latency peak (MLP) at ~ 300 ms of delay. We aimed to investigate the kinematic mechanism of the SLP and MLP processes identified in the SVS-GRF coupling. Using full body kinematics we investigated the effect of fear of falling on the timing of the GVS response of the whole kinematic chain.

Methods: For 16 young healthy adults (10 men and 6 women, age: 25.9 ± 5.1 years, height: 1.74 ± 0.1 m, weight: 69.5 ± 13.5 kg, BMI: 22.9 ± 3.5) vestibular-evoked balance responses were studied while standing on a narrow walkway at ground level and at a height of 3.85 m to induce fear of falling (Fig. 1A). In the height condition some participants appeared to have difficulty to leave the safety of the first floor mezzanine and step onto the exposed walkway. Full-body kinematics was collected (Vicon Motion Systems Ltd., Oxford, UK) and skin conductance was recorded during all trials as a measure of physiological arousal. GVS was delivered using carbon rubber electrodes (46 by 37 mm) placed in a binaural bipolar configuration similar to the method of Osler et al. [1]. Each subject was tested in the high and ground walkway conditions in counter-balanced order. Subjects' feet were placed together, directed along the antero-posterior axis of the walkway. They stood with eyes closed and head facing directly forwards. In each condition 30 GVS impulses of 2 seconds (15 anode-left, 15 anode-right, randomly ordered) were applied at intervals of 20 seconds.

Results: Between 1-1.5 s after GVS onset the maximum mediolateral displacement of the COM was higher at ground level ($t=3.45$, $df=15$, $p=0.004$) than at height (Fig 1B, lines are averages and shaded areas are 95% confidence intervals). When the mediolateral COM acceleration time series at ground and height are compared, three peaks can be distinguished (Fig. 1C). We refer to these peaks as short latency peak (SLP: minimum 0.05-0.3s), medium latency peak (MLP: maximum 0.2-0.8s) and late latency peak (LLP: minimum 0.5-1.5s). In the height condition SLP amplitude was increased ($t = -2.15$, $df = 15$, $p = 0.049$) and MLP and SLP occurred earlier compared to ground, (MLP: $t = 5.21$, $df = 15$, $p < 0.001$; LLP: $t = 3.39$, $df = 15$, $p = 0.004$). Figure 1D shows the mediolateral anode sided knee acceleration. SLP

amplitude of the mediolateral sway acceleration of the knees was increased at height (Anode sided knee: t = -2.27, df = 15, p = 0.039; Cathode sided knee: t = -2.74, df = 15, p = 0.015). No height effect was found on neck and lower back joint angle acceleration GVS responses in the frontal plane.

Figure:



Conclusion: The time domains and directions of our SLP and MLP COM acceleration data was congruent with SVS-GRF coupling data from Horslen et al. [2]. We interpret the SLP and MLP to be part of a reflexive response that initiates increased body sway, whereas LLP is mediated by higher order sensory integration of proprioceptive and vestibular information that terminates the body sway caused by GVS. The increase of early (SLP and MLP) body segment acceleration at height was only present in the lower extremities. This effect was strongest in the acceleration of the knee joint centres and it is in line with a more excited early motor response to vestibular stimuli. This might also provide the mechanism of the early effect of postural threat on the SVS response identified by Horslen et al. [2]. Our results are in accordance with Forbes et al. [3] who found early GVS neck muscle responses to be task independent as opposed to appendicular muscle responses that were attenuated when they were less relevant for balance control. In conclusion, fear of falling changes the effect of vestibular sensory feedback on lower extremity kinematics during standing and these postural effects are present within a short time delay of 0.1 s. This indicates modification of appendicular vestibular fast reflexive pathways caused by fear of falling.

ARE MANDIBULAR KINEMATIC MEASUREMENTS RELIABLE DURING MAXIMUM MOUTH OPENING IN HEALTHY SUBJECTS?

Letícia B. Calixtre [1,*]Theresa Helissa Nakagawa [1]Lianna Rosa [1]Bruno Leonardo Grüninger [1]Francisco Alburquerque-Sendín [2]Ana Beatriz Oliveira [1]

[1]Physical Therapy, Federal University of São Carlos, São Carlos, Brazil, [2]Physical Therapy, Salamanca University, Salamanca, Spain

Introduction and Objectives: The knowledge about reliability of kinematic measurement during maximum mouth opening (MMO) can provide information regarding the consistency of motor patterns. This measurement is often compromised among patients with temporomandibular dysfunctions (TMD), affecting their functionality.

Fixing markers on the skin can cause movement artifacts due to the skin stretching and the palpation of anatomical structures that can vary according to the evaluator skill and anthropometric characteristics of the subjects.

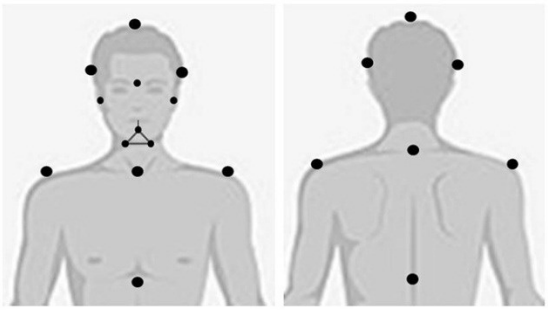
Therefore, the purpose of this study was to analyze test-retest reliability and standard error of measurement (SEM) of mandibular movements during MMO recorded with a motion capture system and a vernier caliper.

Methods: Twenty-one healthy subjects (8 males and 13 females; 23.95±2.47 years; 23.61±2.73kg/m^2) with no current history of mandibular or neck trauma and absence of signs and symptoms of TMD, like: pain on temporomandibular joint (TMJ), difficulty to perform mandibular movements, muscular pain or fatigue during chewing, clicking during mandibular function, and parafunctional habits. They achieved at least 3.5mm of MMO.

Two evaluations were performed in the same day (E1 and E2), and a third one was performed 5-7 days later (E3). MMO was measured three times with a caliper (Somet, 150mm, Inox, Czechoslovakia) while the subject was seated (E1). Markers were positioned and kinematics recordings were performed (E1). After 10 min, the same rater replaced the markers and kinematics was recorded again (E2) for intra-session reliability analysis. The same procedure (E1) was repeated in E3 to evaluate inter-session reliability. All kinematic data was recorded at 120 Hz with a six-camera motion capture system (Qualisys Inc., Gothenburg, Sweden). The subject performed two series of five MMO at free velocity, starting from mandibular intercuspal position. Tridimensional movements of head, mandibulla, and trunk were tracked through passive markers (Figure 1) by the Qualisys Track Manager (Qualisys AB Packhusgatan, Gothenburg, Sweden). An equilateral triangular stainless steel extraoral antenna (side 40 mm; weight 2 g), fixed on the mandibular anterior gingiva using surgical adhesive, and markers on the TMJs, provided a mandibular reference system. On the static take, a marker was located on the midline incisal edge to identify a dental landmark, relative to the antenna system. Three-dimensional reconstruction was performed using Visual 3D software. Incisor displacement (mm), MMO on sagittal plane (deg), condylar translation during mouth opening and closing (mm) were analysed by a custom made Matlab software (version 7.0.1, MathWorks Inc., Natick, USA) [1]. Intra and inter-session reliability was evaluated through the Intraclass Correlation Coefficient (ICC) using SPSS software (v19, SPSS, Chicago, IL). SEM was calculated using Excel (SEM = SD×√1−ICC). ICC's upper to 0.61 and 0.81 were considered as good and very good, respectively [2].

Results: All kinematic data are presented in Table 1. The MMO measurements with caliper from the first session (E1) presented mean±standard deviation of 48.8±6.9, 48.95±6.8 and 49.3±6.4, while on the second session (E2) of 49.23±7.1, 49.23±6.5 and 49.6±7.1. The intra-session ICCs were very good (0.987 and 0.972) with low SEMs (0.75 and 1.14) and as well as the inter-session ICC (0.91) and SEM (2.01).

Figure:



Caption: Figure1. Position of the passive markers.

Conclusion: Incisor displacement as well as MMO measured with the caliper presented very good intra-session and inter-session reliability, both with low SEM. The other kinematic variables had good intra-session reliability and low SEM, while inter-session reliability was low and SEM was high. These results support the use of 3D kinematic video analysis and caliper rule to measure mandibular movements during MMO. However, caution must be taken when interpreting MMO on sagittal plane, and condylar translation movements over time due to the low inter-session reliability and high SEM.

Table:

Variable	E	Mean (SD)	ICC		SEM	
			INTRA	INTER	INTRA	INTER
Incisor displacement (mm)	1	40.34 (7.7)	0.871	0.827	2.48	2.88
	2	40.14 (6.2)				
	3	40.96 (7.7)				
MMO on sagittal angle (deg)	1	-27.90 (4.2)	0.86	0.37	1.59	7.64
	2	-27.02 (4.4)				
	3	-27.95 (13)				
Condylar translation - mouth opening (mm)	1	14.02 (4.9)	0.699	0.204	2.51	5.25
	2	12.35 (4.2)				

	3	17.18 (6.4)				
Condylar translation - mouth closing (mm)	1	14.93 (4.9)	0.671	0.192	2.71	5.51
	2	13.57 (4.6)				
	3	18.06 (6.7)				

Caption: Table 1. Mean, standard deviation (SD) of kinematic measurements recorded in the three evaluations (E). ICC and SEM are presented for both intra (INTRA) and inter-session (INTER) comparisons.

GAIT ANALYSIS OF TKA PATIENTS AT 2 WEEKS AND 4 WEEKS AFTER SURGERY USING WEARABLE SENSORS

Ryo Takeda [1,*]Tadashi Fujisawa [1]Giulia Lisco [2]Laura Gastaldi [2]Stefano Pastorelli [2]Harukazu Tohyama [3]Shigeru Tadano [1]

[1]Engineering, Hokkaido University, Sapporo, Japan, [2]Mechanical and Aerospace Engineering, Politecnico di Torino, Torino, Italy, [3]Health Science, Hokkaido University, Sapporo, Japan

Introduction and Objectives: This work investigates the changes in kinematic and spatio-temporal gait parameters of patients with total knee arthroplasty (TKA) after 2 and 4 weeks of surgery using wearable sensors. The objective of this work was to compare the gait parameters of TKA patients between 2 and 4 weeks after surgery and verify the rehabilitation training effects within those time periods. All the materials of this work was conducted with wearable sensors attached to the lower limbs.

Methods: The wearable gait analysis system H-Gait (Development Code, Laboratory of Biomechanical Design, Hokkaido University, Sapporo, Japan) was used in this work. Seven sensors units containing tri-axial acceleration and tri-axial gyro sensors were attached to seven locations of the lower limb (pelvis, both thighs, both shanks and both feet). The acceleration and angular velocity data of each sensor unit of each body segment of the patient could be collected by a computer in real-time by Bluetooth wireless transmission.

Five patients with TKA surgery (3 right TKA, 2 left TKA) to only one knee participated in the measurements. All patients gave their consent for the measurements. Seven sensors units (WAA-006, Wireless Technologies, Inc.) were fixed by straps to the lower limb segments of the patient. The acceleration and angular velocity data of each sensor unit were measured at a sampling rate of 100Hz during level walking (7 to 10m) at 2 weeks and 4 weeks after surgery. In between the measurements patients were went through rehabilitation training at the Hokkaido University Hospital (Sapporo, Japan). For safety purposes the walking speed for each measurement was at the discretion of the patient. These measured data were sent to a computer via Bluetooth and then converted to three dimensional segment orientation data using a developed quaternion based algorithm [1]. The developed algorithm contained countermeasures to reduce the effect of signal drift errors such as, an infinite impulse response (IIR) digital 4th order Butterworth filter, mode value offset extraction, double derivative and integration (DDI) and two posture sensor attachment calibration [2]. In addition the lower limb segment length of the patients was measured using reflective maker attached to anatomic characteristic points. Lower limb gait joint kinematic parameters such as: flexion-extension angle (hip and knee), dorsi/plantar flexion angle (ankle), adduction-abduction angle (hip, knee and ankle), internal-external rotation angle (hip, knee and ankle) , sagittal joint center trajectory (hip, knee and ankle) and horizontal joint center trajectories (knee and ankle) were calculated. Furthermore, spatio-temporal gait parameters such as: gait cycle, cadence, step length, step width, stride length, walking speed, limp index, stand ratio, swing ratio and heel contact timing and toe off timing of the foot were calculated.

Results: As a result, the following was found by comparing the gait data of all patients between 2 and 4 weeks after surgery. The range of motion of the TKA side's knee increased by 40%, the range of motion of the TKA side's hip by 26%, the range of motion of the not TKA side hip by 27%, the stride length by 40%, the cadence by 25%, the walking speed by 72%, the step length of TKA side by 51% and the step length of the not TKA side by 32% and the ratio of stance phase in

TKA side decreased 5.7% and the ratio of stance phase in not TKA side decrease 7.1% on average. And the difference of each side's step length has decreased from 4.3cm to 0.4cm. This means that the patients at 4weeks after surgery were able to walk more symmetric than at 2 weeks. The increase of knee extension angle at heel contact timing by 4.7deg and the increase of hip flexion angle at heel contact timing by 2.7deg result in developed stride and step length increase.

Conclusion: From the result presented above, it was verified that a wearable sensor system can evaluate a patient's rehabilitation progress by providing quantitative kinematic and spatio-temporal gait parameters in clinical situations.

Table:

Parameter	Side	2 weeks	4weeks	p-value
Walking speed [m/min]	-	28.89	46.37	0.01
Step length [cm]	TKA	32.14	48.65	0.00
	NOT TKA	36.42	47.96	0.00
ROM of Hip [deg]	TKA	29.75	37.43	0.00
	NOT TKA	28.51	36.14	0.00
ROM of Knee [deg]	TKA	22.84	33.37	0.00
	NOT TKA	41.08	44.25	0.25

VALIDATION OF A NEW ALGORITHM FOR THE DETECTION OF STEP DURATIONS IN SHORT EPISODES OF GAIT USING A SINGLE ACCELEROMETER DEVICE ON THE LOWER BACK.

María E. Micó Amigo [1,*] Idsart Kingma [1] Erik Ainsworth [2] Stefan Walgaard [2] Martijn Niessen [2] Rob van Lummel [2] Jaap H. van Dieen [1]

[1]MOVE Research Institute Amsterdam, Faculty of Human Movement, VU Amsterdam University, Amsterdam, [2]McRoberts B.V., McRoberts B.V., The Hague, Netherlands

Introduction and Objectives: To assess the validity of a new algorithm for the detection of step durations in healthy elderly subjects from accelerometry signals measured on the lower back during short episodes of gait.

Short episodes of gait are common in daily-life activity of the elderly [1], who select gait strategies with different spatio-temporal parameters for different distances. Thus, the assessment of short episodes of gait may provide clinical information that differs from information based on the assessment of long episodes of gait [2]. Subjects who cannot participate in long gait protocols due to their limited mobility might be able to perform short gait episodes instead, which are relevant for their independency at home. Moreover, short gait protocols are well suited to studying the initiation of gait and are easily implemented in clinical practice, given limited space and time requirements [3,4] However, only a few studies have analysed short episodes of gait with the use of body-fixed-sensors (BFS) to date. The location of the sensor on the lower back is near to the centre of mass, and it is well accepted by older adults. Furthermore, this location permits to assess postures and transitions in daily-life activity, and it may predict risk of falling [5].

Methods: 22 healthy elderly subjects (74.3±8.4 years old) walked a distance of 5 meters twice, wearing a BFS (DynaPort McRoberts) on the lower back, and a BFS (DynaPort MiniMod McRoberts) on the outside of each heel. Data were recorded at a sampling rate of 1 sample/10 ms. For step duration detection we developed a novel algorithm, which defines a template based on the autocorrelation of the raw acceleration signal in the anterior-posterior direction (AP).Subsequently, it calculates a signal (Diff), which is the difference in amplitude between the template and the raw AP signal. Then, the SD of the Diff signal is normalized to the SD of the template, giving a new signal (SD_Diff). The cross correlation signal between SD_Diff and the raw AP signal contains pronounced peaks, which remark periodic events being detected close in time to heel-strike events. The intervals between these events define the step durations. Step durations from the lower back acceleration signals were validated by comparison with step durations calculated from the combination of the right and left heel acceleration signals. Absolute differences between both methods for each interval were averaged within and over trials and subjects.

Results: 4 trials were excluded from the results due to the loss of a heel accelerometer during gait. The average difference for the other 40 trials was 28.6±14.6 ms (5.02 % of the average step duration).

Conclusion: A novel method for the detection of step durations in short episodes of gait based on a single accelerometer placed on the lower back is described and appears to provide valid estimates. The extraction of temporal parameters from short episodes of gait might provide relevant clinical information, starting from the detection of each step duration.

3D BODY CENTRE OF MASS TRAJECTORY IN LOCOMOTION: COMPARISON BETWEEN DIFFERENT MEASUREMENTS METHODS

Gaspare Pavei [1] Elena Seminati [1 2,*] Dario Cazzola [2] Alberto Enrico Minetti [1]

[1] Dept of Pathophysiology and Transplantation - Human Physiology Section, Università degli Studi di Milano, Milano, Italy,

[2] Department for Health, University of Bath, Bath, North East Somerset, United Kingdom

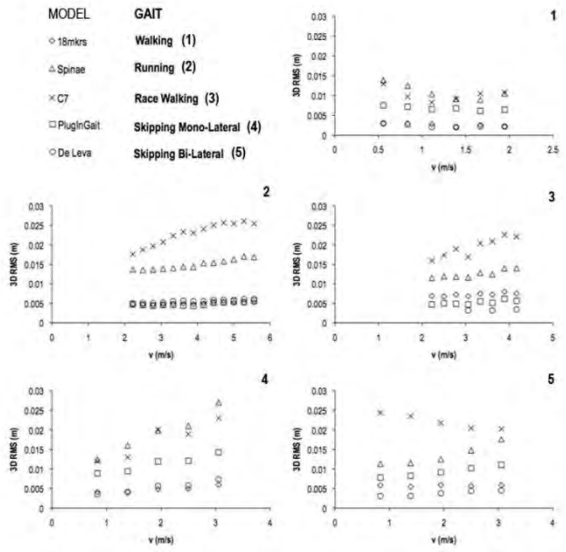
Introduction and Objectives: Body centre of mass (BCoM) trajectory is largely used to describe human and animal locomotion with the final aim to estimate the mechanical work performed by muscles. The BCoM can be calculated through 2 different methods: i) by double integration of ground reaction forces (GRF) and ii) by the weighted mean of the local centres of mass of the body anatomical segments, which are collected through an optoelectronic system. Although both methods are currently exploited, the use of the GRF is considered the gold standard as it provides a (relative) BCoM trajectory as caused by both hard and soft tissue motion. However, it allows capturing only a limited number of strides and repeated trials are requested for reliable results. Kinematic measurements, conversely, can be carried out while moving on a treadmill, so that an adequate strides number and speed could be collected. Several biomechanical models are available to analyse the kinetics of human body and the use of different anthropometric tables could bring discrepancies in the BCoM computation. In addition, markers placement, skin motion and the rigid segment assumption could lead to systematic errors. Previous studies compared these methods, but only few locomotion paradigms were investigated, mainly analysing only BCoM vertical motion. Aim of this study was to compare the 3D BCoM trajectory and the associated mechanical work (W_{EXT}) concurrently calculated by means of GRF and kinematic in 5 gaits and a wide range of speeds. Kinematic results were compared across 5 different sets of markers in order to verify their reliability.

Methods: One participant (1.78m, 63kg), performed different gaits on treadmill at incremental speeds: walking from 0.28 to 1.94m/s (increment 0.28m/s); running from 2.22 to 5.56m/s (increment 0.28m/s); race walking from 2.22 to 4.17m/s (increment 0.28m/s), mono- and bi-lateral skipping from 0.83 to 3.06m/s (increment 0.56m/s). An 8-camera Vicon system (Oxford Metrics, UK) sampled kinematics data at 300Hz for 1 minute at each velocity. Simultaneously a Mercury LT med treadmill (HP Cosmos, Germany), equipped with 4 3D strain-gauge force traducers, recorded GRF at 900Hz.

5 markers set were compared at the same time: 1) a single marker placed on the 7th cervical vertebra (C7); 2) the mean of anterior and posterior superior iliac spines (Spinae); 3) a 11-segments body model based on Dempster tables (18mkr); 4) a 14-segments body model based on De Leva tables (DeLeva); 5) a 14-segments body model based on the Vicon Plug-in-Gait model (PIG). In addition BCoM was obtained by double integration of the filtered GRF (low pass filter 4th order Butterworth with 30Hz cut off frequency). BCoM trajectory of each stride (local coordinates on treadmill) was isolated and the loop forced to close, according to Minetti's method [1]. A point-by-point 3D root mean square (3D RMS) was computed between the (reference) trajectory evaluated with GRF method and the one calculated with each of the 5 kinematic models. W_{EXT}, i.e. the positive work done to accelerate and raise BCoM, was calculated for each trajectory by summing the increment of total energy time course.

Results: The 3D RMS between the trajectories calculated with GRF method and kinematic methods indicated that the marker set exploiting C7 and Spinae showed the greatest discrepancy from GRF, whereas 18mkr and DeLeva models well matched all gaits and PIG was in accordance to GRF method only in running (see Fig.). Although the BCoM trajectory in race walking showed a small discrepancy in terms of RMS, its 3D contour was very different when compared to the one computed from GRF. W_{EXT} obtained from kinematic showed the slightest discrepancies when adopting PIG, 18mkr and DeLeva models (see Tab.).

Figure:



Caption: 3D RMS (in meters) between the trajectories calculated with GRF and kinematic methods.

Conclusion: The choice of the method (GRF or Kinematics) and of the biomechanical model has to be considered carefully, to obtain a reliable characterization of the BCoM. Commonly used whole-body biomechanical models (18mkr and DeLeva), lead to BCoM trajectories and W_{EXT} in walking, running and skipping very close to the one calculated through the gold standard. In contrast the use of a single marker placed on the trunk or the mean position from the pelvis landmarks is not a reliable estimation of the 'true' BCoM position, and negatively affects W_{EXT} calculation.

Kinematic measurements can be exploited to describe the BCoM in locomotion, but the result could be completely different from the real one when the gait differs from standard locomotion paradigms. In race-walking for example, although the pattern of the BCoM travels within an acceptable 3D volume, its shape completely differs from the 'reference' one (GRF).

Table:

	Walking	Running	Race Walking	Skipping
C7	+16%	-18%	-24%	+4%
Spinae	+35%	+106%	+78%	+30%
18mkr	+13%	+22%	+10%	+15%
DeLeva	+13%	+10%	+17%	+3%
PlugInGait	+6%	+12%	-13%	+15%

DEVELOPMENT OF A BESPOKE BIOMECHANICAL MODEL FOR REAL-TIME CALCULATION OF LOWER LIMB KINEMATICS.

Lindsay Clarke [1,*] Andrew J Murphy [1] Phil Rowe [1]

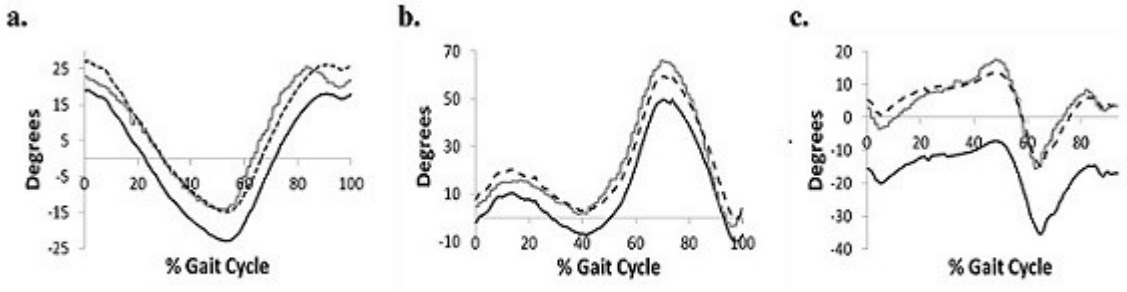
[1]Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom

Introduction and Objectives: Human movement analysis may be considered an essential tool in clinical and research biomechanics[1,2]. A number of commercially available systems allow the accurate and quantitative description of a participant's gait[3]. However, the use of these systems generally limits the user to predefined models or requires users to have significant technical expertise for creating bespoke models. Further, while it is possible to manipulate certain aspects of the established motion analysis process, current platforms do not allow complete customisation. The aim of this investigation was to build a customisable, bespoke biomechanical model (LJC) using an object-oriented application development package with integrated Lua based programmatic scriting modules; D-flow (Motek Medical, The Netherlands). The components of the model include a marker set, a method of calibrating a participant and calculation of kinematics.

Methods: A bespoke cluster marker set with strategically placed anatomical markers was implemented. Marker trajectory data was captured, labelled and streamed into D-Flow using Vicon hardware and acquisition software (Vicon Motion Systems, Oxford, UK). A static calibration method was devised whereby the offsets of the calibration markers from the clusters are calculated for each segment. The Winter method[4] was used to reconstruct calibration markers during dynamic trials and the Grood and Suntay[5] method was used to calculate kinematics. This was implemented in D-Flow using bespoke scripting modules written in Lua programming code. Pilot testing against Plug in Gait (PIG; Vicon Motion Systems, Oxford, UK) was completed with one typically developing adult participant.

Results: Flexion angles of the hip, knee and ankle were examined during normal treadmill walking (figure 1). Results demonstrated similarities in trace and range of motion (ROM), however, for all joint angles there was a consistent offset of absolute angle. When the mean difference between datasets was added to PIG data, there was much stronger agreement.

Figure 1. Black - PIG; grey - LJC; dashed - PIG plus mean difference. **a.** Hip **b.** Knee **c.** Ankle.



Conclusion: Initially, results do not indicate good agreement between PIG and LJC. However, the offset between data sets appears to be consistent across all joints. It may be that inaccurate PIG marker placement contributed to errors in PIG data. Tibial and femoral wands were not used which could contribute to inaccuracies. Further, PIG ankle data suggests that no dorsiflexion occurs throughout the cycle. This is highly unlikely for a typical adult which suggests that there may be some error in PIG data. Work is ongoing to determine the source of the errors.

The development of a bespoke biomechanical model allows complete customisation. The model can be altered to allow a choice of marker set or calibration methods. The possibility also exists to build specific functionalities for specific users, providing an advantage over commercially available models.

EFFECT OF WEARABLE TRUNK SUPPORT FOR WORKING IN SUSTAINED STOOPED POSTURE ON LOW BACK NET EXTENSION MOMENTS

Chris T.M. T. Baten [1,*] Remon van der Aa [1] Annechien Verkuyl [2]

[1]Ambulatory 3D Analysis of Movement, Roessingh Research and Development, Enschede, [2]Intespring, Delft, Netherlands

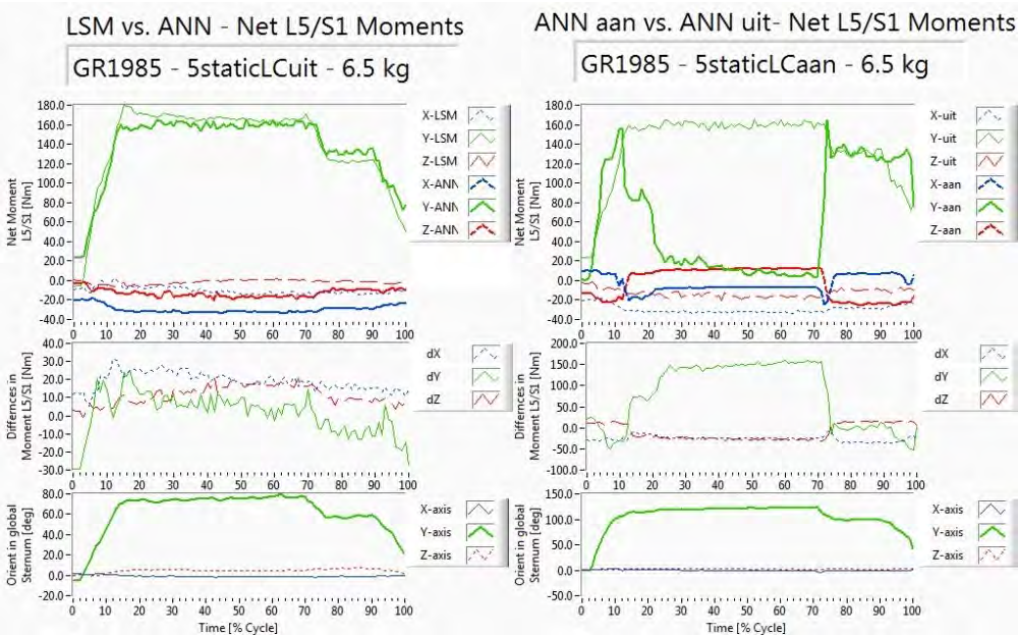
Introduction and Objectives: Recently a unique method has been further developed by Baten et al. [1] for direct estimation of low back load exposure to low back structures during actual work in terms of the net moment around the intervertebral body at level L5/S1. This paper applies this method to evaluate a concept version for a novel wearable trunk support for working in sustained stooped posture [Laevo, Intespring]. This is a comfortably wearable trunk support device that claims to assist the low back structures in generating the extension net moments required to cope with the load exposure of working in repetitive static stooped posture. This paper discusses the experimental evaluation of this claim in simulated real life working conditions.

Methods: Three series of experimental sessions were done (each around 30 trials); one series under laboratory conditions to test hardware and software, one session in a hospital setting with five nurses as subjects and one session in an industrial environment with four metal workers as subjects. For each subject a series of recordings was done comprising calibration movements, a series of simulated tasks with the Laevo prototype not active, plus a series of the same simulated tasks with the prototype actively supporting the trunk of the subject. For each subject 3D kinematics of all body segments were recorded using 3D Inertial Magnetic Motion tracking Units (Xsens MTw) and surface EMG recordings (2 x TMSI, Moby) from the main back extensor and flexor muscles. In the first session and also in two of the subjects of the second session also 6-DOF ground reaction forces were recorded with instrumented shoes (own development). All data was recorded synchronously together with 2 wireless video streams and analyzed with the custom developed FusionTools ambulatory monitoring software suite. Net moment generated by the back structures are estimated by an artificial neural network (ANN) from surface EMG and kinematics data, that was trained with target net moment estimates from kinematics and force shoes alone (supervised, known load handling). For these sessions the net moment estimates for training and testing of the ANN method were calculated using a linked segment model from the ground up (LSM-BU) validated against those calculated top-down (LSM-TD), applying standard solid body equations. ANN estimates were trained with, and validated against, both LSM methods. Comparisons were made visually and numerically (peak net moments differences estimates and coefficient of determination (R^2).The differences in net moment generated by the trunk structures with and without active support of the Leavo prototype were assessed in a variety of tasks by comparing the net extension moments curves estimated with the ANN method for all corresponding trials.

Results: Net sagittal extension moments estimated from kinematics assessments from the upper body (LSM-TD) versus those estimated from kinematics assessments of the lower body (LSM-BU) appear to be similar within ca. 10% of the maximum in both all stooped tasks in the sagittal plane and also in all stooped tasks somewhat to the side. Also all ANN estimates were within 10% of corresponding LSM-TD and LSM –BU estimates. When comparing net back extension moments for all trials in which the same task was performed with and without active support of the Laevo prototype, a

clear effect of the Laevo prototype was found. Smoothed Rectified EMG data (SRE) of some of the main trunk supporting muscles dropped to zero whenever the Laevo prototype was actively supporting in stooped posture and simultaneously the net extension moments generated by the low back structures dropped to 10% of the value without Laevo support.

Figure:



Caption: Figure 1: L5/S1 joint net moment estimation comparison LSM-TD, representing the total net moment of Laevo plus back structures, against TD-trained ANN, representing only net moment generated by low back structures. Left: with Laevo prototype inactive; right: with Laevo prototype active. Top row: Data from a straight “static” lifting task of a box 6.5 kg. 2nd row: Absolute differences between the methods, representing effect of the Laevo prototype. 3rd row: The orientation of the sternum in the global frame.

Conclusion: The data suggests that extension net moments normally generated by the low back structures are taken over by this version/configuration of the Laevo prototype trunk support for about 90% from a certain stoop angle. Still some freedom of movement can be enjoyed in this Laevo prototype, because it is constructed in such a way that when the subject first flexes the knees the Laevo prototype trunk support is deactivated.This study implies that the ANN method for net trunk extension moment estimation can be a valuable tool in evaluating the actually support percentage function achieved in test and final versions.

THE RELATIONSHIP OF ENERGY COST TO BIOMECHANICS AND MUSCULAR RESPONSES DURING PROLONGED LOAD CARRIAGE

John W. Ramsay [1 2,*] Tyler Brown [1] Meghan O'Donovan [1] Kari Loverro [1 2] Carolyn Bensel [1 2] Leif Hasselquist [1]

[1]Natick Soldier Research, Development and Engineering Center, Natick, MA, [2]Oak Ridge Institute for Science and Education (ORISE), Belcamp, MD, United States

Introduction and Objectives: During military operations, soldiers often march with heavy body-borne loads (i.e. ≥40 kg) for an extended period of time covering large distances over varied topography. During marches, energy cost reportedly increases with greater loads and steeper grades. However, there is a dearth of information on the relationship of load and grade to biomechanical and muscular responses during a prolonged march. Modified joint kinematics and altered muscular responses may contribute to decreased mechanical efficiency and changes in energy cost over time. These adaptations may also increase risk of injury and decrease physical performance, which will ultimately change a soldiers' ability to perform military functions effectively. Therefore, the objective of this study was to determine the physiological, kinematic and muscular responses that occur during prolonged load carriage over different levels of exertion.

Methods: Joint kinematics, energy expenditure and muscular activity were collected on 11 males (age 23±3 yrs; wt. 83.1±19.8 kg; ht. 178.6±6.5 cm; mean $VO_{2,max}$ 49.1±4.3 ml/kg/min) during prolonged treadmill walking with three levels of exertion (I: 0% grade, ~2-kg; II: 0% grade, 40-kg; III: 4% grade, 40-kg). Each exertion level lasted 120 min and data were recorded at 5 time intervals (0, 30, 60, 90, 120 min) for 20 seconds. Joint kinematics were recorded using an 8-camera motion analysis system as each subject walked on a split-belt instrumented treadmill. Kinematic variables included sagittal range of motion (ROM) for the ankle, knee, hip and trunk. Energy expenditure was measured using a metabolic measurement system and determined by oxygen consumption (VO_2). Raw EMG from the tibialis anterior (TA), medial gastrocnemius (MG), vastus medialis (VM), vastus lateralis (VL), medial hamstrings (MH) and lateral hamstrings (LH) were collected at 1200 Hz, filtered using a band pass filter (20-500 Hz), rectified, and a linear envelope was obtained by using a 10 Hz low pass filter. The root mean square (RMS) was determined for the middle 16 sec of each condition and each muscle signal was normalized to the RMS calculated from a prior baseline walking condition. Due to incomplete data sets for three subjects, only 8 subjects were included in the EMG analysis. Two-way (Level x Time), repeated measures ANOVA (p<0.05) were performed to assess the effects of the three exertion levels at five time intervals on VO_2 (ml/kg/min), joint ROM (degrees) and EMG RMS (% of baseline). If the ANOVA yielded a significant main effect, Bonferroni post-hoc analyses were performed (p<0.05).

Results: The level of exertion significantly increased VO_2 ($p < 0.001$) and across time VO_2 increased at a greater rate as level increased ($p < 0.001$). Steady state energy expenditure was not achieved for levels II and III, and responses were significantly different as time progressed ($p < 0.001$). Soldier kinematics were significantly altered by exertion level and there was an interaction found between exertion level and time. Joint ROM for III, when compared to I and II differed significantly with increasing ankle ($p < 0.001$), decreasing knee ($p = 0.002$), and increasing hip ROM ($p = 0.027$). As time progressed, maximum trunk and hip angles reflected a significantly increased flexed posture for II and III ($p = 0.016$).

EMG RMS increased during II and III for the medial gastrocnemius ($p < 0.001$), vastus lateralis ($p = 0.006$) and medial ($p = 0.004$, $p = 0.015$) and lateral hamstrings ($p = 0.007$). For III, when compared to I and II, we saw additional significant increases in medial gastrocnemius EMG RMS (Table 1).

Conclusion: During prolonged load carriage, soldiers increase energy cost with higher levels of exertion, but may not achieve steady state when walking with load and/or up a grade. The observed biomechanical changes indicate a greater flexed posture with extended periods of increased exertion. These changes may decrease the soldier's metabolic efficiency and increase energy requirements over time. Patterns of muscular response to load indicate an increase in overall muscular activity of the ankle plantar flexors, knee flexors and knee extensors. The findings indicate an additional increase in gastrocnemius activity due to the increase in grade. Further investigation is required to determine whether any changes occur in the underlying EMG signals components (i.e. frequency shift) that may contribute to increases in energy cost over time.

OLDER ADULTS AND RECOVERED LOW BACK INJURED PARTICIPANTS HAVE UNIQUE TRUNK MUSCLE MOTOR ADAPTATIONS TO A DYNAMIC LEG LOADING TASK

David A. Quirk [1,*] Cheryl Hubley-Kozey [1]

[1]Biomedical Engineering, Dalhousie University, Halifax, Canada

Introduction and Objectives: Relative to young healthy adults, older healthy adults and recovered low back injured (rLBI) participants have been shown to use altered neuromuscular control patterns to perform dynamic tasks [1,2]. Findings from spatial-temporal analysis of trunk electromyograms (EMG) suggest that rLBI and older adults have similar recruitment including sustained agonist activity and increased antagonist co-activity [1,2]. These patterns are thought to increase active spinal stiffness compensating for changes in osteoligementous, muscular, and neural components of the spine associated with both aging and spinal pathology. Whether neuromuscular adaptations are general or unique responses in these populations is not clear. However, trunk muscle synergies found in older adults [2] suggest these populations have unique motor adaptations. The objective of this study was to test the hypothesis that rLBI and older adults would have similar neuromuscular adaptations in response to a controlled dynamic leg loading task, but would differ from a young healthy control group.

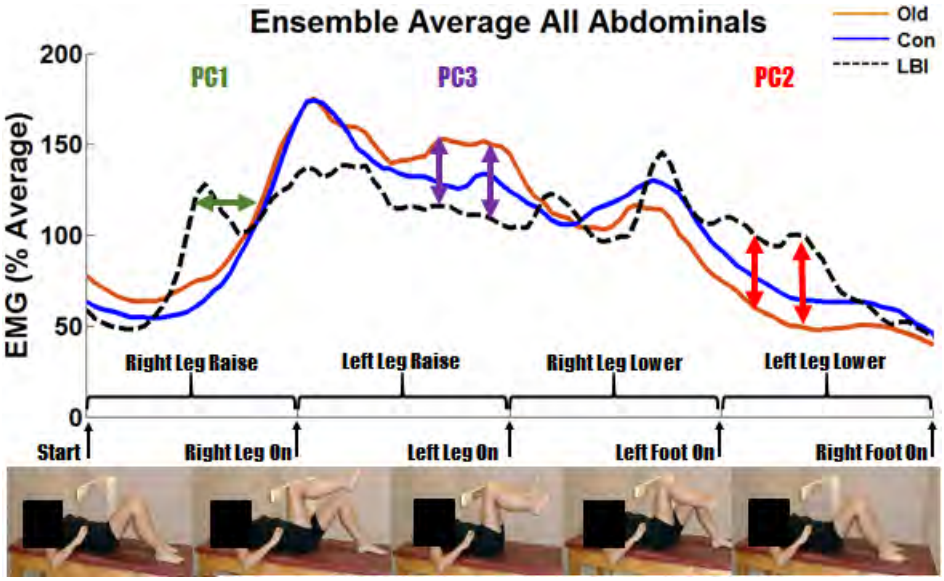
Methods: Twelve older adults (65+ yrs) were sex, height, and mass matched to a younger cohort (20-45 yrs) of rLBI (n=15) (4-12 weeks post injury with minimal pain and disability) and no-LBI controls (n=21). Starting in supine, participants performed 3 trials of a leg loading task timed to a 4 second count while instructed to minimize pelvic motion (Figure). Surface EMG were collected from 24 trunk muscle sites (12 abdominal and 12 back extensors) at 1000Hz synchronized with 3D angular motion data collected from magnetic sensors placed on the iliac crest. Root mean square (RMS) EMG amplitudes were calculated and normalized to maximum voluntary contractions. To examine temporal patterns, EMG data were full-wave rectified, low-pass filtered (6 Hz), time normalized to 100% and amplitude normalized to average task amplitude. Motion data were low-pass filtered (1Hz) and maximum displacements were calculated for the entire task for 3D angles. EMG ensemble-average profiles were calculated from the waveforms for three trials for each muscle site and subject. Temporal features were captured using principal component (PC) analysis models constructed separately for the abdominal and back sites. Mixed model ANOVA (group, muscle) were conducted on RMS amplitude and PC scores. One way ANOVA (group) compared angular displacement and movement time (α=0.05). Tukey HSD post-hoc analyses were performed.

Results: Participants completed the task in 3.7±0.3 seconds with no group differences. Pelvic motion was less than 5.5° in all directions, with between group differences ($p<0.05$). rLBI had less flexion/extension motion than older adults and controls, and older adults had more axial rotation than rLBI and controls.

Mean abdominal RMS amplitudes over the entire exercise were not different between groups ($p>0.05$). All three abdominal PC scores had group*muscle interactions ($p<0.001$) as illustrated by the unique temporal patterns for each group (Figure). PC1 captured early onset activity for rLBI relative to older adults and controls (Figure). PC2 captured differences between older adults and rLBI for all sites. Older adults had a pattern of lower activity whereas rLBI had

sustained activity during right leg lower (Figure). PC3 scores were different between older adults and rLBI for all sites. Older adults had sustained mid-task activity while rLBI supressed activity (Figure). PC2-3 differences were found between controls and both rLBI and older adults. These differences were not consistent across all muscle sites, with controls having an intermediate temporal response between both groups (Figure). rLBI group had no PC score differences among abdominal muscle fibres indicative of temporal synergies, whereas older adults and controls had differences among abdominal muscle sites indicative of differential responses. Back muscle sites RMS amplitudes had a group*muscle interaction ($p<0.05$). All 12 rLBI and 4/12 older adult back sites had higher antagonist co-activation than controls.

Figure:



Caption: Ensemble average waveform response to dynamic task.

Conclusion: Consistent with previous findings, both rLBI and older adults differ from controls having sustained abdominal activation and higher antagonist co-activation [1,2]. However, rLBI and older adult groups had different temporal patterns to one another, including differences in temporal synergies. While sustained/higher activation can increase spinal stiffness, less spinal motion was only found in rLBI participants. Altered oblique muscle synergies used by older adults (PC2) may explain their higher transverse plane motion. In conclusion, these data reject our hypothesis showing that both older and rLBI groups had unique motor adaptations compared to controls, and to each other, providing evidence that adaptations are not general, but are sensitive to changes in specific spinal components.

NON-NEGATIVE MATRIX FACTORIZATION FOR MUSCLE SYNERGY ANALYSIS: ROBUSTNESS ASSESSMENT AND IMPROVEMENT

Mohammad S. Shourijeh [1,*] Teresa E. Flaxman [1] Daniel L. Benoit [1 2]

[1]Faculty of Health Sciences, [2]Faculty of Engineering, University of Ottawa, Ottawa, Canada

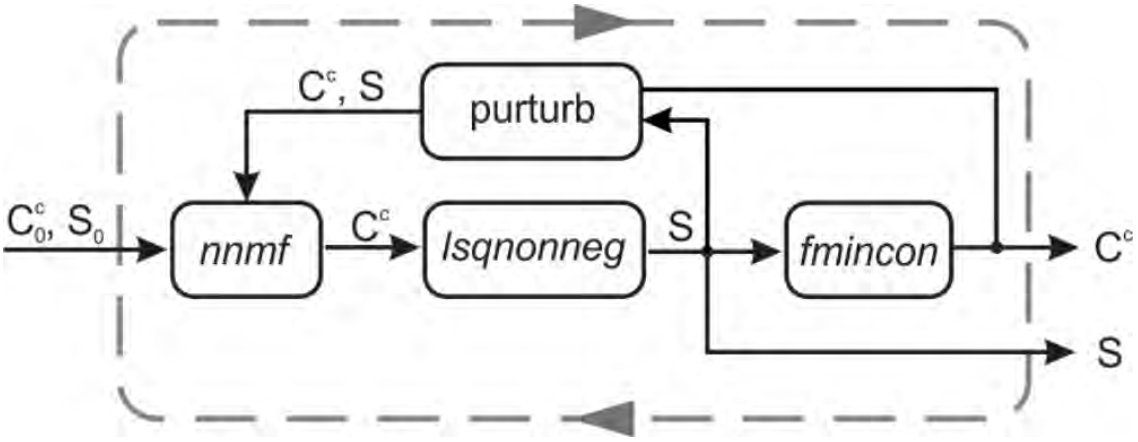
Introduction and Objectives: Muscle synergies have been extracted by means of non-negative matrix factorization (NMF) in recent studies during static and dynamic tasks. NMF is a linear decomposition technique that outputs the optimized basis (synergy) vectors and corresponding weight (coefficient) vectors through minimizing the error between the original signal and the reconstructed data. NMF has been used by a number of studies for simplifying the representation of muscle activities using EMG values obtained during both static and dynamic tasks. By extracting muscle synergies, the number of variables required for describing neuromuscular control may be reduced. However, NMF might have many local minima caused by (1) scaling optimal coefficients and synergies by an invertible matrix so that the error still remains the same, (2) swapping of the coefficient/synergy indices, and (3) not convergence of the optimization problem, thus leading to repeatability issues. In order to address this, Frère and Hug [1] proposed using paired comparisons for each extracted synergy and generating a number of random permutations of the coefficients. This resulted in 3600 Pearson coefficients. Mean r-values of the paired comparisons were >0.71 and were not considered statistically different. Although these results suggest the outputs of NMF are repeatable for each subject and robust between subjects, the overall outputs may not be deemed consistent across runs since the variability is split between coefficients and synergies. Another issue arises when trying to use the NMF to evaluate the similarity between subjects in a given group. Again, Frère and Hug [1] used paired comparisons for each of their 9 subjects, resulting in 9*8 cases. In each paired comparison, the first subject was set as the reference subject, and then fixed the synergy of the second subject equal to that of the first subject, and computed the coefficient matrix. This was repeated but rather the coefficient matrix was fixed in order to compute the synergy matrix. Aside from the tedious process required to evaluate many paired cases, the differences are split between those considered pairs, and also between two variables of coefficients and synergies. Thus, interpretation of the similarity of the NMF outputs may not be valid. Due to the local minima issue, NMF outputs require a functional sorting method when comparing different sets of data. Studies have tried to reorganize the indices by finding the maximum correlation between the repeated runs or between subjects. Regardless of what measure is used for order reorganization, it might not be conclusive as the synergy order switch has occurred along with a numerical local minimum effect, in which case the sorting might be done by a poor correlation.

Methods: In order to minimize the aforementioned issues, we propose using a concatenated non-negative matrix factorization (CNMF) approach. A concatenated matrix will be formed that consists of the EMG signals of all subjects; there will be a corresponding concatenated coefficient matrix that includes the coefficient array of all subjects. An unknown synergy will be kept fixed between all subjects (and/or trials--if any), which will be determined within the CNMF. This will facilitate to assess consistency between subjects, as we will be left with only coefficients to be compared. For this

approach, we will not use paired comparisons; we believe that we should compare all subjects together simultaneously, by running intra-class correlation between the output coefficients of the CNMF.

Results: NMF and CNMF were both used to extract knee joint muscle synergies from the EMG data (taken from [2]) using the framework shown in Figure 1. Acceptable number of synergies must provide a VAF (Variance accounted for) of greater than 95%. Repeatability and between subject similarity were evaluated for each method using intra-class correlation coefficients (ICCs). High repeatability was found for CNMF compared to NMF: ICCs of >0.99 for the CNMF versus >0.26 in the NMF. Reasonable consistency across subjects was improved using the CNMF over the NMF approach.

Figure:



Caption: Framework schematic used for synergy identification: C is the coefficient matrix and S is the muscle synergy array; subscript 0 refers to random initial array, and superscript c designates concatenated matrix. nnmf, lsqnonneg, and fmincon are MATLAB routines.

Conclusion: This study evaluated NMF and introduced concatenated NMF (CNMF) to analyze and robustly extract muscle synergies. CNMF is proposed to be a more reliable approach than NMF and suitable for between subject comparison of muscle synergies. As applications of muscle synergies are growing in rehabilitation and motor control research every day, the CNMF approach will be helpful for deductions on muscle synergies and EMGs from different subjects and populations in different movements.

AS-0256

NEURO-MECHANICAL CONTROL OF THE PRECISION JUMP. EFFECTS OF AMPLITUDE AND PRECISION CONSTRAINTS IN A FITTS' LIKE TASK.

David Pagnon [1,*] Olivier Martin [1]

[1]Saiga, Gipsa-Lab, Grenoble, France

Introduction and Objectives: A precision jump (PJ) consists in a standing jump toward a thin landing area, requiring a stabilization of the posture at landing without additional step. It requires both preparatory and on-line complex neuro-mechanical controls of the whole body balance. Currently, one single study has questioned the control processes associated to jump amplitude and precision altogether, and it focused on short amplitudes and low index of difficulty (ID)[1].

The purpose of this study was to analyze how the neuro-mechanical control system deals with the distance D to jump and the width W of the reception area. First we determined the phases affected the most by each constraint, then we focused on the differences in the management of both constraints, and lastly we compared the PJ with a Fitts task[2].

Methods: 7 male subjects participated in the experiment, all experts in Parkour (6.7±3.2 years of practice) which involves such abilities. They performed PJs from one force plate, toward another one on which was fastened a reception area. For each subject, 3 D conditions were set at 40, 60 and 80% of their maximal jump distance (Dmax) performed during pre-tests. 3 W conditions were set at 264, 132 and 44mm which made ID = log2(2D/W) range from 9.5 to 13.4. Each PJ condition (3Dx3W) was repeated 10 times. Resting period and jump start were at the subjects' decision.

Integrated surface electromyography (iEMG) of lower limb muscles (Tibialis anterior Ta, Gastrocnemius Ga and Quadriceps Qc) was recorded, as well as dynamics of the ground forces (antero-posterior forces FAp and their derivative dF/dt) on impulsion and reception plates.

Data were processed and analyzed all along the 6 phases composing a PJ: preparation PR, counter-movement CM, push-off PO, flight FL, reception RE, and stabilization ST. ST was defined as the phase going from 1 to 2 seconds after RE. A trial was considered successful if FAp during ST never went under 70% of the bodyweight.

A 3Dx3W factorial ANOVA design was conducted for each phase of successful trials, from all subject's means of times, iEMGs, force data and success rate to estimate the effects of D and W on neuro-mechanical strategies. Correlations were additionally sought among times of PR and FL and ID.

Results: The overall success rate was 85%. D played a lesser role than W in the success rate reduction (-9% vs. -17%). More precisely, the chronological phase's analysis showed that at **PR**, time increased more with D than with W (see Table for significances). At **CM**, forces and iEMGs of Ta increased with D, whereas they decreased with W. At **PO**, an increase of D implied a decrease of time, whereas force and iEMG activities of Ga and Qc increased. W had no significant effect. At **FL**, time increased with D and iEMG of Ta increased both with D and W. At **RE**, FAp, dF/dt and iEMG of Ta and Qc increased with D, whereas dF/dt and iEMG of Ta decreased with W. At **ST**, iEMG of Ta and Qc increased with W. D had no significant effect.

The analysis of ID effect showed that PR time was not correlated with ID, contrary to time of FL (T=0.36+0.041xID, r=0.36, p<0.05).

Caption: Table: Effects of D and W on time (T), antero-posterior forces (FAp) and lower limb muscle activities (iEMG) along each jump phases. *p<0.05, **p<0.01, ***p<0.001

Conclusion: Our results show that both distance and precision of the jump involve adjustments of forces and lower limb iEMGs, but not at the same time nor in the same way. Both D and W constraints increase time of PR. Then the key phases for D are PO and RE, whereas for W it is ST. PO and RE reflect the early need of a greater impulse to reach the reception area, and ST reflects the subsequent need of a greater sensori-motor control to stabilize the balance on a thin area. Thus the neuro-mechanical system allows a prioritization of the constraints, and anticipates first both D and W in parallel in a feedforward mode, and then it deals with D then W in a series in feedback mode.

The effects of D and W are opposed during CM and RE. Whereas both constraints affect the same variables, they are processed differently. This is due to the fact that an increase of D requires an global amplification of the jump parameters, whereas W constraint involves rather modulation and fine control. While with a wide reception area an over-estimation of the impulse needed let some latitude to adapt the PJ on line, this over-estimation becomes deleterious in case of a majored W constraint: means of forces and iEMGs are consequently reduced.

Fitts' law is followed during FL but not during PR, which doesn't corroborate the common hypothesis that the law reflects preparation of movement (feedforward) rather than on-line adjustments (feedback). Time of FL can be adjusted by jumping higher or by extending the legs later. That might be emphasized by the expertise of the subjects, who are able to make on-line adjustments quick and accurate enough not to involve a long PR.

MUSCLE ACTIVATION PATTERNS DIFFERENCES IN RUNNING TECHNIQUES

Victor H. Munoz-Martel [1,*]

[1]Kinesiology, Universidad SEK, Santiago, Chile

Introduction and Objectives: Running biomechanics is highly related with competition performance and lower limb injuries. Three different techniques has been described[1], differentiated by foot strike pattern. These techniques behave very different on biomechanics elements [2] and natural technique selection by a subject is associated with evolutionary and socio-cultural elements[3].

Global limbs movement pattern are achieved by stimulation of neural pools within the spine[4], reinforcing the idea that neural organizations at the spine are responsible for cycling activities, this organization are known as central pattern generators (CPG) which are believe to be task specific[5].

EMG patterns from individual muscles during locomotion show high variability within steps. Nevertheless, if several cycles are considered, a stable pattern representative for inter-subjects muscle activity during the cycle is possible to obtain[6]. This pattern is associated with task specificity for each muscle contribution within the cycle and, therefore, task related muscle synergies might be studied[7].

Principal component analysis (PCA) is a high order statistical tool that permits to determine common characteristics within a data set in order to reduce the dimensions of the data array and represent the signal by a few new set of patterns. For EMG signals PCA reduces the number of signals to a fewer number of patterns that account for EMG activity of individual muscles. It has been suggested that principal components might represent the activity of a few oscillator controlling complex EMG activity within a cycle[8]. Since foot positioning is a relevant task for load response during locomotion is possible to theorize a synergy for it and, therefore it might have a control component associated.

It has been reported that five basic component accounts for over 90% of EMG activity during walking and running, however running techniques has not been considerate. The present study proposes that since there is more than one running techniques is possible to theorize more than one control strategy for each technique, which would be associated to a specific central command.

Objectives.

The aim of this study is to determine if there is different spinal control mechanism for each running techniques expressed as different synergies observed by principal component analysis.

Therefore, objectives are:

- Determine muscular activation patterns as control elements for the two most common techniques in habitual runners
- Describe muscular synergies differences between running techniques by principal components analysis

Methods: All trials were performed in the Human Performance Laboratory of the Universidad de Chile's Kinesiology School.

Four habitual runners run on a treadmill at 12 Km/h per 5 minutes. Wireless electromyography surface signals (BTS EMG capture, Milano Italy) were obtained from 16 lower limb and trunk ipsilateral muscles during 3 minutes. Cycles were determined by a foot switch that generated an electric pulse to the capture module whith pressure threshold of 5 mm/hg, foot switch was attached to running shoes and had two sensors, one on the calcaneus area and one on the metatarsal-phalanges region.

EMG signals from individual muscles were trimmed according to each cycle's duration and averaged to obtain a signal pattern representative to muscle activity during a stride.

Each muscle stride pattern was concatenated to obtain a matrix containing all 16 muscles cycle activity. Activation patterns and muscular sequences were obtained by principal component analysis. Principal components weight were obtained. Components representing over 95% of EMG activity were selected for further analysis and techniques comparison.

Principal component were rotated by a varymax rotation. Components were analyzed to obtain time to peak activity from initial contact. Componentes were then organized in ascending order based on to time to peak from initial contact. Each principal component weight was calculated and a morphological analysis was performed in order to match principal components to a task according to Ivanenko's previous work[9]. Muscle synergie contribution was clasiffied by svm.

Component's time to peak, weigth, statics and muscle contribution were compared between techniques.

Results: Differences were observed in components composition and weigth.

Conclusion: Recognizing activations patterns as neural control elements may contribute to understand how running techniques are organized by CNS.

Differences in activation patterns were observed between running techniques suggesting different task oriented oscillators activity within the spine.

Considering the relationship between mechanical element with running techniques, understanding neuromuscular variables associated with running may contribute to orientate to a neuromuscular vision of distance running performance training, injury prevention and treatment.

EFFECTS OF ADDITIONAL CONSTANT AND IMPROMPTU COGNITIVE LOADINGS ON LOWER EXTREMITY GAIT PERFORMANCE

C.K. Chan [1,*] J.C. Teoh [1] Luis C. Hernandez-Barraza [1] Desmond Y.R. Chong [1] C.H. Yeow [1]

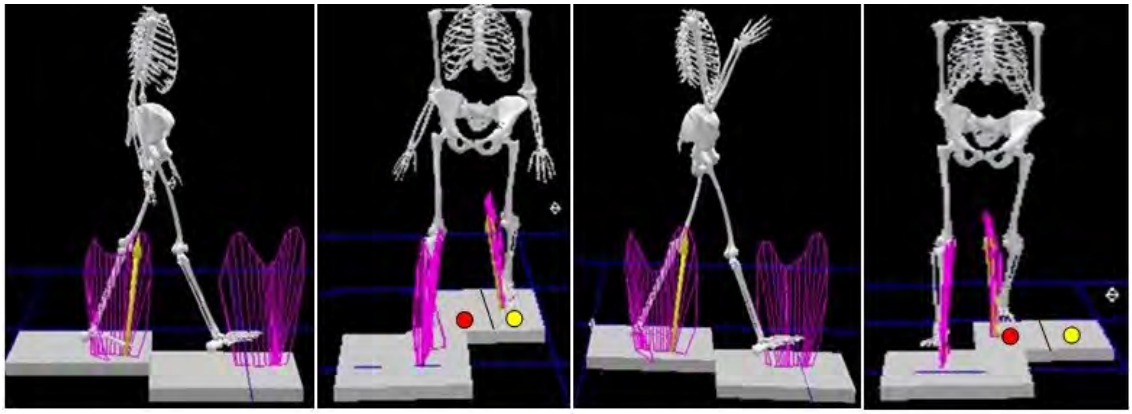
[1] BIOMEDICAL ENGINEERING, NATIONAL UNIVERSITY OF SINGAPORE, SINGAPORE, Singapore

Introduction and Objectives: Recent research has delineated that simultaneous dual-task texting and walking affect the sensorimotor balance control and locomotion. This may lead to accidents due to navigational complications among pedestrians. Although past studies have examined both upper and lower extremities biomechanical analysis during dual-task scenarios [1-2], little attention is given to the effects of constant and impromptu cognitive loading on the gait performance of the pedestrian. This study, thence, aimed to investigate how additional constant and/or impromptu cognitive loading may be prioritized and affect the gait parameters, which comprise of sagittal-plane kinematics, kinetics and energetics analysis. Constant and impromptu cognitive loadings, introduced in this study, were texting and attending auditory cue respectively.

Methods: Twelve young voluntary participants (six male and six female) were recruited. Trials were conducted in gait laboratory, comprised eight infrared cameras and two force-plates. Four walking modalities were designed: (a) normal walking; (b) walking while texting on cellphone; (c) walking while attending auditory cue; and (d) walking and cellphone texting whilst attending to auditory cue. The cue was given to the subject to step onto designated colour regions placed on the force-plate. The force-plate was equally separated into two different colour regions. Failing to step onto the required region, the respective trial was repeated with different colour combination. As for texting on cellphones, sentences were instructed to the participants. Accuracy of the sentences was evaluated, which the trial shall be repeated if the accuracy was less than 50%. Data extracted from Vicon Nexus. Two-way ANOVA analysis and Tukey post-hoc testing was performed.

Results: Our findings indicated a reduction in ankle joint power in the late stance. The plausible reason for the reduction is the deviation of the prioritization [2] during texting-walking while attending auditory cue, resulting in reluctance to propel forward. This factor further elicited lower gait velocity and smaller step length during texting-walking as reported in [3]. Moreover, the percentage of texting success for the subjects in following the auditory cue was reduced in the case where the subjects performed texting while walking as compared to normal walking. Due to additional cognitive loading, the alertness of the subjects was attenuated in order to divert their attention partially to the phone. Furthermore, human locomotion depends on the optic flow in steering the motion direction [4]. Reduction in the sagittal knee moment and knee power suggests that both optic flow and cognitive loading may contribute to deviation in prioritization [2] and cascade consequences in both kinetics and energetics.

Figure:



Caption: Figure 1: (a) Normal walking; (b) Walking while attending to auditory cue in stepping onto the yellow region of the force-plate; (c) Texting while walking; and (d) Walking and texting while attending to auditory cue in stepping onto the red region of the force-plate.

Conclusion: Two key factors that contributed to the walking control strategy were cognitive loading and optic flow adjustment. Furthermore, prioritization in cognitive loading may alter the balance and stability in maintaining walking trajectory. Hence, simultaneous adjustment of additional cognitive loading and interrupted optic flow in attending sudden obstacles besides texting while walking will further disturb the prioritization strategy. Consequently, this may affect the stability and cause unforeseen mishaps. This research is essential in conveying that pedestrians, who perform texting while walking, are prone to accidents as they may not be aware of their surroundings and are unable to react promptly if there is an additional impromptu cognitive loading.

Table:

Maximum Ankle Power			
Factor B	Factor A		P-value
	Walking without texting	Walking with texting	
With auditory cue	3.30 (0.90)	4.05 (0.35)	0.0413*
Without auditory cue	3.50 (0.92)	4.01 (1.00)	0.338
Minimum Knee Power			
Factor B	Factor A		P-value
	Walking without texting	Walking with texting	
With auditory cue	-0.49 (0.30)	-0.05 (0.45)	0.287
Without auditory cue	-0.76 (0.59)	-0.48 (0.14)	<0.001*
Maximum Knee Flexion Moment during Swing Phase			
Factor A	Factor B		P-value
	With auditory cue	Without auditory cue	
Walking with texting	0.17 (0.11)	0.23 (0.14)	0.031*
Walking without texting	0.31 (0.24)	0.38 (0.30)	0.208

IDENTIFYING TREADMILL RUNNING FATIGUE USING TRUNK ACCELEROMETRY BASED MEASURES

Kurt H. Schutte [1 2 3,*] Ellen Maas [2] Rachel Venter [1] Vasileios Exadaktylos [3] Daniel Berckmans [3] Benedicte Vanwanseele [2]

[1]Dept of Sport Science, Stellenbosch University, Stellenbosch, South Africa, [2]Dept of Kinesiology, [3]Dept of Biosystems, KU Leuven, Leuven, Belgium

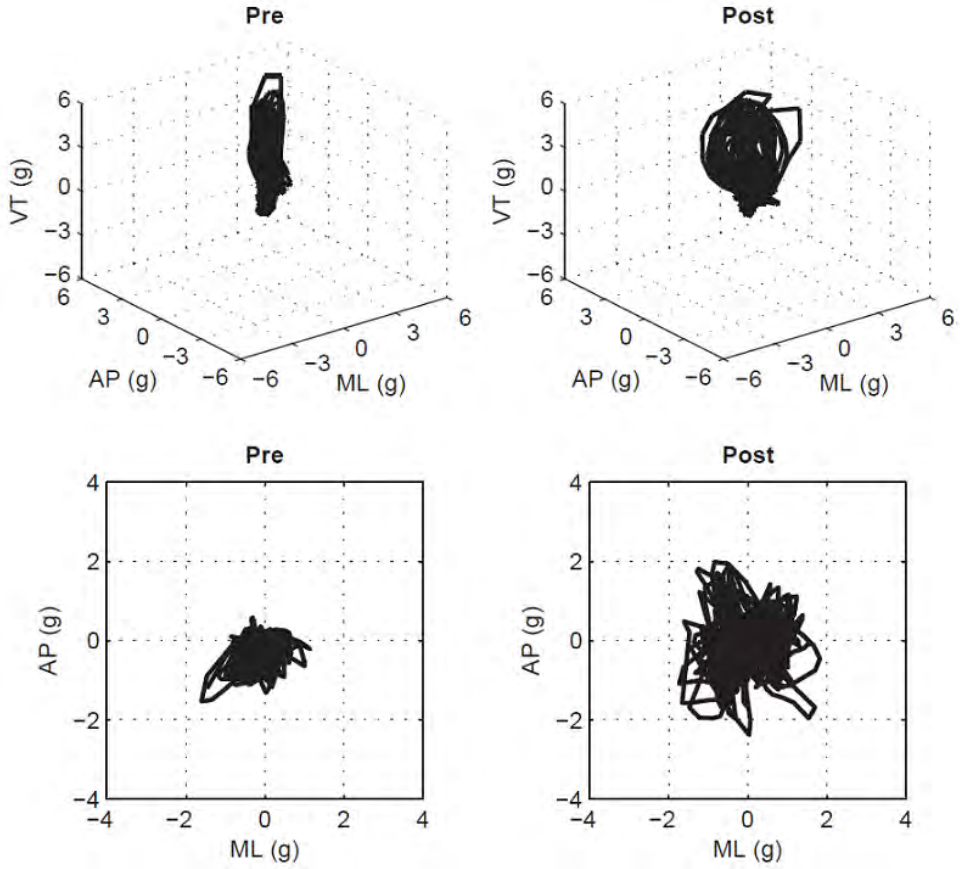
Introduction and Objectives: The ability to identify and correct deterioration in a runner's technique due to fatigue is of value to enhancing athletic performance and might have potential to prevent injuries [1]. In the context to running, fatigue may play a role in the complexity of the neuromuscular control system output, whereby movement errors become more apparent and necessitate frequent movement corrections [2]. Controlling centre of mass (CoM) movement while running has been considered as a plausible safety mechanism for pain avoidance, self-preservation of musculoskeletal structures [3], and conserving and maintaining efficiency [4]. This suggests that CoM control during running could play an important role in the prevention of running injuries.

In contrast to traditional 3D motion capture, wireless body-worn tri-axial accelerometers offer a novel approach to movement analysis that eliminates the need for timely set-up of gait analysis equipment, and facilitates easier data collection over a diverse array of indoor or outdoor settings. To the best of the authors' knowledge, no previous study has applied accelerometry methods to analyse dynamic gait stability of the CoM during running until exhaustion. The aim of this study was therefore to investigate dynamic CoM stability in relation to running-induced fatigue in both novice and competitive runners using tri-axial lower-back accelerometry based measures. We hypothesized that tri-axial lower-back accelerometry would be able to detect 1) higher step irregularity 2) higher complexity (unpredictability), and 3) greater horizontal plane (mediolateral and anteroposterior axes) contribution to the resultant acceleration with running fatigue in both competitive and novice runners.

Methods: Twenty-two age-matched (18-33 years) runners (10 novice; 12 competitive) were recruited to participate in this repeated measures study. Ten seconds of raw, tilt corrected tri-axial (vertical, mediolateral, and anteroposterior) accelerations extracted from a lower-back mounted accelerometer at the start and end (volitional exhaustion) of a treadmill running fatigue protocol. Step and stride regularity, sample entropy, and each independent axis root mean square (RMS) contribution to the resultant RMS were used to quantify both linear and non-linear dynamic CoM stability of running. Accelerometry measures were collected in two speed conditions, namely a standardized low speed (1.94 $m \cdot s^{-1}$), and self-selected high speed ranging 2.11 - 3.33 $m \cdot s^{-1}$.

Results: After treadmill running to exhaustion, fatigue runners experienced a significant decrease in step regularity in the anteroposterior (22 % low speed; 26 % high speed) direction, an increase in sample entropy in the vertical (25% low speed; 23 % high speed) and anteroposterior (12 % low speed; 8 % high speed) directions, and an increase in horizontal plane contribution to the RMS ratio for the mediolateral (17 % low speed; 12 % high speed) and anteroposterior (17 % low speed; 9 % high speed) directions.

Figure:



Caption: Stabilograms from 10 seconds of extracted accelerometry signals for an exemplary novice runner, represented as 3D resultant acceleration vector (above) and 2D horizontal accelerations (below) at Pre and Post fatigue. Observed increases in horizontal accelerations with fatigue consisted of increases from the mediolateral (ML) and anteroposterior (AP) acceleration components.

Conclusion: Running fatigue influenced both novice and competitive runners to alter dynamic accelerometry measures of CoM control in the form of more irregular steps, higher complexity (more unpredictability), and increased contribution of horizontal plane accelerations to the resultant, demonstrating that a single lower back-mounted accelerometer can provide useful information about the process of treadmill running fatigue. Our results support the concept that accelerometry signals during running are not confined only to discrete measurements but are also well suited for measuring raw continuous time-varying measures from independent axes. Applying different accelerometry based measures serves to broaden our understanding as to how runners control their CoM in response to fatigue.

HOW PLAYERS CONTROL TENNIS RACKET VIBRATION TRANSFERRED TO THEIR FOREARM?

Delphine Chadefaux [1,*] Guillaume Rao [1] Philippe Androuet [2] Eric Berton [1] Laurent Vigouroux [1]

[1]Institute of Movement Sciences, UMR CNRS 7287, Aix-Marseille University, Marseille, [2]Department of Movement Sciences, Oxylane Research, Villeneuve d'Ascq, France

Introduction and Objectives: The ball impact on the tennis racket stringing leads to vibration waves propagating into the handle and the player's forearm through his hand. The characteristics of these vibrations may influence the pathology risks and contribute to the player's comfort and feeling. In spite of a well-extended knowledge of tennis racket physics leading to accurate racket models, little is known about the player's ability to control stroke-induced vibrations. The hand/racket interaction is however crucial in the vibration waves propagation. This study contributes to get insight into such a control mechanism by analyzing stroke-induced vibration at the racket and the forearm levels for various stroke intensities and spectral contents.

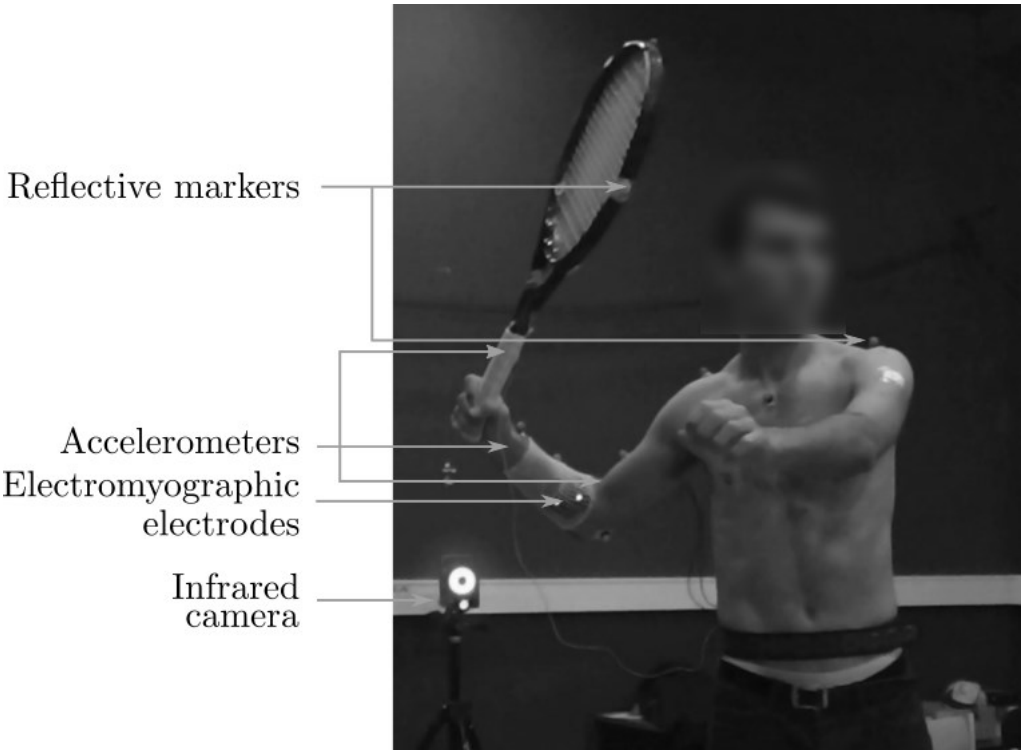
Methods: 14 right-handed male participants with no pathology were involved in the experiments. They were tennis experts (ITN > 3.5), 21 ± 3 years old, 182 ± 8 cm tall, and weighted 73 ± 8 kg. After an unlimited warm-up period with their own racket, they were asked to hit forehands toward a target in 15 conditions. To investigate stroke-induced vibration signals in a wide range of intensities and spectral contents, 5 rackets with various mechanical characteristics as well as 3 stroke intensities (weak, medium and hard) were tested. A one dimensional accelerometer (Dytran ; ± 500 g ; [1.6 – 10000] Hz) was disposed on the racket handle at 15 cm of the butt cap and two three-axis accelerometers (Endevco ; ± 50 g ; [20 – 6000] Hz) were fixed on participant's wrist and elbow (see Figure). Note that motion reproducibility was controlled through a high-resolution motion-capture system (Vicon, Oxford UK, 8 infrared cameras, 200 Hz). Besides, a grip force index was computed according to electromyographic signals (extensor digitorum communis, extensor carpi radialis longus, flexor digitorum profondus and superficialis, and flexor carpi ulnaris) recorded with a wireless Delsys system combined with a preliminary calibration task. These databases were gathered at 12000 Hz.

Results: Regarding first the intensity, results indicated that the vibration energy at the wrist and the elbow increases with the stroke intensity. A linear relationship, specific to each participant, occurred between wrist and elbow energies. The participants' action thus could lead to a constant ratio of energy transferred to the forearm, dependent on the participant but not on the stroke intensity. Additionally, the grip force increased with the stroke intensity which obviously modified the mechanical linkage between the hand and the handle. These grip adaptations can be seen from two points of view. First, it could be assumed that grip force adjustments participate in keeping the former energetic ratio constant. A second hypothesis is that participants stabilized the hand/racket interaction by increasing the grip force. Indeed, when increasing the grip force, a minimization of the vibration energy transmitted in the plane perpendicular to the racket was shown while the vibration energy transmitted in the longitudinal plane grows.

Although most of the spectral content of a tennis racket was lower than 1500 Hz, only the first bending mode at about 140 Hz appeared in the accelerometer' signals measured at the wrist. Moreover, the modal parameters were modified by the grip when assessing frequency and damping values through classical modal analysis in free boundary condition.

Indeed, the modal damping raided from less than 1 % to about 10 %.Meanwhile depending on the participant and the racket, the modal frequency decreased of 1 Hz to 20 Hz. By controlling the grip position and the force intensity, players can thus finely tune vibration waves transferred to the forearm such as an adaptive filter. Due to these modifications, two different rackets held by a given participant showed closer modal parameters than the same racket held by two participants. Interestingly, it results that the participant effect is at least as significant as the racket physical features on the spectral properties of the vibration waves propagating from the racket to the participant's forearm.

Figure:



Caption: Experimental setup. Forehand strokes were performed by participants with 5 rackets and 3 intensities. Classical biomechanical signals were gathered (EMG, kinematics and vibration waves) on the racket as well as on the participant

Conclusion: The main results of this study pointed out that the vibration characteristics are highly dependent on the player's grip. The players seemed to adopt strategy by modifying the grip of the racket. The individual grip strategy seemed to determine both the intensity and the orientation of the vibration transferred to the forearm. These results enforce consideration of the hand-grip as an adaptive filter, whose characteristics are more dependent on the player than on the racket itself. Assuming this non-negligible effect of the player's grip on vibration waves, a renewal of equipment designs could emerge by considering the deep interaction between the player and the racket.

RELATIONSHIP BETWEEN PRE-STRETCH AUGMENTATION OF JUMP PERFORMANCE, ANKLE DORSIFLEXION RANGE OF MOTION AND ANKLE STIFFNESS DURING THE SUPPORT PHASE OF DROP JUMP IN WUSHU ATHLETES

Léo Benouaich [1,*]Philippe Rouch [1]Françoise Natta [2]Patricia Thoreux [1 3]

[1]LBM/Institut de Biomecanique Humaine Georges Charpak, Arts et Metiers ParisTech, [2]Institut National du Sport, de l'Expertise et de la Performance, [3]Hôpital Avicenne, APHP, Université Paris 13, Sorbonne Paris Cité, Paris, France

Introduction and Objectives: Research in sports biomechanics enables better understanding of performance mechanisms, leading to improved performance and reduced risk of injury. Wushu, better known as kungfu, is the sportive and modern form of Chinese martial arts, and consists in performing a routine of martial movements associated with acrobatic jumps. Athletes must have both an important ankle range of motion in dorsal flexion to perform low stances with heels on the ground, and a high vertical jump for acrobatics. As in many sports, jumps are performed with a running up followed by a support phase with eccentric and concentric phases. One challenge for athletes is to be able to benefit from initial velocity to jump higher than they would do without any prior eccentric phase [1]. In this ability, ankle function can be studied threw ankle stiffness [2]. The aim of this study was to analyze if there are links between the benefic use of initial velocity, ankle stiffness during the concentric phase and maximal dorsiflexion angle in wushu athletes.

Methods: After a standardized warm-up and maximal ankle dorsiflexion angle measures, 12 athletes of the French wushu team performed 3 repetitions of 2 maximal jumps: squat jump (SJ) and drop jump (DJ). 42 reflective markers were placed over skeletal landmarks. Kinematics were registered at 300 Hz with a 13 cameras Vicon system and ground reaction forces with 2 AMTI force plates at 900 Hz. Marker positions were filtered with an adaptive Butterworth filter [3] and body segment inertial parameters were personalized [4]. Flexion moments, calculated using inverse dynamics, and flexion angles of both ankles were expressed between 0 and 100% of the support phase.

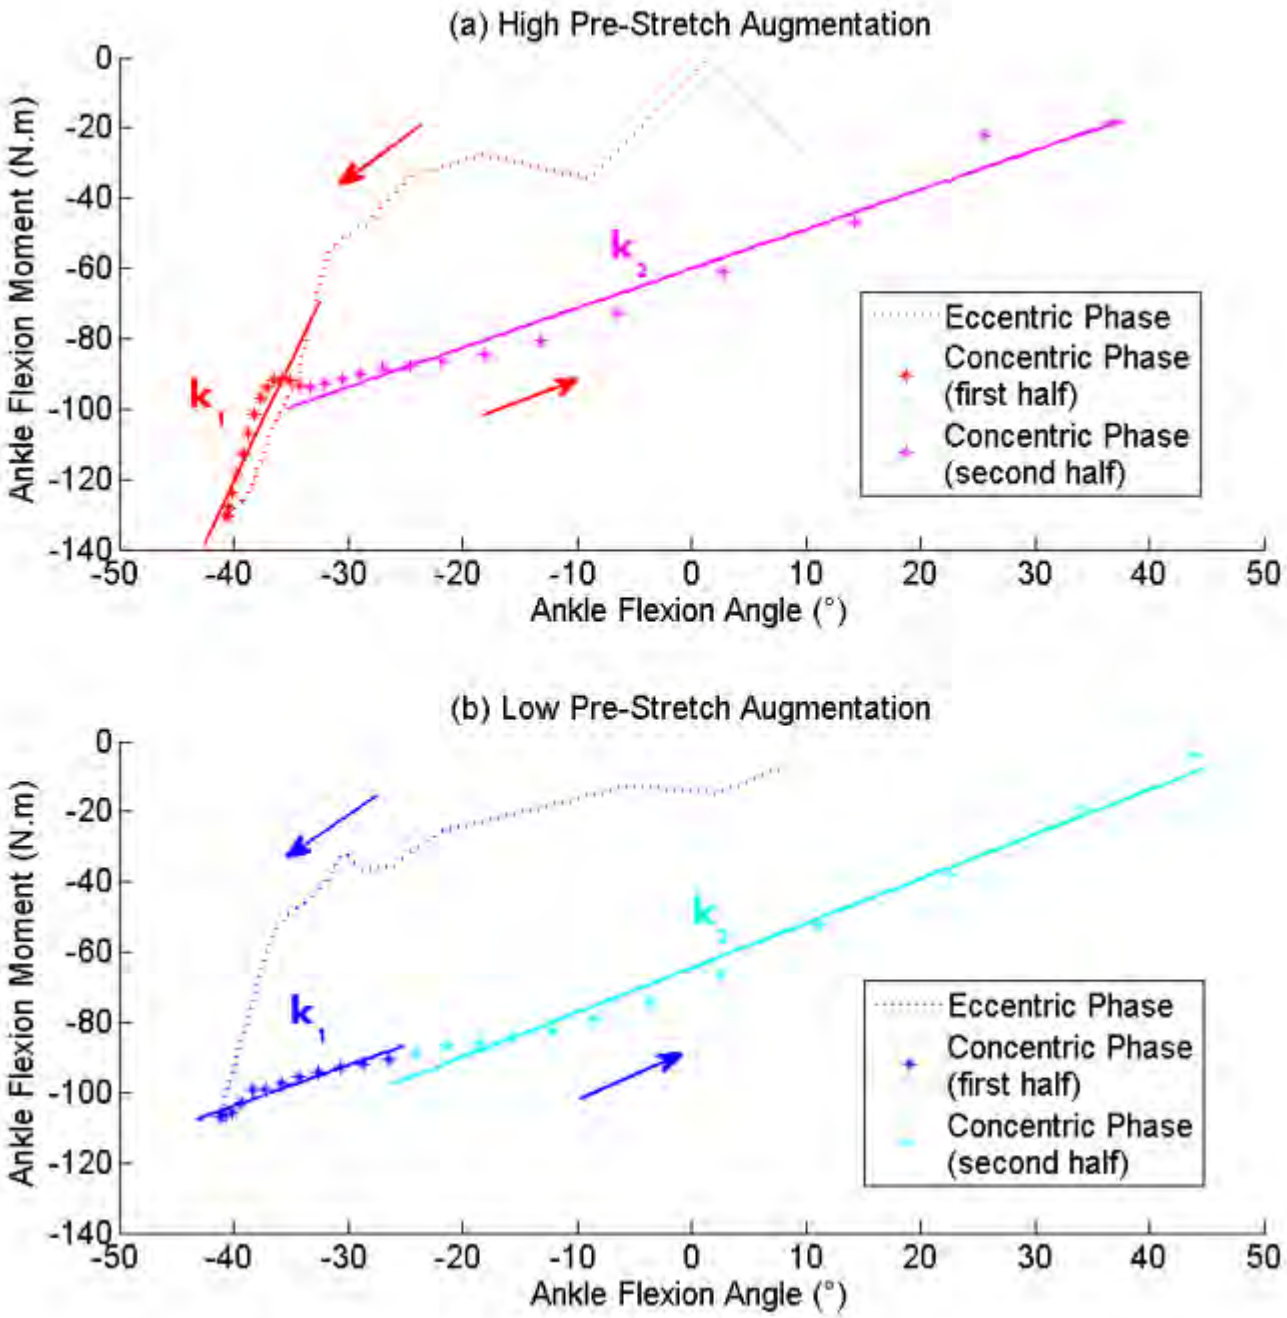
Performance was defined as the maximum height of the Center of Mass (CoM) during the flight phase minus the CoM height in static position. Pre-stretch augmentation (PSA) is defined as the ratio between the maximal performance in DJ and the maximal performance in SJ, minus 1 [5]. Ankle flexion moments were plotted versus ankle flexion angles, and two linear regressions were performed for the two halves of the concentric phase. The two regression slopes were defined as the ankle dorsiflexion stiffness in the first half of the concentric phase (k_1) and the ankle dorsiflexion stiffness in the second half of the concentric phase (k_2).

Athletes were separated into three groups with respect to their PSA during DJ: Low (LPSA), Medium (MPSA) and High PSA (HPSA). Data of the best performance for each subject and each jump condition were kept for analysis. Wilcoxon tests were performed for k_1, k_2 and maximal dorsiflexion angle for LPSA and MPSA, with HPSA as reference.

Results: PSA was different between groups whereas performance, anthropometric data and training experience were similar. In LPSA and MPSA, k_1 was lower than in HPSA ($p<0.05$). Maximal dorsiflexion angle was lower in LPSA than in HPSA ($p<0.05$), 0° corresponding to the dorsiflexion angle in static standing position. Results are presented in the table.

Typical flexion moment vs. flexion angle curves of HPSA and LPSA, and their respective k_1 and k_2 are presented in the figure.

Figure:



Caption: Typical ankle flexion moment vs. ankle flexion angle curves during the support phase in HPSA (a) and LPSA groups (b)

Conclusion: The ankle stiffness bilinear evolution in HPSA can be interpreted as two different mechanisms predominating consecutively during the concentric phase. The first and higher slope could be mainly explained by the passive shortening of previously stretched tissues, whereas the second and lower slope could be the effect of the active shortening of the triceps surae muscle fibers. In LPSA, the second mechanism appears to be predominant. The higher dorsiflexion RoM observed in LPSA could explain the difficulty for this group to store and recoil elastic energy, and their choice of a predominant 'active strategy' during the stance phase, in opposition to the 'combined active-passive strategy' used by HPSA.

As PSA in drop jump does not only depend on the ankle joint, athletes of the MPSA group used both strategies at the ankle level, explaining the absence of characteristic ankle strategy for this group.

Those two different strategies involving two different dynamic behaviors of the ankle joint, it would be interesting to take them into account for personalized training optimization, injury prevention and the return to training after injury.

Table:

	PSA (%)	**DJ Performance** (cm)	**k_1** (Nm/°)	**k_2** (Nm/°)	**Maximal Dorsiflexion Angle** (°)
HPSA	19 ± 3	54 ± 7	5.5 ± 2.6	1.5 ± 0.3	- 34 ± 4
MPSA	12 ± 2	46 ± 5	3.0 ± 2.3 *	1.5 ± 0.6	- 41 ± 8
LPSA	7 ± 2	54 ± 6	2.9 ± 1.2 *	1.9 ± 0.4	- 42 ± 6 *

Caption: PSA, Drop Jump performance, k1, k2 and Maximal Dorsiflexion Angle for the 3 groups, HPSA, MPSA and LPSA. * correspond to p-values lower than 0.05.

DIFFERENCES IN ANKLE AND KNEE JOINT KINEMATICS AND KINETICS DURING THE FIRST STANCE PHASE OF THE ACCELERATION PHASE DIFFERENTIATE BETWEEN YOUNG AND ADULT HIGH LEVEL SPRINTERS

Jeroen Aeles [1,*] Ilse Jonkers [1] Sofie Debaere [1] Christophe Delecluse [1] Benedicte Vanwanseele [1]

[1] Department of Kinesiology, KU Leuven, Leuven, Belgium

Introduction and Objectives: Sprint running can be divided in several distinct phases including the sprint start, acceleration phase and maximum velocity phase [1]. In the acceleration phase, the first stance phase is a unique element, in which power is transferred from the block phase to the rest of the acceleration phase. To better understand the difference in sprinting performance between adult and youth sprinters, joint power, joint stiffness and individual muscle-tendon complex maximal stretching and shortening velocities at the ankle and knee joint of the stance leg were determined during the first stance phase following a block clearance.

Methods: Eleven adult athletes (6 male and 5 female) and thirteen young athletes (5 male and 8 female) performed an explosive sprint start action. Twelve MX3 cameras (250Hz) and a Kistler force plate (1000 Hz) were used to collect 3D marker coordinates and the ground reaction force (Nexus, Vicon). A musculoskeletal model [2] was scaled to each subject's individual anthropometry using OpenSim 1.9. An inverse kinematics procedure was conducted to obtain joint angles and to derive joint angular velocity and individual muscle-tendon complex lengths of ankle plantar flexor and knee extensor muscles. An inverse dynamics procedure was conducted to calculate the net joint moments and joint power at the ankle, knee and hip. Joint stiffness was defined as the slope of the linear regression line on the moment-angle curve. For each joint this curve was split in two at the maximal moment, joint stiffness was thus calculated for the ascending limb and the descending limb of both the ankle and knee joint. Muscle-tendon complex length changes were normalised to the muscle-tendon complex lengths in a neutral standing position (ankle, knee and hip joint angles were set to 0 deg. for each individually scaled model). Aftwerwards the derivative of these curves, showing the muscle-tendon complex length changes were calculated for maximal stretching and shortening velocities of 7 individual muscle-tendon complexes. All parameters were first tested for skewness, after which a one-way ANOVA was used to determine significant ($p < 0.05$) differences between groups for the non-skew parameters. All data presented in the results section were normally distributed.

Results: Joint power contribution to total power generation (sum of ankle, knee and hip joint power) was significantly different between the youth and adult sprinters. The contribution of the ankle joint was larger ($p = 0.024$) in the youth sprinters (32 ± 10%) compared to the adult sprinters (21 ± 12%). The adult sprinters, on the other hand, had a larger ($p < 0.001$) contribution from the knee joint (34 ± 12%) to total power generation compared to the youth sprinters (12 ± 5%). Knee joint stiffness on the descending limb of the moment-angle curve was larger ($p = 0.005$) in the adult (5.56 Nm/deg. ± 2.18 Nm/deg.) compared to the youth sprinters (3.38 ± 1.18 Nm/deg.). Although maximal stretching velocities were not different between groups, the maximal shortening velocities were larger ($p < 0.045$) in the adult (0.94 ± 0.12 mm/ms; 0.87 ± 0.11 mm/ms; 0.89 ± 0.11 mm/ms for the) compared to the youth sprinters (0.79 ± 0.20 mm/ms; 0.71 ± 0.20 mm/ms; 0.73 ± 0.21 mm/ms) for the m. soleus, m. gastrocnemius medialis and m. gastrocnemius lateralis respectively.

Conclusion: Joint power and joint stiffness results suggest that the faster adult sprinters rely more on the knee joint than on the ankle joint, as opposed to the youth athletes. Although youth sprinters have a larger power generation in the ankle joint, their plantar flexor muscles are shortening at a lower maximal velocity compared to the adult sprinters. Since the knee but not the ankle joint stiffness was different between our groups and increasing running velocity has been linked with an increased stiffness in the knee and not in the ankle joint [3], it appears that sprint running performance may be more dependent on knee rather than ankle joint stiffness.

THE ROLE OF TORSIONAL ROTATION OF TRUNK IN SPRINT RUNNING

Natsuki Sado [1,*] Senshi Fukashiro [1]

[1]The University of Tokyo, Tokyo, Japan

Introduction and Objectives: In various dynamic movements of sports, the trunk muscle activities exert an influence on the performances. From this view point, many studies have reported on the kinematics of the pelvis and trunk during running (Novacheck 1998; Schache et al. 2002). However, the kinetics of the trunk are not yet fully examined. The purpose of the present study was to investigate the role of trunk in sprint running, based on the kinetics of the trunk.

Methods: Ten healthy, male sprinters (age: 20.8 ± 1.3 years, height: 1.75 ± 0.03 m, and body mass: 64.7 ± 3.3 kg) participated in this study. All subjects preformed 40 m sprint running with maximal effort. The motion capture system (mac 3D system, USA/nac, Japan, 200 Hz) with a synchronized force platform (Force Plate 9281E, Kistler, Switzerland, 200 Hz) was used to collect kinematics and ground reaction force data. An inverse dynamics approach was used to calculate forces and torques at the ankle, knee, hip, and lumbosacral joints. Mechanical powers induced by forces and torques at the joints were calculated. The kinetics of all participants were divided by their respective body masses. The anatomical components of the hip and lumbosacral joint torques were projected onto the z_{pel} axis (superior-inferior axis of the local coordinate system defined at the pelvis). The contribution to pelvic moment around the z_{pel} axis from each of the anatomical components of the hip and lumbosacral joint torques was determined. A two-tailed paired t-test was used to determine the differences between the contributions of the anatomical components of the hip and lumbosacral joint torque. The significance was accepted at $p < 0.05$.

Results: Fig.1a showed an example of mechanical power induced by x_{pel}, y_{pel} and z_{pel} axes components of force at the hip joint of the support leg. Although the x_{pel} (right-left axis of the local coordinate system defined at the pelvis) and z_{pel} axes components exerted little power, the y_{pel} (anterior-posterior axis of the local coordinate system defined at the pelvis) axis component exerted a large negative power during the late swing phase and a large positive power during the early swing phase. Fig.1b showed an example of the contribution of the anatomical components of hip and lumbosacral joint torques to the pelvic moment around the z_{pel} axis. The rotational torque exerted by the lumbosacral joint had a large negative contribution (toward the support leg side) during the late swing phase and a large positive contribution (toward the free leg side) during the contact and early swing phase. During the late and early swing phases, there were significant differences between the mean contributions of the rotational torque exerted by the lumbosacral joint and the mean contributions of all anatomical components of the hip joint torque ($p < 0.001$). The moment of the pelvis toward the free leg side applies an anterior force to the support leg. Conversely, the moment of pelvis toward the support leg side applied a posterior force to the support leg. These results suggested that the rotational torque exerted by the lumbosacral joint mainly generate the force at the hip joint, generating great mechanical power.

Figure:

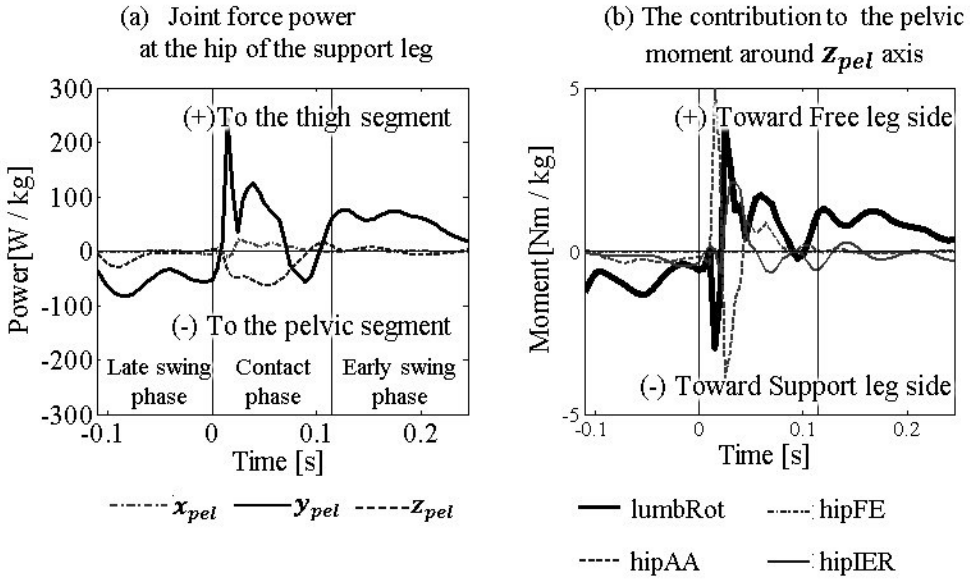

Fig.1 An example of mechanical power induced by x_{pel}, y_{pel} and z_{pel} axes components of force at the hip joint of the support leg (a), and the contribution of the anatomical components of hip and lumbosacral joint torques to the pelvic moment around the z_{pel} axis (b).
lumb: the lumbosacral joint, Rot: Rotation, FE: Flexion / Extension, AA: Abduction / Adduction, IER: Internal / External Rotation

Conclusion: The rotational torque exerted by the lumbosacral joint contributed the largest to the pelvic moment around the z_{pel} axis. By applying the anterior force to the backward leg and the posterior force to the forward leg, the rotational muscles generated negative mechanical power to the forward leg and positive mechanical power to the backward leg.

PUSHOFF FORCES AND POSTURE ANALYSIS OF TACKLE IN ELITE RUGBY PLAYERS: A PILOT STUDY

Davide Pavan [1] Fabiola Spolaor [2] Annamaria Guiotto [2] Claudio Cobelli [2] Giorgio Sbrocco [1 3] Zimi Sawacha [2,*]

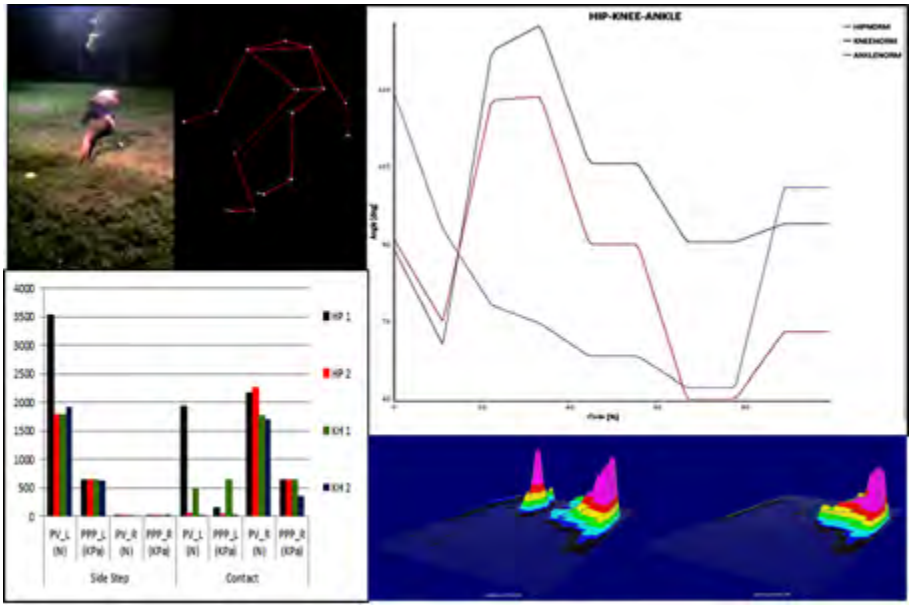
[1]Department of Biomedical Science, [2]Department of Information Engineering, University of Padova, [3]Italian Rugby Federation (FIR), Padova, Italy

Introduction and Objectives: Increased professionalism in rugby has elicited rapid changes in the techniques for evaluating the performance of elite players [1]. Commonly state of art concentrate on the physiological assessment of rugby players through protocols including vertical jump, weight lifting tests, timed short sprints and the isokinetic machine tests [1,2]. However, these measuring techniques represent an indirect measure of the ability of the players and can't be applied to directly assess their performance in the real game. Furthermore there is a paucity of research dedicated to investigating the biomechanics of tackling [2]. There is the need for significant refinement of investigations on task-specific testing procedures, in particular with respect to the assessment of tackling performance in rugby players. The aim of this work is to study the differences in the maximum individual pushing force produced by tackling in two different body postures (2 body heights) with a self-developed tracking of motion software [3] and a plantar pressure (PP) insoles system.

Methods: 10 subjects participated in the study (mean ± standard deviation (SD) BMI: 27.3±1.6, age: 21.4 ± 3.1 years) however in the present contribution only the results concerning a single athlete will be presented. All the athletes belong to the University Team of Padova (CUS Padova) that plays in the National Championship. Subjects were asked to perform 6 repeating tackles (see Figure 1) at two different heights: between the knee and the hip (KH) and between the hip and the pelvis (HP). Plantar pressure (PP) distribution was recorded (see Figure 1) by means of Novel Pedar system (novel GmbH, Germany) and 4 synchronized cameras (Logitech, C525) were used for capturing the subjects' motion. Trunk, hip, knee and ankle joints kinematics were determined by tracking specific features bilaterally (acromions, C7, anterior iliac spines, lateral femoral epicondyles, lateral malleoli, a point on the shoes approximately corresponding to the 5th metatarsal head, elbows, wrists) directly on the motion sequences with a self developed software [3]. Joints angles, peak PP (PPP) and peak vertical force (PV) were determined in Matlab (Matlab R 2013) codes [4] and their position with respect to 4 different events estimated: side step (SS), contact (C), landing, standing and ball catching.

Results: The current protocol enabled highlighting differences in the lower limb joints angles excursion between the tackle performed in the two different conditions (see Figure 1 Top right). With this respect the maximum flexion was reached at the ankle joint (130°) between 60 and 80% of the SS-C phase in HP condition, and the maximum extension was reached at the knee joint at 30% of the SS-C phase. Results concerning the PPP and PV values registered in the 2 best tackles in each condition were reported in Figure 1. It can be noticed that the subject displayed the highest PV value in correspondence of the tackle performed in HP condition at SS with a PV of 3535.8 N (left foot in contact with the ground).

Figure:



Caption: Figure 1. Top left figure: an athlete while performing a tackle in condition HP and his video sequence's 3d reconstruction. Top right figure: hip (blue)-knee (black)-ankle (red) joints flexion (-) and extension (+) angles of the best tackle in HP condition from SS (0% cycle) to C (100% cycle). Lower left figure: comparison between PPP and PV of the best 2 tackles respectively in condition KH and HP. PPP and PV are reported with respect to their values in the 4 different events. Lower right figure: comparison between 2 tackles' PP distribution in the two conditions KH (KH1) and HP (HP2) respectively (from left to right) during the contact.

Conclusion: Preliminary results showed that the present protocol allowed highlighting differences in the two tackle conditions either in the ground reaction forces or the joint angles. Furthermore differences in PV and PPP were observed with respect to significant events that characterized the tackle task. In particular a better performance of the athlete in term of PV was registered in HP condition. Future development will include completing the data analysis over the complete sample subjects and investigating the relationship between peak of forces and joints' angles.

DOES CARDIAC MUSCLE EXHIBIT HISTORY-DEPENDENT PROPERTIES?

Kevin Boldt [1,*] Venus Joumaa [1] Walter Herzog [1]

[1] Kinesiology, University of Calgary, Calgary, Canada

Introduction and Objectives: Force enhancement is a property of muscle which occurs during and following the stretch of an activated muscle, or an eccentric contraction1. Specifically, residual force enhancement (RFE) occurs when an activated muscle is stretched from a short length to a long length, which results in a greater steady-state isometric force than that produced in a purely isometric contraction at the long length2. Conversely, passive force enhancement (PFE) is defined as the increase in passive force following deactivation of an actively stretched, compared to a passively stretched muscle3. These history-dependent properties have been well identified across skeletal muscle hierarchy including whole muscle, fascicles, fibres, and myofibrils1, 4, 5. However, RFE and PFE have not been investigated in cardiac muscle. Cardiac muscle has a distinctly different structure, particularly with regards to its passive components. Importantly in this context, the structural protein titin, which is thought to be a crucial molecule in contributing to RFE and PFE, is much shorter in cardiac compared to skeletal muscle6, and is deficient in the so-called N2A region7 which has been implicated as a crucial regulator of RFE and PFE. Therefore, the purpose of this study was to determine if RFE and PFE were also present in isolated cardiac myofibrils.

Methods: Hearts were dissected from New Zealand White Rabbits and strips of tissue from the left ventricle were skinned overnight using a 1% Triton skinning solution and stored at -20°C. On the day of experiments, the strips of tissue were blended and a myofibril with a good striation pattern was identified and suspended between a glass needle and a nanolever allowing for length changes and force measurement, respectively. Myofibrils were set at an average sarcomere length (SL) of 2.4μm and activated isometrically to establish a reference contraction before being deactivated and passively stretched to a SL of 3.2μm to establish resting passive forces. After a rest period, myofibrils were activated at a SL of 2.4μm, actively stretched to a SL of 3.2μm, held for one minute and then deactivated. RFE was calculated as the difference between the steady-state force obtained after active stretch and the corresponding isometric force at 3.2μm which could be calculated based on the isometric reference force at optimal SL. PFE was calculated as the difference between the passive force following deactivation of the actively stretched myofibril and the corresponding passive force following passive stretching of the myofibril to an average SL of 3.2μm.

Results: All myofibrils (n=5) produced more force when stretched actively compared to the calculated reference isometric force, indicating the presence of RFE in cardiac myofibrils (Figure 1). The average RFE was 55±15%. Similarly, all myofibrils (n=5) had a greater passive force following active compared to passive stretching (Table 1). The average PFE was 55±11%.

Conclusion: The presence of RFE and PFE in cardiac myofibrils supports that these properties are universal across striated muscle. However, RFE was substantially smaller than the more than 200% observed in skeletal muscle myofibrils[4]. Rabbit cardiac muscles contain titin isoforms that are substantially smaller than those found in skeletal muscle, and they lack the N2A region of skeletal muscle titin, a region that is thought to be crucial for binding titin to actin, thereby

causing a large part of the RFE (LeWinter et al., 2006). Therefore, the much smaller RFE in cardiac compared to skeletal muscle myofibrils might be explained with the different titin isoforms and the lack of the N2A region in cardiac muscle. In future work, we will evaluate cardiac fibres and fascicles to see if the properties observed on the myofibrillar level are maintained, or altered across different structural levels of cardiac muscle. Investigation using cardiac muscle may shed new light and provide new avenues for investigating the mechanisms underlying force enhancement and its properties, particularly the role of titin in residual and passive force enhancement.

Table:

	Passive Force Enhancement (%)	Residual Force Enhancement (%)
Myofibril 1	70	107
Myofibril 2	94	42
Myofibril 3	50	80
Myofibril 4	30	14
Myofibril 5	32	31
Mean	55	55
SEM	11	15

IN VIVO EFFECTS OF EPIMUSCULAR MYOFASCIAL FORCE TRANSMISSION ON SARCOMERE LENGTH OF MUSCLES IN THE RAT HINDLIMB

Chris Tijs [1,*] Jaap H. van Dieën [1] Huub Maas [1]

[1] MOVE Research Institute Amsterdam, Faculty of Human Movement Sciences, VU University Amsterdam, Amsterdam, Netherlands

Introduction and Objectives: Finite element models predict that, for active muscle conditions, epimuscular myofascial force transmission may cause non-uniformities in sarcomere length in-series within muscle fibers [1]. Imaging studies have reported inhomogeneous strains in soleus (SO) muscle [2] and shortening of SO muscle fibers [3] due to passive knee extension (i.e. proximally lengthening of the two-joint gastrocnemius (GA) and plantaris (PL) muscles). While these studies did not actually measure sarcomere length, they do suggest regional effects of epimuscular myofascial force transmission on sarcomere length. The purpose of the present study was to assess effects of epimuscular myofascial force transmission on i) mean sarcomere length and on ii) the distribution of sarcomere lengths within passive fibers of one-joint muscles within the anterior (tibialis anterior, TA) and posterior (SO) compartments of the rat hindlimb.

Methods: After anaesthesia and euthanasia, left and right rat hindlimbs (n=24) were shaved, positioned in predefined knee (55^0, 90^0, 125^0, 160^0) and ankle angles (90^0, 125^0), and fixed in a 3.7% formalin solution. Note that knee flexion results in shortening of GA and PL and lengthening of EDL, while the muscle-tendon unit length of TA and SO remains constant. The applied combinations of joint angles were used to assess if length changes of synergistic muscles affect the length of sarcomeres within TA and SO for two different ankle angles. Whole fibers (2-4) were taken from multiple regions within the lateral half of SO and TA muscles. Photographs of small fiber sections (~280 μm) were made using a microscope and mean sarcomere length of each section was calculated. Each fiber was divided into three regions (proximal/intermediate/distal) and mean sarcomere lengths of the proximal and distal regions individually as well as for the entire muscle fiber were assessed.

Results: Soleus: fiber mean SO sarcomere length was not affected by knee angle (mean: 2.43±0.03μm; p=0.727 and mean: 2.19±0.05μm; p=0.403 for ankle angles of 90^0 and 125^0, respectively). Sarcomere lengths in the proximal and distal region were also not affected differently by knee angle (p=0.432 and p=0.997 for ankle angles of 90^0 and 125^0, respectively).

Tibialis anterior: fiber mean TA sarcomere length was not affected by knee angle (mean: 2.33±0.05μm; p=0.957 and mean: 2.51±0.07μm; p=0.888 for ankle angle of 90^0 (Fig. 1A) and 125^0, respectively). However, non-uniform length changes were found for both ankle angles. A significant interaction between knee angle and fiber region was found (p=0.002) at 90^0 ankle angle (Fig. 1B), with sarcomeres proximally within TA muscle fibers lengthening (p=0.013) and sarcomeres in the distal region shortening (p=0.014) when the knee was flexed from 160^0 to 55^0. At 125^0 ankle angle, also a significant interaction between knee angle and fiber region was found (p=0.031), but there were no main effects of knee angle on the sarcomere length in the proximal and distal regions (p=0.589 and p=0.222, respectively).

Figure:

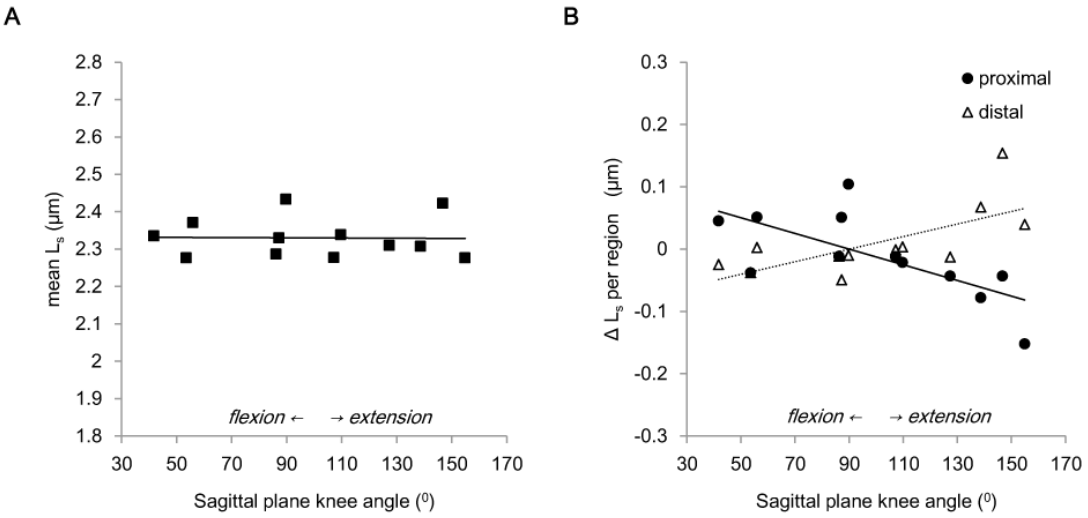

Fig 1. Effects of knee angle on the sarcomere length (L_s) within muscle fibers of tibialis anterior muscle with the ankle set to 90⁰ (n=12). (A) Absolute sarcomere lengths for the entire fiber (■). (B) Changes in sarcomere length (relative to 90⁰) for the proximal (●) and distal (Δ) region of the same fibers.

Conclusion: We found no effects of knee flexion on SO sarcomere length, indicating that SO muscle is not affected by surrounding structures. This is in agreement with a previous study in cats [4], which found no effect of knee angle on active ankle moment exerted by SO. Our results showed that knee flexion and, hence, proximally lengthening of EDL increased the sarcomere length in the proximal region and decreased the sarcomere length in the distal region of TA muscle fibers. In contrast, finite element modelling studies predicted proximal shortening and distal lengthening of TA sarcomeres when EDL was lengthened proximally [1]. This discrepancy may be explained by i) the state of the muscle (active in finite element models vs. passive in our study) and by ii) the non-specific geometry of muscles within the model. Therefore, a general finite element model that does not take into account muscle specific geometry (e.g. pennation angle) may not be able to explain effects of myofascial force transmission accurately.

Our study shows that the relative position of synergistic muscles does not affect the mean sarcomere length of SO and TA muscle fibers, but that it does result in non-uniform length changes of in-series sarcomeres within TA muscle fibers. Therefore, we conclude that, while SO acts independent from its surroundings, epimuscular myofascial force transmission is present between TA and neighbouring structures in vivo.

A NEW METHOD FOR ESTIMATING MUSCLE-TENDON PARAMETERS FOR SUBJECT SPECIFIC MUSCULOSKELETAL MODELS OF THE LOWER LIMB

Luca Modenese [1,*] Elena Ceseracciu [2] Monica Reggiani [2] David Lloyd [1]

[1]Centre for Musculoskeletal Research, Griffith University, Southport, Australia, [2]Department of Management and Engineering, University of Padua, Vicenza, Italy

Introduction and Objectives: Tools and methodologies are currently available to create subject specific anatomical musculoskeletal models from medical images. However, due to difficulties in estimating personalized muscle-tendon parameters these models have not been used in muscle actuated simulations that can be applied clinically. The aim of this work was two-fold: 1) present a methodology that allows estimation of optimal fibre length (Lopt) and tendon slack length (Lts) for Hill-type muscle actuators representing muscles of the lower limb from a subject specific model, and 2) to demonstrate a practical case of application.

Methods: A subject specific musculoskeletal model of the hip joint was created using bone and muscle meshes available through the publicly available LHDL dataset (www.physiomespace.com). The medical images were from a female donor (81 years old, 1,67 m, 63 kg) and 27 muscle-tendon lines were created with pathways travelling within the 19 muscle volumes spanning the hip joint (see Figure). NMSBuilder [1] was used to generate a model usable in OpenSim 3.2 [2].

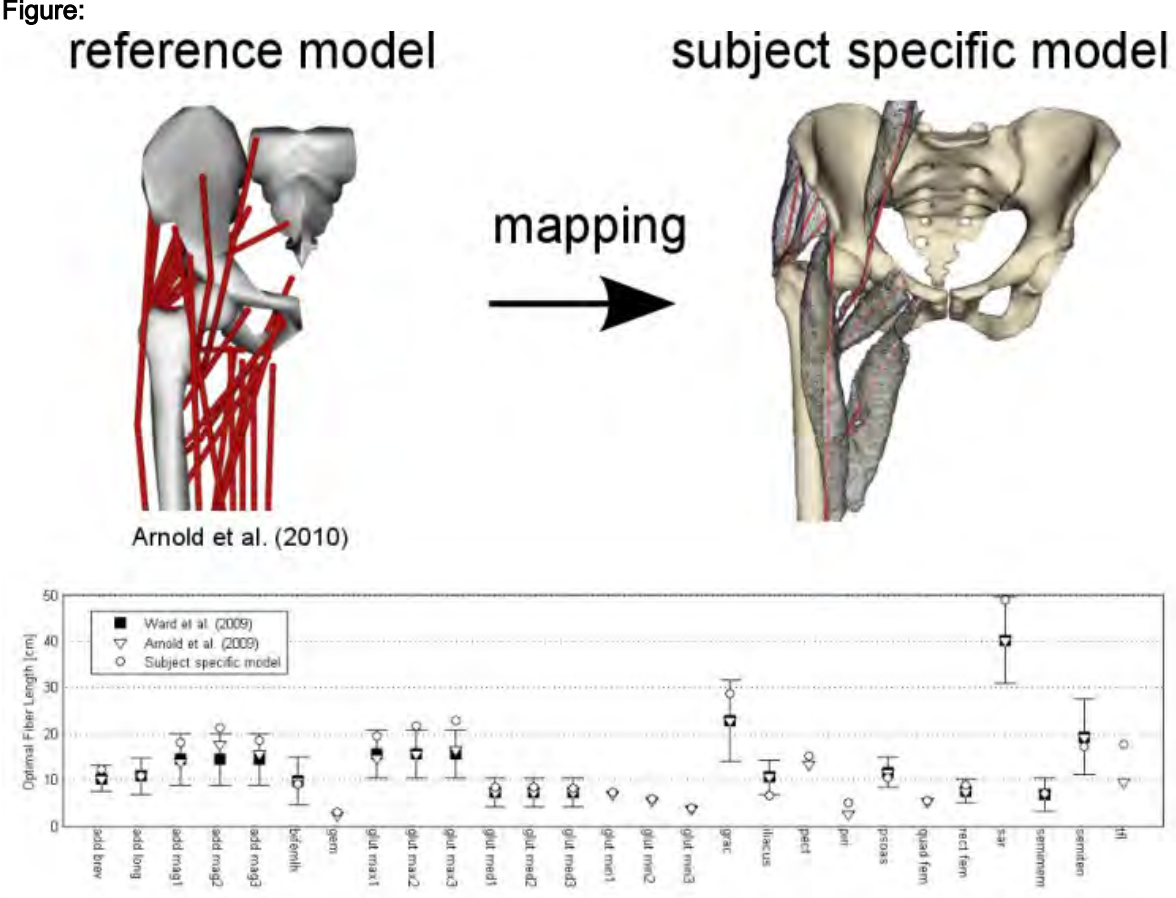
The muscle-tendon parameters were estimated for each muscle-tendon unit by: 1) uniformly sampling the spanned joints' ranges of motion using 10 points per generalized coordinate in the reference model [3], thus generating a set of model poses, and 2) mapping the reference model's normalized fibre lengths, obtained by "equilibrating" muscle-tendon, in each pose into the corresponding pose of the subject specific model. Equilibrating was achieved ensuring that for the given values of Lopt and Lts the tendon force equalled the muscle contractile element force, multiplied by the cosine of pennation angle, with the muscle fully activated. This mapping operation was implemented as an optimization procedure with Lopt and Lts being the design variables that were adjusted to minimised the difference in the normalized fibre lengths between reference and subject specific model. We included constraints to prevent solutions causing infeasible muscle-tendon states and pennation angle was set equal to the reference model.

The results were evaluated in terms of root mean squared error (RMSE) and mean tracking error (absolute value) between the reference and subject specific normalized fibre lengths in all model poses. The obtained results were also compared against a recent dataset of muscle parameters [4].

Results: Using the described methodology, the normalized operative fibre lengths of 27 muscle actuators of the reference model were mapped into the MRI-based model with a mean RMSE of 0.0799, standard deviation (SD) 0.0571, and mean mapping error calculated across all muscles of 13% (SD: 17.4). Average variation of muscle parameters was 18% (SD: 26) for Lopt and -22% (SD: 45) for Lts.

The comparison of the muscle parameters obtained through our mapping procedure against the reference model and [4] yielded values within two SD of the measured Lopt, except some bundles of the gluteus maximus and adductor maximus (Figure).

Figure:



Caption: The reference and subject specific model are in top row and the comparison between the muscle parameters obtained by optimization, included in the reference model [3] and measured in 21 cadaveric specimen [4] is in the bottom row.

Conclusion: This method generated acceptable muscle parameters without using experimental data, and can serve as starting point for further optimization or to integrate existing muscle datasets [5]. Being the reference model mostly based on [4], it is interesting to note that muscles for which parameters were not measured in that study but included from older datasets, eg gemellis, yielded the larger mapping errors.

Remarkably, the method was implemented as an OpenSim plugin and already used in other practical cases such as optimizing the muscle parameters of linearly scaled musculoskeletal models and estimating tendon slack lengths in a model with measured optimal fibre lengths.

RESIDUAL FORCE ENHANCEMENT CONTRIBUTES TO INCREASED PERFORMANCE IN FAST STRETCH-SHORTENING CYCLES OF HUMAN SKELETAL MUSCLES

Wolfgang Seiberl [1,*] Geoffrey A. Power [2] Walter Herzog [2] Daniel Hahn [3]

[1]Biomechanics in Sports, Technische Universität München, Munich, Germany, [2]Human Performance Laboratory, University of Calgary, Calgary, Canada, [3]Human Movement Science, Ruhr-University Bochum, Bochum, Germany

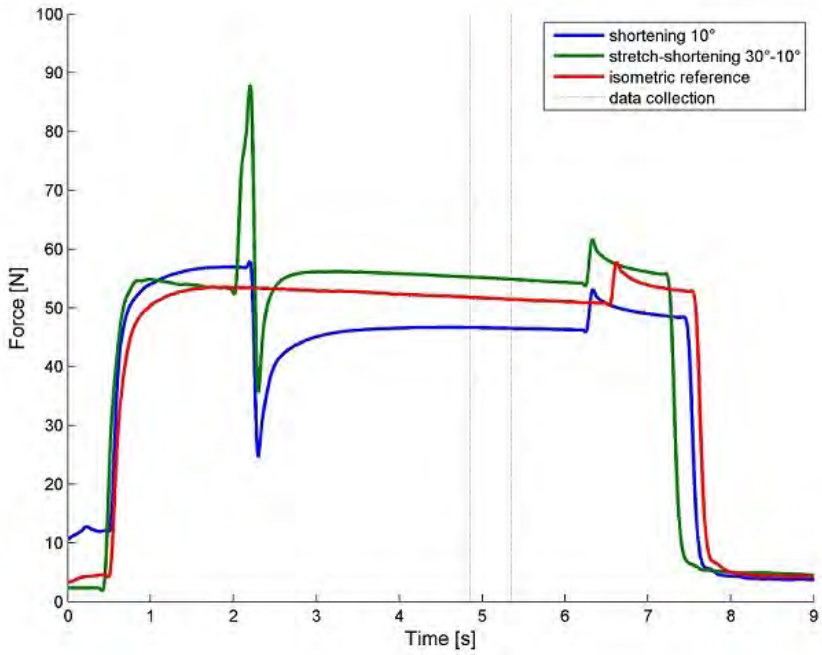
Introduction and Objectives: Combinations of lengthening and shortening muscle actions, so called stretch-shortening cycles (SSC) [1], lead to a performance enhancement during the shortening phase of the SSC. Early explanations this enhancement of work/force incorporated the idea that mechanisms responsible for residual force enhancement (RFE) may play a significant role [2], since RFE is known to generate increased isometric steady-state forces after active stretch compared to isometric reference forces at identical muscle length and activation. However, direct evidence is missing and the primary mechanisms associated with performance enhancement during SSCs are (i) the activation dynamics, (ii) the contribution of stretch reflexes, and (iii) the storage and release of elastic energy. If RFE indeed also contributes to force increase in the shortening phase of SSCs, persistent enhanced forces should be measureable beyond shortening during an isometric phase following the SSCs This prediction has never been tested, and the aim of this study is to test if there is remnant RFE following SSCs.

Methods: The adductor pollicis of 14 healthy male subjects was electrically stimulated over the ulnar nerve Digitimer, UK; 50Hz; square-wave pulses; 100µs pulse-width). Thumb adduction forces were measured using a strain-gauge based, custom-designed dynamometer (sample rate 2kHz). Testing consisted of three blocks using a pseudo-randomized design. First block: Three pure shortening contractions beginning at a thumb angle of 30° and shortening amplitudes of 10°, 20° and 30° (thumb angles increase with abduction, ranging from 0-30°). Second block: Three SSCs and the corresponding isometric reference contractions. SSCs started with 30° lengthening, followed by 10°, 20° or 30° shortening. Third block: A pure lengthening contraction from 0° to 30°, and the corresponding isometric reference contraction. All dynamic contractions were performed using an angular acceleration of 500°/s^2. Force data were low-pass filtered (10Hz), and peak force, minimum force (end of shortening), concentric work during shortening, and force during a 500ms time period (2.5-3s after shortening) were used for statistical analysis (repeated measures ANOVA and Bonferroni-Holm post-hoc comparisons; $\alpha<0.05$). All experimental procedures were approved by the Conjoint Ethics Committee of the University of Calgary.

Results: Mean electrically evoked isometric forces reached 50% of the maximum voluntary contractions. Pure shortening contractions resulted in significantly ($p < .01$) depressed forces reaching approximately 90% of the corresponding isometric reference forces (Fig. 1). Pure lengthening contractions resulted in enhanced forces reaching 116% of the corresponding isometric reference forces. Forces after the stretch-shortening contractions with shortening amplitudes of 20° and 30° did not differ from the corresponding isometric reference contractions. Forces after SSCs with 10° shortening showed enhanced forces averaging 111% compared to the corresponding isometric reference contractions (Fig. 1).

Concentric work for pure shortening contractions averaged 60% of the corresponding work produced during shortening in SSCs.

Figure:



Caption: Force-time histories of exemplar contractions ending at the same thumb angle position. Note, at interval of data collection, there is residual force enhancement (green over red) or force depression (red over blue) after stretch-shortening or pure shortening, respectively.

Conclusion: Active lengthening of the adductor pollicis muscle reduced the amount of force depression observed if shortening was not preceded by stretch. Furthermore, for SSCs in which shortening was only 1/3 of the stretch amplitude, there was a remnant RFE averaging 11%. Conventional explanations for the increase in positive mechanical work in SSCs, such as the storage and release of elastic energy, cannot explain the enhanced steady-state force after SSCs. Therefore, it appears that the stretch-induced RFE is not immediately abolished during shortening, but contributes to the increased force and work during the shortening phase of SSCs. This novel finding indicates that the mechanisms underlying residual force enhancement likely contribute to the increased amount of work performed during active shortening compared to situations where shortening is not preceded by stretch. The increased mechanical work in SSCs compared to pure shortening contractions was caused by the increased forces at the beginning of shortening and the persistent force enhancement throughout the shortening phase. Since the speed of shortening is inversely related to force depression, but the speed of stretching does not affect RFE, the results obtained here might have been favored by the high speeds of shortening, and might not have been as obvious had we chosen a relatively slow speed of shortening.

METABOLIC AND MUSCLE CONTRIBUTORS TO DIABETIC FOREFOOT DEFORMITY

Victor Cheuy [1,*] Mary Hastings [1] Michael Mueller [1]

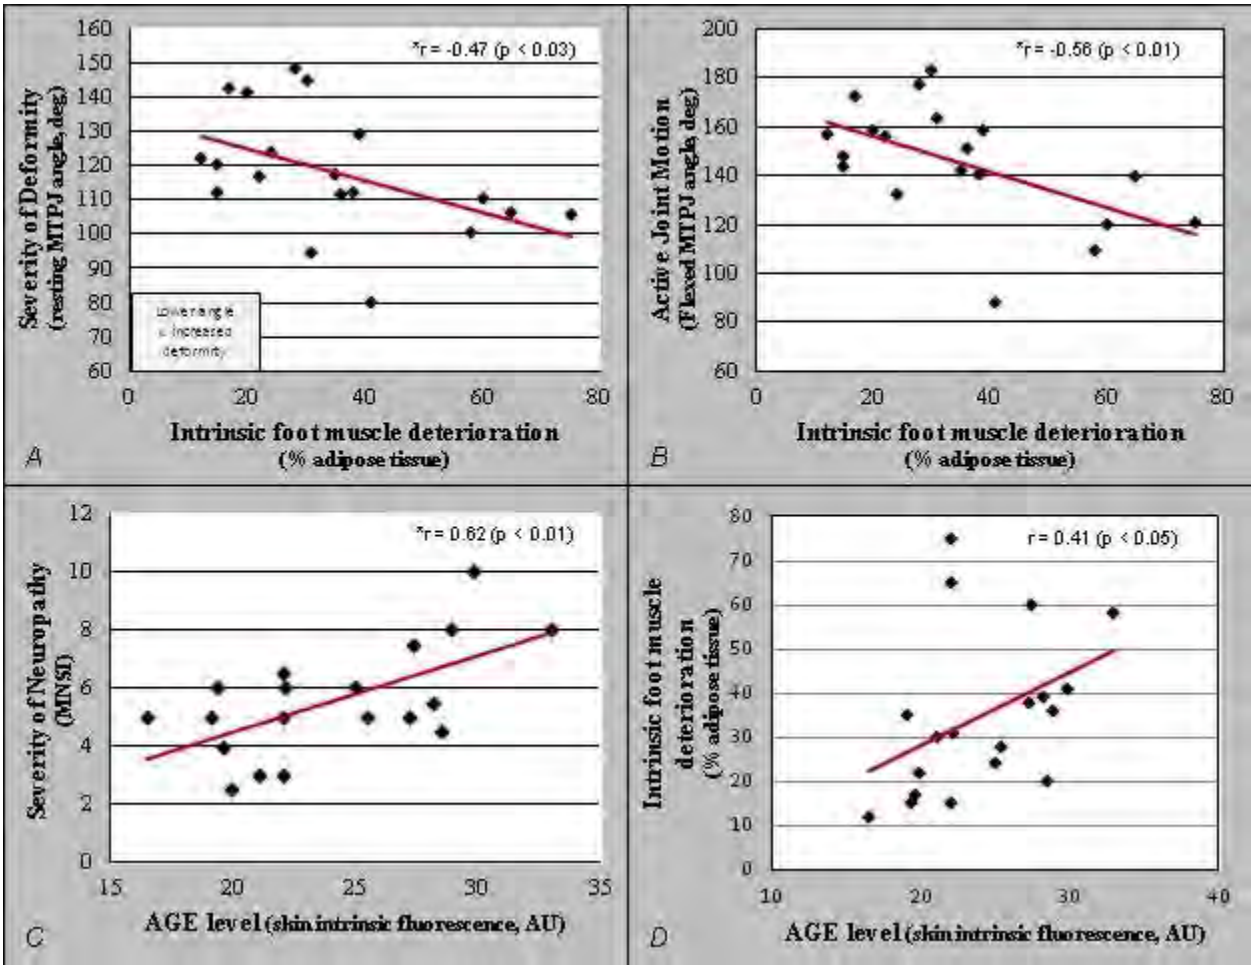
[1]Physical Therapy, Washington University in St. Louis, St. Louis, United States

Introduction and Objectives: Identifying the mechanisms that contribute to the development of diabetic foot deformity is imperative to reducing the incidence of neuropathic ulceration and lower extremity amputation. Metatarsophalangeal joint (MTPJ) hyperextension is a forefoot deformity (i.e., hammer or claw toe) associated with excessive peak plantar pressures under the metatarsal heads, and is a known risk factor for skin breakdown and amputation.[1] A hyperglycemic environment and advanced glycation end-product (AGE) accumulation are thought to contribute to three potential risk factors of deformity: neuropathy, intrinsic foot muscle deterioration, and limited joint mobility at the ankle.[2] Weakened intrinsic foot muscles from neuropathy and adipose infiltration can no longer stabilize the MTPJ, and AGE accumulation increases random collagen cross-linking, resulting in limited joint mobility. Decreased ankle dorsiflexion range of motion may contribute to extrinsic toe extensor compensation, resulting in muscle shortening and MTPJ hyperextension. The objectives of this study were 1) to determine the relationships between intrinsic foot muscle deterioration, joint deformity, and active joint motion, and 2) to determine the relationships between AGEs, severity of neuropathy, and limited joint mobility.

Methods: 19 participants (59±9 years) with diabetic neuropathy were studied. To measure MTPJ and ankle joint angles, CT scans were taken at three foot positions: resting MTPJ neutral, max active MTPJ flexion, and max ankle dorsiflexion. A custom MatLab program was used to measure the percent adipose tissue of the intrinsic foot muscle compartment from coronal MR images taken from the talonavicular joint through the midpoint of the second metatarsal.[3] Severity of neuropathy was assessed using the Michigan Neuropathy Screening Instrument (MNSI), involving a foot inspection, and reflex and sensory testing. Skin intrinsic fluorescence was measured using the SCOUT DS device (Veralight, NM, USA) as an indicator of AGE accumulation in the dermal collagen and oxidative stress levels in the epidermis. One-tailed Pearson correlation coefficients were calculated between the variables of interest.

Results: Intrinsic foot muscle deterioration was significantly correlated with MTPJ deformity ($r = -0.47$, $p < 0.03$, Figure 1A) and max active MTPJ flexion ($r = -0.56$, $p < 0.01$, Figure 1B). Skin intrinsic fluorescence was significantly correlated with the MNSI score ($r = 0.62$, $p < 0.01$, Figure 1C) and intrinsic foot muscle deterioration ($r = 0.41$, $p < 0.05$, Figure 1D), but not with max ankle dorsiflexion ($r = -0.05$).

Figure:



Conclusion: The results of this study show that intrinsic foot muscle deterioration and AGE levels are important indicators of disease progression. Increasing intrinsic foot muscle deterioration was associated with more severe MTPJ hyperextension, and reduced max active MTPJ flexion. Increasing skin intrinsic fluorescence, an indicator of larger AGE accumulation, was associated with more severe neuropathy. These findings are preliminary, and further work is necessary to define these relationships prospectively. Identifying deterioration of the intrinsic foot muscles as a risk factor for MTPJ deformity supports the need for targeted interventions early in the disease process that preserve these muscles, perhaps through strengthening exercises.

MECHANICAL INTERACTIONS BETWEEN HUMAN LOWER LEG MUSCLES IN VIVO SHOWN USING ELASTOGRAPHY

Filiz Ates [1 2,*] Ricardo Andrade [2 3] Sandro Freitas [3] Lilian Lacourpaille [2] Can A. Yucesoy [1] Antoine Nordez [2]

[1]Biomedical Engineering Institute, Bogazici University, Istanbul, Turkey, [2]Faculty of Sports Science, University of Nantes, Nantes, France, [3]Faculdade de Motricidade Humana, Universidade de Lisboa, Lisboa, Portugal

Introduction and Objectives: Lateral transmission of muscle force mediated by the epimysium (i.e. via collagenous linkages between muscles and common connective tissues) is referred to as epimuscular myofascial force transmission (EMFT). EMFT is characterized by the interplay of stiffness of intramuscular and epimuscular tissues as determined by relative positions of muscles and non-muscular structures [1, 2]. Shear elastic modulus measured using supersonic shear imaging (SSI) provides accurate estimates of changes in muscle tissue stiffness [3]. In addition, it is well correlated to localized passive muscle tension developed during stretching imposed in relaxed state [4, 5]. Thus, it can be a useful tool to assess the in vivo local EMFT effects. We hypothesized that lateral gastrocnemius (GL) length change due to externally imposed knee angle positioning would alter the stiffness of mono-articular soleus (SOL), peroneus longus (PERL), and tibialis anterior (TA) muscles. The aim of this study was to test this hypothesis and hence to analyze intermuscular interactions in human lower leg by using SSI technique.

Methods: Two experiments were performed on healthy adults. The participants lied (prone for Exp I, n=8; supine for Exp II, n=10) in an isokinetic dynamometer system with the right foot fastened to a footplate. The knee and hip were fixed. An Aixplorer ultrasound scanner was coupled with a linear transducer array in SSI mode. From 40° plantarflexion to -20° dorsiflexion (at 2°/s), shear wave elastography recordings were done for tested muscles during passive ankle motion: Exp I, GL and SOL proximally and SOL distally. Exp II, GL, PERL, and TA proximally. Each measurement was repeated 3 times. Assessments were performed with the knee flexed (90°) and fully extended (0°) in a randomized order. SSI recordings were exported in “mp4” format, sequenced into images (“jpeg” compression) and were processed using MATLAB. An average value of the colored map converted into shear elastic modulus was calculated for each image. Stiffness values were synchronized with the ankle angle and torque values.

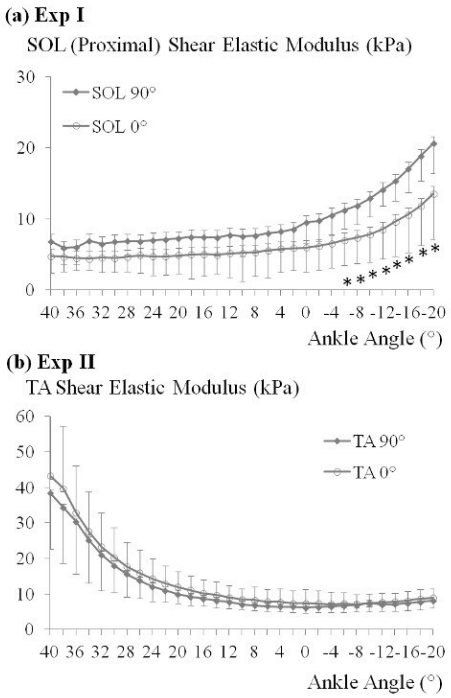
Two-way ANOVAs for repeated measures (factors: ankle and knee angles) subsequently Bonferroni post-hoc procedure were used to analyze the effects of knee angle change on stiffness of each muscle. P values < 0.05 were considered as significant.

Results: *Exp I:* Significant main effects and interaction showed increased stiffness for the GL (maximally by 26.9±1.8%) in dorsiflexed positions (starting from 4° plantar flexion) due to altered knee angle. The imposed length change on the GL caused quite complex effects on the SOL located in the same compartment: Proximally, significant main effects and interaction showed a decrease in stiffness (maximally by 65.4±4.1%) only in dorsiflexed ankle positions from 6° plantar flexion. Distally, significant main effects but no significant interaction demonstrated increase in stiffness (43.8±9.5% in average) independently from ankle position.

Exp II: Significant main effects and interaction showed that the GL stiffness increased (maximally by 55.9±8.5%) in dorsiflexed positions (starting from 2° plantar flexion) due to altered knee angle. Significant main effects but no significant interactions were found for the PERL stiffness (mean increase of 10.4±3.8%) and for TA muscle (mean increase of 12.3±4.4%) due to altered knee angle.

These findings show occurrence of mechanical interactions between lower leg muscles leading to local muscle stiffness changes. Differently changing stiffness of the SOL proximally and distally is remarkable and in concert with EMFT phenomenon previously reported [2]. Overall, the knee angle change imposes relative position changes affecting muscle stretch and length of epimuscular connections. Ankle movement leads to varying stretches of lower leg musculature and their epimuscular connections. For some muscles a balance of these effects causes a net stiffness increase.

Figure:



Caption: Shear elastic modulus of (a) SOL (proximal) and (b) TA muscles with respect to ankle angle. * indicates that modulus values measured at 90° and 0° of knee angle are significantly different for SOL (proximal).

Conclusion: Our results show that altered knee angle imposes changes in shear elastic modulus for not only the GL but also the SOL, PERL and TA muscles. These findings confirm our hypothesis and show the strength of SSI technique in assessing effects of intermuscular mechanical interactions in terms of muscle stiffness.

AS-0270-2

TOWARDS AN UNDERSTANDING OF THE MECHANISMS UNDERLYING FORCE ENHANCEMENT

Krysta L. Powers* [1], Kiisa Nishkawa[2], Walter Herzog[1]

[1]Faculty of Kinesiology, University of Calgary, Calgary, Canada, [2]Department of Biological Sciences, Northern Arizona University, Flagstaff, AZ, United States

Introduction and Objectives: Since the early 1950's, a single theory has governed our basic understanding of muscle force production, which predicts force by sarcomere length, or number of attached cross-bridges (CBs) [1]. Under this theory, the predictions of force following active lengthening are vastly underestimated [2]. The state of enhanced force following active lengthening above that predicted by the CB theory is referred to as residual force enhancement. Residual force enhancement has been demonstrated in vivo and down to the level of the sarcomere [3], prompting the development of alternative mechanisms to explain the history-dependence of muscle force. Experiments from our laboratory suggest that titin, a dynamic spring protein in the sarcomere, is the primary source of sarcomere force enhancement. Titin stiffness increases up to 400% in actively stretched sarcomeres, partly by a Ca2+-based increased in its spring stiffness, but predominantly by an unknown mechanism [4]. We speculate that titin becomes stiffer and contributes to residual force enhancement when it binds to the thin filament, becoming shorter and stiffer during active sarcomere stretch [3], thus for a given amount of stretch, more force can be produced. This idea has been conceptually validated using a mathematical model to predict the force of actively stretched sarcomeres with titin bound to the thin filament [4]. Therefore, the aim of this study was to experimentally investigate this mechanism of titin binding by examining the mechanical properties of sarcomeres in a titin-mutation model [5], in which the region of the titin protein predicted to bind to the thin filament is deleted.

Methods: Mechanical testing of intact sarcomeres was achieved using isolated psoas myofibrils from normal wild type mice and mice with a deletion in the distal N2A-PEVK region of titin (mutant) [5]. Myofibrils were mounted between a motor for controlled length changes, and cantilever of known stiffness for force calculations, at 100X magnification. Myofibrils were then slowly stretched at a speed of 0.1 um per sarcomere per second passively and at maximal Ca2+-activation from optimal filament overlap (2.2-2.5 um) to sarcomere lengths well beyond filament overlap (6.0 um) for direct observation of titin based force enhancement in the absence of CB force.

Results: The passive mechanical properties of normal and mutant myofibrils did not differ suggesting that in the absence of Ca2+-activation the stiffness of the mutant sarcomere is not altered by the deletion in the titin protein. However, when activated and stretched, the mechanical properties of mutant sarcomeres were distinctly different from wild type controls (Fig 1). Force was lower at all sarcomere lengths and titin-based force enhancement was deficient in actively stretched mutant sarcomeres compared with the wild type controls (Fig.1).

Figure:

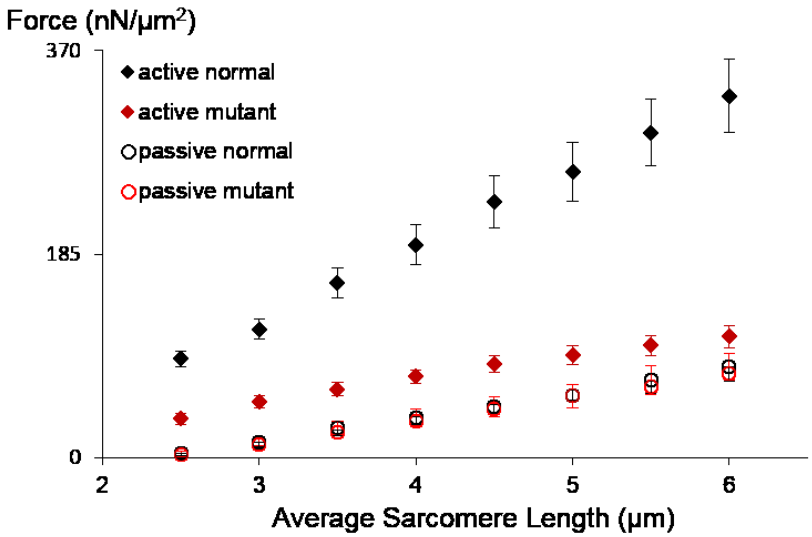

Fig. 1. Force sarcomere length relationships of actively (diamonds) and passively (circles) stretched myofibrils from normal (black) and mutant mice with a deletion in the titin protein (red). Mutant sarcomeres generate less force than normal myofibrils at all sarcomere lengths during active stretch.

Conclusion: This study demonstrates that a deletion in the titin protein can directly influence active force production. In actively stretched mutant sarcomeres the total force and titin based force enhancement were severely disrupted. These findings suggest that the region of titin that modulates its spring stiffness is contained within the deleted region of the mutant protein and that titin force modulation likely plays a role in muscle contraction as well as residual force enhancement. We remain in support of the idea that titin binds to the thin filament during active stretch; effectively shortening it's mechanical spring. As the force of actively stretched mutant sarcomeres was vastly reduced at all sarcomere lengths, we suggest that titin thin filament binding is relevant within the muscles working sarcomere lengths and provides additional structural support by strongly resisting extension of contracting sarcomeres. This is an important mechanism for predicting muscle force during dynamic locomotion and for the prevention of stretch-induced muscle injury. While there are many possible mechanisms by which titin based force enhancement occurs, we believe titin provides the sarcomere with additional force during active stretch by binding to the thin filament, which offers a viable explanation of how skeletal muscles achieve enhanced force following active lengthening. Future studies will aim to validate the results of this study in a skinned fiber preparation and further elucidate the mechanism.

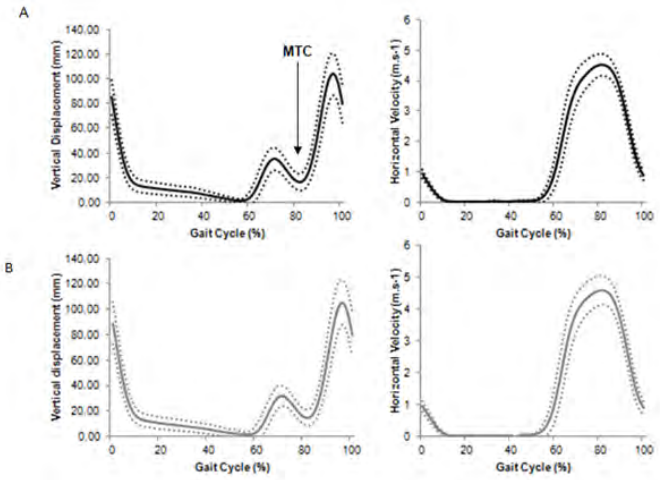
THE EFFECTS OF A DUAL-TASK ON OVERGROUND MINIMUM TOE CLEARANCE AND GAIT PARAMETERS DURING WALKING IN OLDER ADULTS

Kim R. Duffy [1,*] Matthew Taylor [1] Jo Jackson [2]

[1]Centre of Sports and Exercise Science, Biological Science, [2]Health and Human Science, University of Essex, Colchester, United Kingdom

Introduction and Objectives: Falls in older adults are common, with the majority occurring due to tripping whilst walking. Although falls are multifactorial, tripping while walking accounts for 53% of all falls [1]. Alterations in gait patterns such as reduced minimum toe clearance (MTC), walking speed and stride length occur in ageing [2]. Insufficient MTC has been found to cause tripping whilst walking and also during dual-tasks [3, 4]. There is a paucity of research looking at MTC during manual dual-tasks (walking whilst holding an object) in older adults. Therefore the aim of this study was to examine MTC and spatial-temporal parameters during normal and dual-task walking in community-dwelling older adults.
Methods: Fifteen healthy older adults (8 males, 7 females; 62.7±1.5yrs) participated. Each performed two tasks on a 10m level walkway, 1: normal walking, and 2: walking whilst holding a cup of water (manual dual-task). A 7 camera Vicon (Oxford, UK) motion analysis system was used. MTC was calculated using the vertical displacement of the shoe-mounted marker on the heads of the 2nd metatarsals. This coincided with maximum horizontal toe velocity in swing (Fig 1). Spatial-temporal parameters were also calculated. Five trials for both tasks were averaged and analysed. A paired t-test was executed for parameters except for toe-off (%) which was analysed using a Wilcoxon test.
Results: There were no significant differences between MTC (15.79±6.67 vs. 15.15±6.95mm) or maximum horizontal velocity (4.55±0.36 vs. 4.60±0.46m.s-1) for older adults performing normal and dual-task walking. Significant differences for the spatial-temporal parameters revealed older adults altered their gait pattern by increasing their stride length and walking speed during dual-task walking when compared to normal walking (1.46±0.17 vs. 1.44±0.16m; 1.44±0.19 vs. 1.39±0.15m.s-1 respectively), with no significant difference for cadence (118±6 vs. 116±6), toe-off (61.0s IQR = 2.4 vs. 62.7s IQR = 3.8) or stride time (1.02±0.06 vs. 1.04±0.05s) (Table 1, Fig 1).
Figure:



Caption: Figure 1 Averaged (±SD) toe vertical displacement and horizontal velocity over one gait cycle for 15 participants during normal walking (A) and dual-task walking (B). Note: initial contact was at 0% and 100% and toe-off approximately at 60%.

Conclusion: MTC for older adults aged 62-64 years did not alter when performing a dual-task whilst walking when compared to normal walking. Previous research found similar findings for MTC during manual dual-task walking (10.3±0.3mm) when compared to normal walking (9.8±0.5mm) [4]. However, stride length and walking speed did increase during dual-task walking and this is potentially due to motor task prioritisation. Previous research [5, 6] comparing dual-task walking to normal walking have found older adults have shown to prioritise their motor performance in dual-task situations by altering their gait to an increased stride length and walking speed. Research comparing young adults found during dual-task walking their gait pattern is consistent to normal walking [5] or it alters to shorter stride length and slower walking speed, whereas older adults increase their stride length and walking speed [6]. This prioritisation of motor performance during dual-task walking has been associated with fall prevention in older adults [5]. Therefore, similar to previous research older adults in this study may have increased their stride length and walking speed to prioritise the motor performance over the dual-task to potentially minimise the risk of falling. Future research is underway involving 107 community-dwelling older adults in three age groups (55-64, 65-74 and 75+ yrs) performing four functional tasks (normal walking; manual dual-task walking; stepping onto and down off a step; obstacle negotiation), to determine the MTC, horizontal velocity and spatial-temporal parameters for all tasks

Table:

Gait parameter	Dual-task walking	Normal walking	*P* Values
Vertical displacement of the toe (MTC) (mm)	15.15 ± 6.95	15.79 ± 6.67	t_{14} = -0.507, P < 0.05
Maximum horizontal velocity of the toe (m.s^{-1})	4.60 ± 0.46	4.55 ± 0.36	t_{14} = 1.262, P < 0.05
Cadence (steps/min)	118 ± 6	116 ± 6	t_{14} = 0.847, P < 0.05
Toe-off (%)*	61.0 IQR = 2.4	62.7 IQR = 3.8	t = 77.00, P < 0.05
Stride length (m)	**1.46 ± 0.17**	**1.44 ± 0.16**	t_{14} = -1.956, P < 0.05
Stride time (s)	1.02 ± 0.06	1.04 ± 0.05	t14 = 2.679, P > 0.05
Walking speed (m.s^{-1})	**1.44 ± 0.19**	**1.39 ± 0.15**	t14 = 2.784, P > 0.05

Note: * signified median values for the parameter which was not normally distributed. **Bold** values represent significant differences.

IS THE DIFFERENCE BETWEEN PREFERRED AND NON-PREFERRED LEADING LEG OBSTACLE CROSSING LARGER IN ELDERLY FALLERS THAN IN NON-FALLERS?

Emmanuel S. da Rocha [1,*] Eliane C Guadagnin [2] Maarten Bobbert [3] Jacques Duysens [4] Felipe Carpes [5]

[1]Federal University of Santa Maria, Santa Maria, [2]Federal University of Rio Grande do Sul, Porto Alegre, Brazil, [3]VU University Amsterdam, Amsterdam, Netherlands, [4]KU Leuven, Leuven, Belgium, [5]Applied Neuromechanics Research Group, Federal University of Pampa, Uruguaiana, Brazil

Introduction and Objectives: Falls in the elderly are frequently associated with obstacle contacts during walking. Recently, we have shown that obstacle crossings with the preferred leg leading are different from those with the non-preferred leg leading. In the present study, we set out to determine asymmetries in obstacle crossings and investigate whether they are larger in elderly fallers than in non-fallers. As in daily life most people will typically be thinking of other things while walking, we had our participants perform a secondary task during the obstacle crossings.

Methods: Elderly fallers (n=10) aged 66 ± 5 years old, body mass of 63.5 ± 13.4 kg and height of 1.52 ± 0.04 m, and non-fallers (n=10) aged 66 ± 4 years old, body mass 72.3 ± 1.5 kg and height 1.47± 0.06 m, all able to walk independently, volunteered for participation in this study. Participants walked barefoot at self-selected speed along an 8 m walkway and crossed a polystyrene obstacle 20 cm wide and with height defined as 20% of leg length, which was placed in the middle of the walkway. Bilateral kinematics was sampled at 200 Hz using Plugin Gait markers (Vicon Motion Systems, Oxford, UK). Kinematic data were low-pass filtered with a 4th order Butterworth filter at a cut-off frequency of 8 Hz.

The following cognitive task was used: when experimenter said “red” or “blue”, the participant had to reply “no” and “yes”, respectively. When the experimenter mentioned any other color name, the participant had to simply repeat the color name. Crossings with different leading legs were elicited by having subjects initiate walking from a standing position with either the left or the right leg. Participants did not receive any instruction concerning which leg should cross the obstacle first. Trials were recorded until we had 10 trials for each leg. Leg preference was determined using the Waterloo inventory. Leading limb toe clearance, trailing limb toe clearance, leading limb heel clearance, trailing limb pre-obstacle distance and leading limb post-obstacle distance were determined. Data normality was verified using the Shapiro-Wilk test. An analysis of variance for repeated measures was performed to verify effects for group (fallers *vs* non-fallers) and limb (preferred *vs* non-preferred), followed by post hoc pairwise tests when suitable. All tests were performed with SPSS 20.0 at a significance level of 0.05.

Results: Table 1 presents results from elderly fallers and non-fallers. Comparison between preferred and non-preferred leg yielded a statistically significant asymmetry in lead limb post-obstacle distance in both groups (Table 1), with an asymmetry index (AI) defined as: [AI= Preferred/(Non-preferred+Preferred)]. Lead limb post-obstacle distance AI was 0.52±0.58 among fallers and 0.53±0.55 among non-fallers. No significant asymmetry was observed for the other kinematic variables, in which AI ranged from 0.49 to 0.53 (Table 1).

We studied obstacle crossing with the preferred and non-preferred leg in elderly fallers and non-fallers, while performing a dual task. Both groups showed a difference between preferred and non-preferred leg for lead-limb post-obstacle distance

but the 2 groups did not differ. This indicates that this parameter is not sufficiently sensitive to discriminate between fallers and non-fallers. The absence of differences for other parameters such as toe clearance is in line with data from the literature on obstacle avoidance without dual tasking. In the review of Barrett et al. (2010) it was concluded that toe clearance did not systematically differ between older fallers and non-fallers. However, variability in this parameter did differ. Hence in future studies it is suggested to take variability into account as well. The present data do not support the contention that this type of dual tasking profoundly affects performance in obstacle avoidance.

Conclusion: No asymmetries were found in obstacle clearance between elderly fallers and non-fallers. We did find an asymmetry in post-obstacle distance, but this asymmetry was not larger in elderly fallers than in non-fallers and hence does not seem to pose an elevated fall risk in fallers

Table:

	Fallers (n=10)			Non-fallers (n=10)		
	P	NP	AI	P	NP	AI
Lead limb toe clearance (cm)	12.2 ±1.3	12.1 ±3.0	0.50 ±0.30	12.2 ±1.3	12.2 ±1.8	0.50 ±0.42
Trail limb toe clearance (cm)	12.5 ±4.7	12.4 ±5.6	0.50 ±0.46	10.1 ±3.9	10.6 ±1.5	0.49 ±0.72
Lead limb heel clearance (cm)	10.6 ±2.0	10.4 ±2.5	0.50 ±0.44	10.6 ±2.9	9.4 ±1.9	0.53 ±0.60
Trail limb pre-obstacle distance (cm)	12.1 ±2.1	11.6 ±1.9	0.51 ±0.53	11.1 ±1.6	11.5 ±2.8	0.49 ±0.36
Lead limb post-obstacle distance (cm)	10.9 ±2.9	9.9 ±2.4 *	0.52 ±0.55	13.9 ±4.2	12.1 ±3.0 *	0.53 ±0.58
Gait speed (m/s)	0.9 ±0.1	0.8 ±0.1	0.53 ±0.50	0.9 ±0.1	0.9 ±0.1	0.50 ±0.50

Caption: Results for gait variables with the preferred leg (P) and with the non preferred leg (NP) leading; * indicates difference between legs ($p<0.05$). No difference was observed between the groups. AI: asymmetry index (see text).

EFFECTS OF TAI CHI EXERCISE ON LOWER EXTREMITY IN ELDERS DURING WALKING

Po-Chieh Chen [1,*] Chen-Fu Huang [1] Bo-Jen Ko [1] Chung-Lin Wu [1]

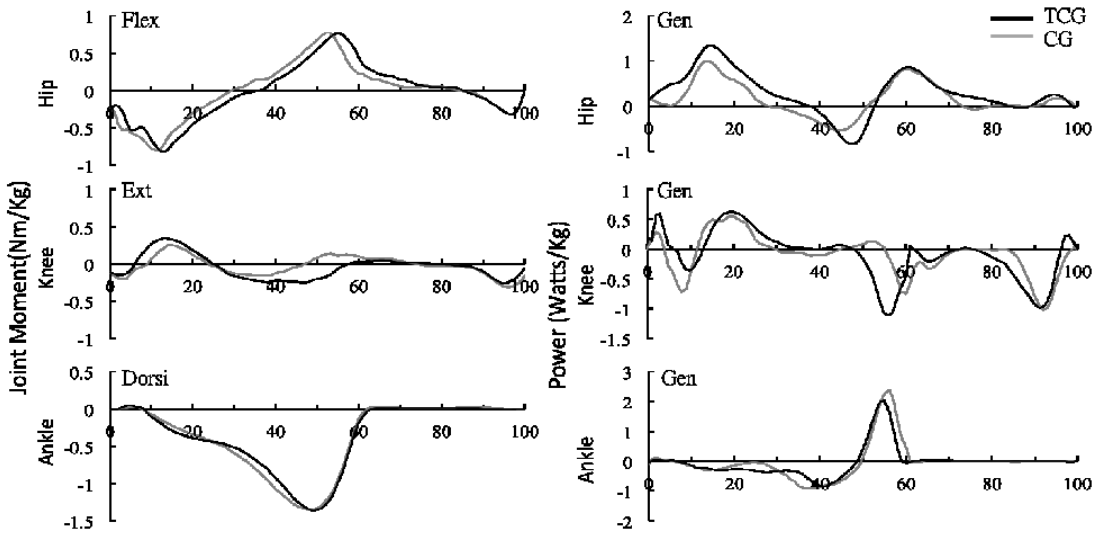
[1] Physical Education, National Taiwan Normal University, Taipei, Taiwan, Republic of China

Introduction and Objectives: Elders were found to have slower walking speed and lower ankle plantarflexor power during gait due to the gait-muscle weakness [1]. The compensation mechanism of lower extremity, therefore, has become very important for elders. Tai Chi exercise has been demonstrated to improve muscle strength and postural stability [2], and thus might enhance the knee and hip ability for reductions of ankle plantarflexor power. The purpose of this study was to investigate the effects of Tai Chi exercise on lower extremity in elders during walking.

Methods: The self-selected speed walking motions and ground reaction forces of thirty elders (Tai Chi group, TCG: N=15, 4 females and 11 males, Experience of Tai-Chi: 8.05±3.67 yrs, Age: 74.27±6.20 yrs, Height: 1.62±0.08 m, Weight: 60.42±6.03 kg; Control group, CG: N=15, 7 females and 8 males, Age: 73.20±6.66 yrs, Height: 1.62±0.09 m, Weight: 62.65±10.63 kg) were collected by a 10-camera Vicon motion capture system (250 Hz) and a Kistler force plate (1,000 Hz) respectively. Inverse dynamic was used to calculate the joint moment and power during support phase of gait. Raw data were filtered using a Butterworth 4th-order low-pass filter with a cut-off frequency of 6 Hz. Kinetic variables were normalized to a percentage of subject's body weight (B.W.) and transferred to 100% of the right foot contact time on the force plate. A *t*-test was used to compare group differences (α= .05).

Results: The results revealed that walking speed in TCG was faster than CG (TCG: 1.17±0.18 m/s; CG: 1.06±0.13 m/s, $p < .05$). The knee extensor moment and the maximum positive power of hip showed significantly greater in TCG during braking phase (TCG-knee: 0.4±0.12 Nm/kg, hip: 1.31±0.42 watts/kg; CG-knee: 0.27±0.16 Nm/kg, hip: 0.97±0.2 watts/kg, $p < .05$). The minimum negative power of knee showed significantly greater in TCG during propulsive phase (TCG: 0.32±0.02 watts/kg; CG: 0.69±0.13 watts/kg, $p < .05$).

Figure:



Caption: Joint moments and powers of lower extremity in Taichi and control group during stance phase.

Conclusion: The reduction of power in hip and knee was found to be relative to the slower walking speed due to the muscle weakness [1] and the increased knee extensor joint moment could enhance the stability of the knee [3]. Therefore, the results in TCG demonstrated that Tai Chi exercise might be able to enhance muscle strength about knee and hip and had more stable knee movement. This might be due to the continuing lower body center of mass and semi-squat position emphasized in Tai Chi exercise. It suggested that Tai Chi exercise might have the potential of maintaining the walking ability, and lessening the muscular weakness caused by aging.

ANKLE POWER PEAK AND DYNAMIC JOINT STIFFNESS OF THE ANKLE IN RHEUMATOID ARTHRITIS POSTMENOPAUSAL WOMEN WITH AND WITHOUT FALLS HISTORY

Pedro Aleixo [1,*] Ivo Roupa [1] Paulo Coelho [2] José Vaz Patto [2] João Abrantes [1]

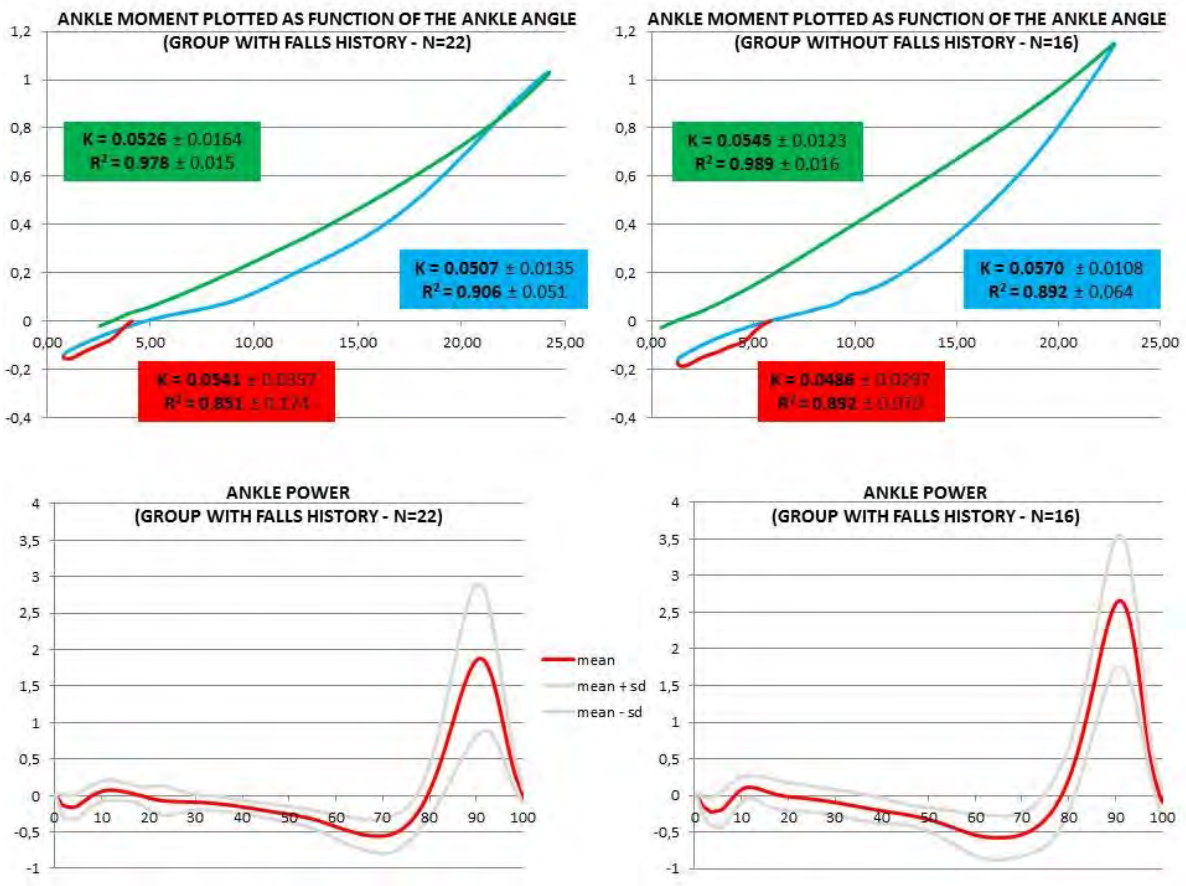
[1]Biomechanics, MovLab/Universidade Lusófona de Humanidades e Tecnologias, [2]Rheumatology, Instituto Português de Reumatologia, Lisbon, Portugal

Introduction and Objectives: The lack of lower limb joint stability could be a reason for the increased fall risk in rheumatoid arthritis (RA) patients[1] and in postmenopausal women[2], well as a reason for the lower functional capacity in RA patients[3]. Proprioception and stiffness play an important role in joint stability[4]. For optimal joint stability is needed some level of stiffness, however too much or too little stiffness it is not advisable[5]. To study the lower limb joint stiffness has been developed the concept of dynamic joint stiffness (DJS)[6]. DJS is defined as the stiffness of muscles and other joints structures during intersegmental displacement as a reaction to the external moment[6,7]. The slope of the joint moment plotted as a function of the joint angle is an approach to the DJS measure and has been used as quantitative reference[6,7]. During the stance phase of walking, the ankle joint supports and propels the body through three distinctive phases of nearly constant stiffness: the controlled plantar flexion, the controlled dorsiflexion and the powered plantar flexion[8]. Moreover, were found lower values of ankle power peak (APP) in elders with low functional capacity[9], and accordingly with literature, APP is an essential component of functional mobility in older women with functional limitations[10]. So, the objective of this study was to compare APP and DJS of the ankle during gait in RA postmenopausal women with and without falls history.

Methods: The 19 RA postmenopausal women selected for this retrospective study (without lower limbs prostheses), answered the question: "how many times did you fall last year?". A tridimensional analysis was used to assess the biomechanical parameters. The Vicon® Motion Capture system recorded kinematics data (9 MX1.3 cameras, 200Hz) synchronized with a force plate (AMTI BP400600-200, 1000Hz). Data analyzed by Vicon® Nexus software (1.7.1) based on an integrated model of 41 reflective markers relocation and subject anthropometric data, developing mechanical segments and joints centers. Subjects performed 14 valid trials (7 left and 7 right foot-step on force plate). Ankle “moment of force-angle” plot was divided in 3 phases and computed the matching DJS: controlled plantar flexion, controlled dorsiflexion and powered plantar flexion. T test was used.

Results: Eleven subjects had at least one fall in the previous year. The DJS of the subjects ankles with falls history did not show differences relatively to the subjects ankles without falls history (K values in figure 1). The R-squared mean of the subjects linear models were higher than 0.85 in all phases for both groups (figure 1). APP was lower in the subjects ankles with falls history (1.97 ± 1.03 W *vs* 2.73 ± 0.90 W, p=0.021).

Figure:



Caption: Figure 1. Ankle moment plotted as function of the ankle angle and ankle power, during foot contact with force plate (groups of subjects with and without falls history).

Conclusion: The R-squared results showed that the three phases of the stance period can be translated into a linear moment-angle relationship in RA postmenopausal women. The DJS results of the second and third phase were consistent with the results of other studies in healthy people[6–8], however the results of these studies in the first phase were much lower than the results observed in our study for both groups. Despite the small sample size, the lack of differences between the subjects ankles with and without falls history seems indicate that DJS of the ankle shall not be a parameter associated with the occurrence of falls. In contrast with DJS, the APP seems to be a gait biomechanical parameter that is associated with falls in RA postmenopausal women. Interventions for enhance this parameter could be advisable and exercise programs appear as a possibility.

THE INFLUENCE OF FUNCTIONAL FITNESS LEVEL ON THE STRATEGIES ADOPTED BY THE ELDERLY TO ACCELERATE THE BODY UPWARDS DURING STAIR ASCENT

Vera Moniz-Pereira [1,*] Thomas M. Kepple [2] Silvia Cabral [1] Filipa João [1] António P. Veloso [1]

[1] Laboratório de Biomecânica e Morfologia Funcional, CIPER, Faculdade de Motricidade Humana - U Lisboa, P-1499-002 Lisboa, Portugal, [2] C-Motion, Inc, Germantown, MD, United States

Introduction and Objectives: The age decline in functional fitness, particularly in muscle strength, leads to problems in mobility and difficulties in performing daily activities[1], especially locomotor activities involving stairs[2]. As a consequence, studies show that older adults re-distribute their joint moments while ascending stairs in order to be able to meet the task demands[3-4]. However, these studies do not directly quantify the consequences of this re-distribution to the body upward acceleration, one of the main goals of stair ascent.

The aims of this study were: to quantify, using induced acceleration analysis (IAA), joint moments and gravity contributions to the vertical acceleration of the center of mass during stair ascent in the elderly and, to verify the influence of the subjects' functional fitness level in those contributions.

Methods: The sample included 6 community-dwelling older adults over 65 years (72.5±5.1y), without any condition that would affect their gait. The subjects were divided in 2 groups according to their functional fitness level (LFFL – low functional fitness level; HFFL – high functional fitness level), established through a score (max: 24 points) composed by the results of 6 field tests: the 8 foot Up&Go and the Chair Stand test from Senior Fitness Test battery[5]; and items 4 – step up and over, 5 – tandem walk, 6 – stand on one leg and 7 – stand on foam eyes closed, from Fullerton Advanced Balance Scale[6].

Kinematic and kinetic data were collected using 8 infrared cameras (Qualisys Oqus 300) working at a frequency of 200Hz and synchronized with 2 Kistler force plates (9281B, 9283U014), one in front of the stairs and the other embedded below the first step. Participants walked at their comfortable pace.

Three trials were analyzed. A 10 Hz 4th order Butterworth filter was applied to both kinematic and kinetic data. The CAST marker set[7] was used and a 7 segments model (feet, shanks, thighs and pelvis) was built and optimized through global optimization[8]. Joint moments were determined through inverse dynamics and expressed relatively to the proximal segment. IAA was processed based on[9], during two phases of the cycle, when the ground reaction forces sum was above (pull up) and below (forward continuance) the body weight. Further, the foot was fixed to the floor when it was flat on the floor and allowed to rotate about the center of pressure for the rest of the time. All data processing was performed in Visual 3D software (Professional Version v5.01.18, C-Motion, Inc).

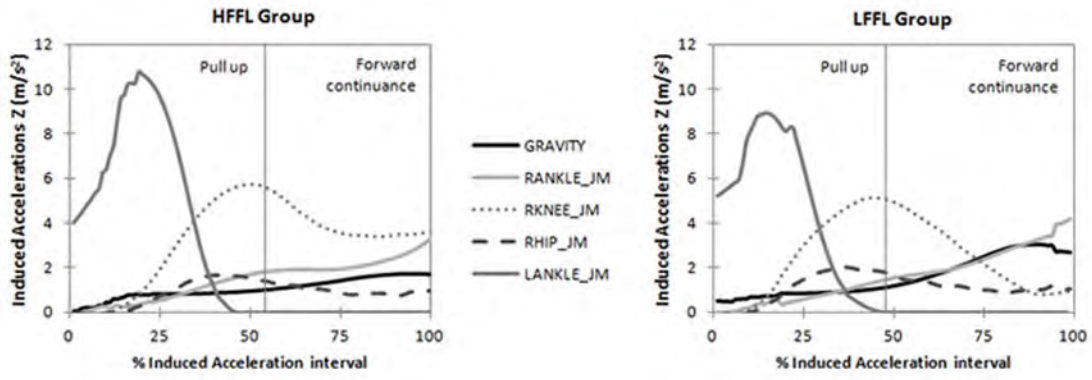
Results: The groups differed in terms of functional fitness level (HFFL: 24±0 LFFL: 19±1 points) and stride velocity (HFFL: 0.62±0.1 LFFL: 0.50±0.1 lower limb length/s), but were similar regarding age (HFFL: 72±3.6 LFFL: 73±7.2 y) and body mass index (HFFL: 26±5.1 LFFL: 27±2.6 Kg/m^2).

Agreeing with the joint moment results, the IAA showed that the plantaflexor moment, together with the knee and hip extensor moments, were the primary contributors to accelerate the body upwards during both the pull up and the forward

continuance phases and added that gravity also plays an important role, especially during the latter phase (Fig 1). All the other contributions were below 5% of the total acceleration and therefore are not presented.

The mentioned contributions varied with the subjects' functional fitness level. In the pull up phase, both groups pushed the body upwards mainly using the plantarflexor and knee extensor moments. However the contribution from the plantarflexors in the LFFL group was relatively lower, which may explain their lower stride velocity. During the forward continuance phase, the HFFL group supported the body more actively through the plantarflexor and the knee extensor joint moments, whereas the LFFL group were more passive, i.e., relied less on muscle activity, which is shown by the higher gravity contribution (Fig 1).

Figure:



Caption: Vertical induced accelerations generated by sagittal plane lower limb joint moments and gravity.

Conclusion: This study shows that the strategy adopted by older adults to accelerate the body upwards during stair ascent depends on their functional fitness level. Due their lack of strength, older adults with a lower functional fitness showed to have a smaller contribution from the plantarflexor moment during the pull up phase and to support the body more passively during the forward continuance phase, relying less on their knee extensor moment.

JOINT TORQUES DIFFER IN OLD AND YOUNG DURING MAXIMUM STEPPING TASK

Kathleen Bieryla [1,*]Christine Buffinton [2]

[1]Biomedical Engineering, [2]Mechanical Engineering, Bucknell University, Lewisburg, United States

Introduction and Objectives: Following a balance perturbation, a stepping response is commonly used to regain support. The maximum step length test, where a person steps out and back with one leg as far as possible, has been used as a clinical assessment of balance. Because this out and back movement does not occur when recovering from a fall, the focus on completing a forward step was examined. The purpose of this study was to examine age-related differences in joint kinetics at maximum step distance.

Methods: Twenty young (mean(SD): 20.0(1.8) years) and twenty old (75.6(4.9) years) adults were recruited for the study. The study was approved by the University's Institutional Review Board and written consent was obtained prior to participation. Participants completed a step starting from double support, with one leg in front of the other, at an initial distance equal to the individual's average step length. The distance was increased by 10% body height until the participant could not successfully complete the step. Whole body kinematics and ground reaction forces were recorded. Lower extremity sagittal plane joint torques were estimated. A one-way repeated measures ANOVA was used to determine the effects of age on joint kinetics during maximum step distance trial.

Results: One young female subject was removed from all analyses due to equipment failure during data collection. Maximum step length was significantly higher in young adults, 1.23(0.138) m compared to old adults, 0.961(0.150) m ($P<0.001$). Young adults were able to safely complete an average maximum step distance of 70.8% height compared to old adults who completed an average maximum step distance of 57.8% height. During maximum stepping trials, old adults had larger peak maximum plantarflexion ankle torques for the stepping leg ($P<0.001$) (Table 1). There was no significant difference in peak plantarflexion ankle torques for the stance leg ($P=0.558$). During maximum stepping trials, young adults had larger peak knee extension torques for both the stepping ($P<0.001$) and stance ($P=0.002$) leg, larger peak knee extension torques for the stance leg ($P<0.001$) and larger peak hip flexion torques for the stepping leg ($P<0.001$).

Conclusion: Young adults completed a significantly longer step distance than old adults. During the maximum step distance trial, in general, kinetic measures were greater in the young than in the old. This test is easy to administer and may be more challenging than the maximum step length test. Future work should be completed to determine the feasibility of this test to discriminate between fallers and non-fallers.

Table:

	Young	Old	*P* value
Peak Ankle Plantarflexion, Stepping	0.186(0.099)	0.368(0.107)	<0.001
Peak Ankle Plantarflexion, Stance	0.275(0.153)	0.254(0.153)	0.558
Peak Knee Extension,	1.384(0.313)	0.878(0.327)	<0.001

Stepping			
Peak Knee Extension, Stance	0.840(0.197)	0.626(0.254)	0.002
Peak Hip Flexion, Stepping	2.120(0.462)	1.521(0.602)	<0.001
Peak Hip Extension, Stance	1.325(0.368)	0.788(0.243)	<0.001

SMART KNEE PROSTHESIS FOR ORTHOPEDIC SURGERY: THE IMPLANTABLE AND WEARABLE MEASUREMENT SYSTEM

Kamiar Aminian [1,*] Arash Arami [1] David Forchelet [2] Philippe Renaud [2]

[1]Laboratory of Movement Analyisis and Measurement, [2]Microsystems Laboratory 4, EPFL, Lausanne, Switzerland

Introduction and Objectives: Recent advances in remote powering and telemetry permitted the use of sensors inside body. A few studies have been already done on smart knee prostheses, but all focused on monitoring the in-vivo contact forces and moments [1-4]. A smart design, compatible with mechanical structure of commercially-available knee prostheses, that provides force and accurate 3D kinematics feedback was suggested with all electronics housed in the polyethylene insert (PE) [6]. The current work addresses the designed kinematics and force measurement system of that smart implant and its validation in a robotic knee simulator.

Methods: *Kinematics measurement-* Two inertial measurement units (IMUs), each consists of a 3D accelerometer and 3D gyroscope, were considered to be fixed on stretch belts and placed around the thigh and shank (Fig.a). Three anisotropic magnetoresistive (AMR) sensors (S1, S2, S3) were configured in PE, based on a sensitivity analysis. A magnet (M) was capsulated in the prosthesis femoral part to convert its movement to changes of magnetic field (Fig. b). Three angle estimators were deigned. First, a linear regression using only the implantable AMR sensors. Second estimator solely used IMUs' measurements using the strapdown integration of angular velocities [6] combined by a linear model for drift removal. Third estimator was based on a fusion of IMUs and low-frequency (10Hz) sampled AMRs in order to reduce power consumption of the implanted part. This estimator used strapdown integration of the angular velocities with a locally linear model, using the difference estimate (IMU-AMR) for drift removal.

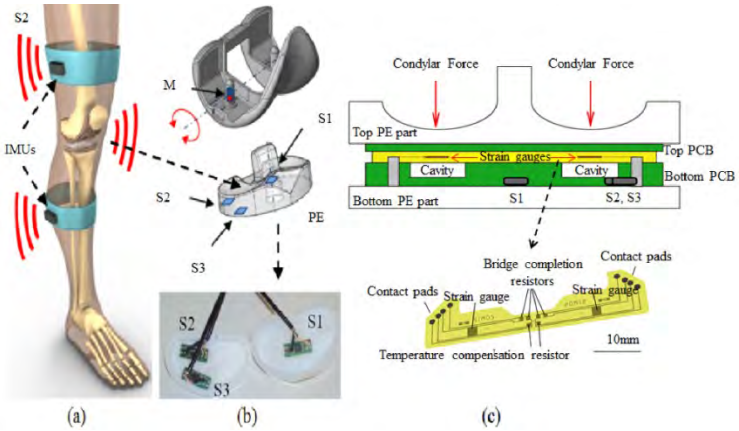
*Force measurement-*Two biocompatible force sensing gauges fabricated and configured in the medial and lateral sides of PE, above two devised cavities in a sealed capsule (Fig.c). The sensors measure the forces applied on each condyle through the stretch of the layer on top of cavities. The sensors are placed into separate Wheatstone bridges where all elements were structured into the sensors for temperature compensation. The capsule was glued in between PE sections, and cured for 16 hours at 45ºC under the pressure. A linear model for each sensor was used for calibration.

Knee simulator- A robotic knee simulator was used to validate the force and kinematics measurements. It held the smart knee prosthesis with embedded sensors. The IMUs were attached to the simulator segments to provide wearable measurements. Data collected from subjects during treadmill walking using X-ray fluoroscopy, optical motion capture systems and an implanted instrumented prosthesis [7-8] were used to replicate 4 gait patterns in the simulator. A motion capture system (Vicon, UK) and reflective markers attached to the simulator segments, was used as the kinematic reference. A force sensor (ATI, USA) was integrated below the prosthesis tibial part in the robotic knee as the force reference.

Results: The obtained performances of AMR-based, IMU-based and IMU-AMR based flexion angle estimators over four gait patterns are shown in Table. IMU-based estimates were not very precise, but the use of AMR sensors either alone or in the fusion framework drastically improved the results, RMS error<1.2º. The raw measurements of the force sensors

showed high corelation with the reference total forces, R^2>0.98. The obtained RMS errors for lateral and medial sensors on train data were 20.0N and 5.9N respectively

Figure:



Caption: (a) Wearable IMUs, (b) implanted AMR sensors (S1-3), (c) the capsule with designed strain gauges

Conclusion: Using implanted (AMR sensors and biocompatible embedded strain gauges) and wearable technology (IMU) a mixed measurement system was proposed able to estimate simultaneously the kinematics and force with a smart knee implant. Angle and force estimators were evaluated with realistic walking patterns replicated in a robotic knee simulator. The best kinematics estimation was obtained from fusion of IMUs and AMR sensors which is also optimum for reducing power consumption. The force sensors behaved linearly in fixed flexion angles, with no measurement drift. They can estimate the M-shape pattern of total force during gait, but showed different sensitivities to the applied forces in different angles. Fusion of estimated angles and force can enhance the force estimations.

Aknowledgment- This work was supported by Swiss Nanotera program- SNF20NAN1-23630

Table:

Estimators	E(error)	SD(error)	RMS(error)	R^2
AMR	0.46±0.09	1.09±0.30	1.19±0.28	0.99+0.00
IMU	1.65±1.45	1.70±1.11	2.43±1.70	0.97±0.03

TASK DEPENDENCY OF KNEE IMPLANT KINEMATICS BY MEANS OF VIDEOFLUOROSCOPY

Pascal Schütz [1,*] Barbara Postolka [1] Hans Gerber [1] Marco Hitz [1] Stephen Ferguson [1] William R. Taylor [1] Renate List [1]

[1] Institute for Biomechanics, ETH Zurich, Zürich, Switzerland

Introduction and Objectives:

In order to better understand the mechanisms leading to unsatisfactory outcome in total knee arthroplasty (TKA), the assessment of kinematic and kinetic data during functional activities in vivo is crucial.

To overcome the limitations of a static image intensifier and motion capture of the knee without the influence of soft tissue artefact [1], an automated moving fluoroscope has been developed [2, 3] that allows tracking of the knee joint throughout complete cycles of level walking and stair descent. The aim of this study was to analyse task dependency of the kinematic behavior, especially anterio-posterior (A-P) translation of a cruciate retaining TKA, during activities of daily living.

Methods: One female and five male subjects (72.8±8.5y, >1 year postop, painfree), who had each received a unilateral PFC Sigma Curved CR fixed-bearing (DePuySynthes) TKA, were assessed during free level gait, stair descending (3-step-staircase), pivot turn (swing phase followed by a 90° pivot turn), rising from a chair and sitting down by means of a moving fluoroscope (25Hz, 1ms shutter) [2, 3].

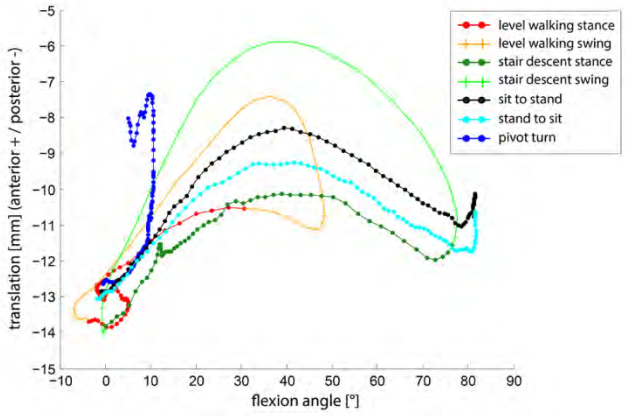
The 2D/3D registration of the 2D fluoroscopic images was performed using CAD models of the implant components. Registration errors, assessed for a similar TKA, were <1degree for all rotations, <1mm for in-plane and <3mm for out-of-plane translations [2]. The relative rotations between the femoral and tibial components were determined using the joint coordinate system by Grood et al. [4] based on the femoral and the tibial implant coordinate systems. A-P translations of the femoral flexion axis relative to the tibial component were described using a medial and a lateral point on the femoral flexion axis. For statistical analysis a linear mixed model (α=0.05) was used.

Results: Stair descent showed a significantly higher A-P translation with no differences in flexion/extension range of motion (ROM) in comparison to sit-to-stand and stand-to-sit. Only the pivot turn showed significant differences to other tasks for internal/external rotation and adduction/abduction.

No significant differences in ROM were found for either medial or lateral femoral A-P translation between level gait and stair descent (Table 1). For stair descent, the A-P translation was significantly larger during the unloaded swing phase than during the loaded stance phase.

At a specific flexion angle the A-P translation showed a clear task dependency and the differences in A-P translations were even more prominent when comparing loaded stance to unloaded swing phases (Fig.1). The two walking as well as sitting tasks showed a similar characteristic of A-P translation-flexion-coupling whereas the pivot turn showed a distinctive pattern. Except pivot turn, maximal A-P translation occured in the range of 36-42° flexion.

Figure:



Caption: Translation–flexion–coupling. Flexion angles and the corresponding A-P translation of the medial condyle point. Mean values are shown for 6 subjects.

Conclusion:

The pivot turn showed the highest ROM in A-P translation and a completely different translation-flexion-coupling pattern from the other activities. However the 90° turn transfers the direction of A-P translation from an in plane to an out of plane direction and the latter is affected by a limited registration accuracy [2].

Although the translation-flexion-coupling patterns lead to the assumption of a movement direction dependency, the ROM of A-P translation did not differ significantly between sit-to-stand and stand-to-sit.

Banks et al. [5] found a slightly higher flexion of 47° and 56° for the maximal A-P translation of the medial contact point in a step up exercise. This can be explained by different definitions of points to describe A-P translation, TKA designs and tasks.

The differences of the tibiofemoral kinematics between the different tasks and the different loading conditions indicate the importance of analyzing whole gait cycles and a variety of functional tasks. For a better understanding of the underlying mechanisms, the loading conditions should be taken into account.

Table:

	flexion/ extension [°]	abduction/ adduction [°]	internal/external rotation [°]	medial ap translation [mm]	lateral ap translation [mm]
level gait	58.5±4.1	3.1±0.9	8.3±1.5	7.8±1.6	7.9±1.8
level gait stance	36.7±3.6	2.2±0.5	6.1±1.2	4.7±1.1	5.5±1.2
level gait swing	57.7±3.6	2.8±0.9	6.8±1.5	7.5±1.6	7.3±1.3
stair descent	83.5±6.1	3.4±0.7	9.3±2.0	10.2±2.5	9.2±1.2
stair descent stance	77.4±6.4	2.9±0.3	6.3±1.8	5.1±1.5	5.3±1.4
stair descent swing	82.9±5.9	2.5±0.8	8.5±2.4	9.8±2.7	9.1±1.3
pivot turn	16.0±4.2	1.6±0.3	5.3±0.9	10.9±1.1	12.3±1.8
sit to stand	83.4±5.6	2.4±1.1	8.9±1.7	6.0±1.6	6.4±0.6
stand to sit	84.9±5.0	2.3±0.7	7.8±1.9	5.1±1.0	6.2±0.8

J-CURVE AND SINGLE-RADIUS FEMORAL DESIGNS DURING DAILY ACTIVITIES. ARE THERE ANY BIOMECHANICAL DIFFERENCES?

Bernardo Innocenti [1,*] Héctor Robledo Yague [1] Raquel Alario Bernabé [1] Walter Pascale [2] Silvia Pianigiani [2]

[1]BEAMS Department, Université Libre de Bruxelles, Bruxelles, Belgium, [2]IRCCS, Istituto Ortopedico Galeazzi, Milano, Italy

Introduction and Objectives: The lack of awareness of the exact number of instantaneous centers of knee flexion/extension rotation leads to the presence in the market of Total Knee Arthroplasty (TKA) femoral components designed under different hypotheses. Single radius (SR) designs are thought to replicate the physiological anatomy in a more realistic way than J-curve (JC) thanks to the constant radius during flexion that should provide a constant lever arm for the patella and isometry of the collateral ligaments. Although these theoretical advantages, surgery experts are usually more confident with the guaranteed performance of multiple radii components like the JC design. Any literature study compares in depth these two solutions for TKAs.

For these reasons, the aim of this study is to compare a SR to JC solution for the same posterior stabilized (PS) TKA design under daily activities conditions. Both kinematic and kinetics outputs have been analyzed. The study has been performed by means of finite element analysis.

Methods: For the two analyzed solutions, the same tibial component has been used. A standard gait cycle and the downward movement of a squatting activity up to 120° were simulated for both situations. The tibiofemoral kinetics and kinematics have been investigated comparing the contact area between components, the internal-external rotation, the position and magnitude of the contact forces and the Von Misses stresses on the polyethylene.

Results: The results show that the two solutions did not present significant differences for any of the analyzed outputs for the low demanding task daily activity (up to 60°) (Figure 1a). On the other hand, significant differences in the behavior are highlighted during the squatting motion especially after 80° of knee flexion. From this point, the contact area and forces, especially for the post-cam interaction, change and also the kinematics is altered presenting an anomalous drop for the SR design both in antero-posterior translation and internal-external rotation. Moreover, the stress on the polyethylene insert presents higher values on the posterior part of the insert (Figure 1b).

Figure:

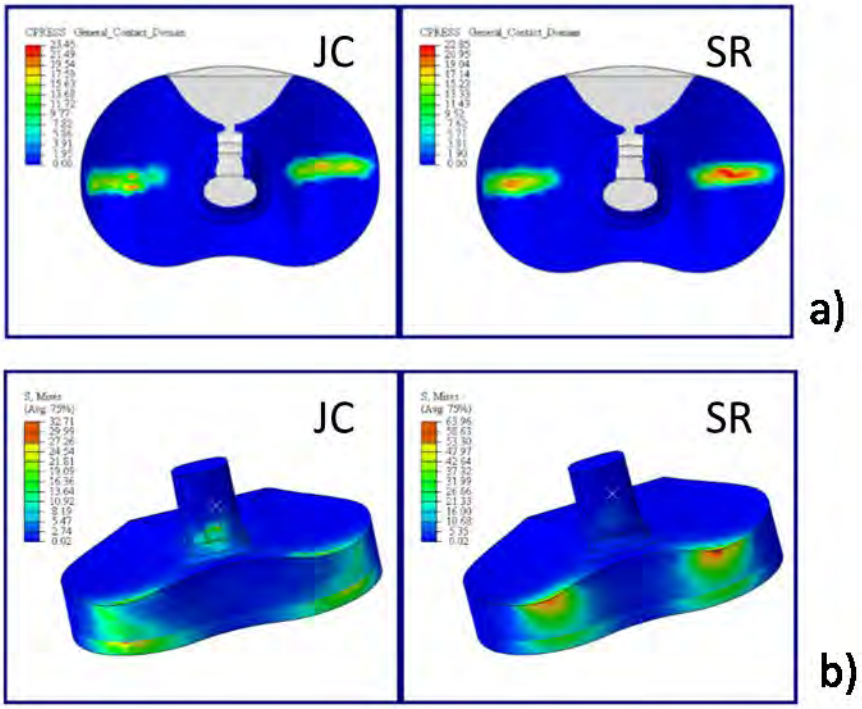

Figure 1: a) Qualitative stress distribution for the maximum flexion reached for the low demanding task; b) qualitative stress distribution for the maximum flexion reached for the high demanding task

Conclusion: The aim of this study was to make a consistent analysis to compare the same PS TKA design for a JC or a SR solution. To be able to perform this analysis in a reproducible manner, a finite element model has been developed to analyzed the solution behavior under walking and squatting conditions.

The results show that the two solutions are comparable for low demanding task like walking obtaining similar kinetics and kinematics outputs, but could diverge for higher knee flexion like during squatting. Even if this numerical model present some limitations, some of the obtained results are in agreement with the literature.

The diferrences in performances can be critical for a possible early wear of the SR prosthesis leading to an early failure of the TKA.

The authors have nothing to disclose.

INVESTIGATION OF THE LOAD CONTRIBUTIONS OF THE ANTERIOR CRUCIATE LIGAMENT BUNDLES AGAINST DEGREE OF FREEDOM RELEASE

Ryo Takeda [1,*] Keisuke Okuzumi [1] Katsuhiko Sasaki [1]

[1] Engineering, Hokkaido University, Sapporo, Japan

Introduction and Objectives: About 40% of knee joint injuries cases are related to ligament damage. Of these cases, the anterior cruciate ligament (ACL) is the most commonly ruptured, and the reconstruction of this ligament has been the attention of study. Single and double bundle reconstruction techniques are the most common methods of treatment but there are controversies on which is more effective in restoring the load capabilities. The difference of the two treatment methods depends on consideration of load capabilities of the anteromedial (AM) and posterolateral (PL) bundles of the ACL. Therefore in this study, the load capabilities of the AM and PL bundles of the ACL will be investigated along its relationship to the release of certain degrees of freedom (DoF) of the knee joint.

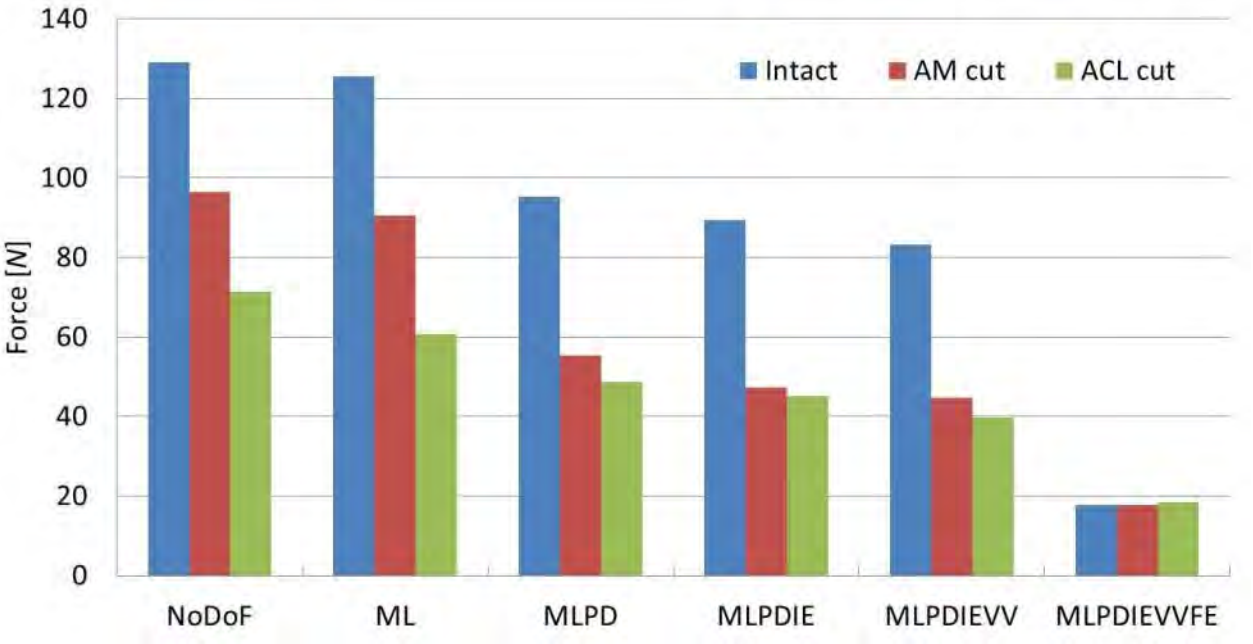
Methods: In this report we measured loads induced during anterior-posterior (AP) translation (drawer) tests of the cruciate ligament bundles. Although works in the past have investigated the force versus displacement behaviour, there has been little data on how releasing or constraining DoFs affects the load measurements[1][2].

For this study, a knee joint biomechanical testing platform was designed and developed. The platform consisted of a 6 axis force/torque sensor (WEF-6A1000-30-RC5, Wacoh-Tech Inc.) attached to a single axis material testing machine (Ezgraph, Shimadzu Corp.) and a bespoke DoF passive fixture. The passive fixture was capable of releasing or constraining 2 translational DoFs (medial-lateral (ML) and proximal-distal (PD)) and 3 rotational DoFs (internal-external (IE), varus-valgus (VV) and flexion-extension (FE) rotation) by means of bearings and locking screws. Ex-vivo knee joint specimens are placed in the testing platform by attaching the femoral bone to the axis force/torque sensor and the tibial bone to the passive fixture. Once attached, AP translational drawer motion can be induced by the material testing machine and the load was recorded by the force/torque sensor. For this report, the knee joint specimens were fixed in the testing platform at 60 deg flexion angle and a ±5 mm AP displacement was induced.

In this work, porcine stifle joints were used as knee joint specimens. The specimens were subject to three different ligament conditions: ACL intact (Intact), AM bundle cut (AM cut) and AM+PL cut (ACL cut). In addition, six DoF release conditions were considered: No DoF release (the passive fixture is totally constrained), ML release, ML+PD release, ML+PD+IE release, ML+PD+IE+VV release and ML+PD+IE+VV+FE release.

Results: The results load capabilities of the ligament in the AP direction are shown in Fig. 1. The results showed that releasing a combination of DoFs lowered the AP directional load when compared to releasing a single DoF or none at all. When comparing the AP load between the No DoF and the ML+PD+IE+VV+FE release state the load decreased down to 14%, 19% and 26% for the intact, AM cut and ACL cut states respectively. Furthermore, the AM bundle contributed to about 25% while the PM bundle about 19% for the AP directional load contributions during a No DoF state. However hardly any differences in load contribution were measured for the ML+PD+IE+VV+FE release state. This means that both the AM and PL bundle load capacities are dependant.

Figure:



Caption: Fig. 1. AP directional load vs. DoFs release conditions vs. ligament conditions

Conclusion: This work inverstigated and measured the load condributions of the AM and PL bundles of the ACL. It was found that the load capacities of both bundles behave differently according to the DoFs release conditions.

Introduction and Objectives: One of the main surgical goals when performing a total knee replacement (TKR) is to ensure the implants are properly aligned and correctly sized; however the effect of alignment on the biomechanics of the knee during functional activities is not well understood. Cardiff University has a unique access to a group of patients within the local region who have a relatively high frequency of poor alignment, and early failure [1]. Despite the obvious disappointment, it provides a rare insight into how mal-alignment of TKR's can affect patients from a clinical and biomechanical point of view to determine how to best align a TKR. The aim of this study was to perform an in-vivo analysis investigating the relationship between alignment and biomechanical function to assist surgeons by determining the optimum alignment for patients. For this particular study we focused on comparing patients with neutral alignment (-2° to 2°) to patients with varus alignment (>2°).

Methods: Fifteen patients with 18 Kinemax (Stryker) TKR's were recruited, 10 with neutral alignment and 8 with varus alignment. Ethical approval was obtained. Single plane video fluoroscopy of the knee was taken for each subject during a step-up and step-down task. Joint Track image registration software (University of Florida, USA) was used to match CAD models of the TKR components to each fluoroscopy image. This technique is known to have high accuracy in measuring TKR kinematics [2]. Further processing using JointView software (University of Florida, USA) calculated 3D joint kinematics and the tibio-femoral contact points. Bespoke code developed within MATLAB (The Mathworks Inc, USA) was utilised to calculate the centre of rotation (CoR) using the contact point data and was normalised to the length and width of the tibial component. The data was separated into three phases of the activity: step-up, step down and transition between the two with CoR calculated for each section. Long-leg radiographs were used to define limb alignment. Hip-Knee-Ankle (HKA) angle was measured from the radiographs to determine long leg alignment in the frontal plane with lateral distal-femoral angle (LDFA), medial proximal tibial angle (MPTA) and tibial slope calculated as secondary measures. CT scans were used to calculate both femoral and tibial component rotational alignment and inter-component rotation.

Results: The mean age of the patient group was 74 (range 60-89). Mean HKA measurement for the varus group was 5.9° and for the neutrally aligned group 0.7°. The mean CoR medial-lateral position for step up and down was found to be 2.83% (Lateral(-) /Medial(+)) for the neutral group and -4.65% for the varus group . Mean tibial slope for varus group was 3.33° and neutral group 5.96°. CoR calculations showed that 75% of the varus aligned patients had a lateral positioned CoR during step up and a medial positioned CoR during step down. In contrast, there was no bias medially or laterally in the CoR position for the neutrally aligned group. The incidence of medial and lateral CoR positions were equal for both activities.

A negative correlation was found between medial-lateral location of CoR during step down and tibial slope angle (Spearmans rank r=-0.486). CoR was found to not be related to frontal plane alignment, inter-component rotation or individual component rotation.

Conclusion: CoR results show that the majority of varus aligned patients have a lateralised CoR during step up and medial CoR position during the step down activity.

It was found that CoR position correlates with tibial slope yet did not correlate with HKA or rotational alignment of components. Further analysis of the kinematic data produced from the fluoroscopy needs to be completed to fully understand the effect of alignment of TKR on biomechanical function post-surgery.

RESIDUAL STRESS OF BOVINE FEMURS IN THREE AGE GROUPS

Satoshi Yamada [1,*] Mai Onuma [2] Shigeru Tadano [1]

[1]Faculty of Engineering, [2]Graduate School of Engineering, Hokkaido University, Sapporo, Japan

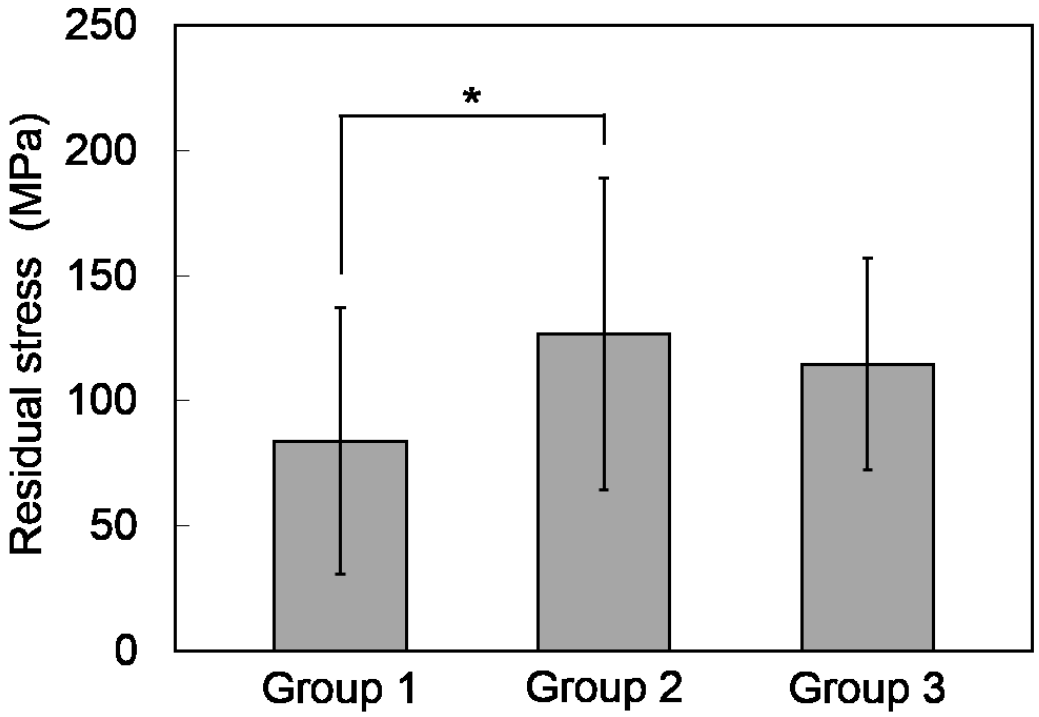
Introduction and Objectives: The presence of residual stress in bone tissue, which is defined as the stress that remains in the tissue without any external forces, has been examined using X-ray diffraction techniques [1]. The residual stress can be calculated on the basis of variation in the interplanar spacing of hydroxyapatite crystals in the bone tissue using the X-ray diffraction. In previous study, the authors have proposed a measurement system using an X-ray diffraction technique with an imaging plate for obtaining the surface distribution of residual stress in the diaphysis of extremities [2]. Stress/strain state in bone tissue is essential for understanding the bone strength and bone adaptation. Especially, residual stress affects the material strength in general. In previous study, the magnitude of residual stress along the bone axis at the bone surface of adult rabbit extremities correlated with osteon population density in the transverse cross-section [3]. It appeared that the residual stress might be related to the bone formation and reconstruction, and might be a circumstantial finding of the adapted state of the bone. However, the generation mechanism and biomechanical implications of residual stresses in bone tissue are not fully understood. To enhance the understanding of generation mechanisms, the present study aimed to investigate the residual stress of bovine femurs in three age groups.

Methods: In the experiments, five specimens were obtained from bovine femurs of three age groups respectively: less than one month old (Group 1), two years old (Group 2), and 8-9 years old (Group 3). The mid-diaphysis part was cut from the femurs such that the measurement position was at both the center of the femur and the center of the specimen. The specimen lengths were 0.13 times of the femoral length. The bone marrow and the soft tissue around the surfaces were removed as much as possible. The specimens were examined under wet condition at room temperature. The residual stresses along the bone axis were measured on the surface of the specimen center at four positions: anterior, posterior, lateral, and medial. The specimen was irradiated with characteristic Mo-Kα X-rays under no external forces using a collimator with a diameter of 1.0 mm. The diffracted X-rays were detected by an imaging plate in the reflection side. The residual stress was calculated from a synthetic Debye ring of the (211), (112), and (300) lattice planes of the hydroxyapatite crystals [2].

Results: The average residual stresses of the four positions in the specimens from Group 1, Group 2, and Group 3 were 83.9 ± 53.3 MPa, 126.8 ± 62.2 MPa, and 114.7 ± 42.2 MPa, respectively. The residual stress in Group 2 was the largest in the three age groups. There was a significant difference between Group 1 and Group 2 ($p < 0.05$). Furthermore, the residual stress had a statistically positive correlation with the cortical thickness at the measured positions ($n = 54$, $r = 0.33$, $p < 0.05$). It was confirmed that the specimen cutting process had less impact on the measured residual stresses [4]. The results suggest that residual stresses may be generated under the bone formation process during growth and may be slowly released under the reconstruction process after the maturation. In general, residual stress is generated in a material by the indeterminate structure. New bone tissue may develop in a nondeformed state under in vivo loading. The stress may be generated in the tissue by the difference of deformation between the inner old and surface new tissues with

increasing the body weight and cortical thickness. Furthermore, the release of residual stress suggests that the tissue may become more uniform structure during the reconstruction process adapting to in vivo stress. In Group 3, the diaphyseal width of the anterior-posterior direction that is the bending direction in bovine femurs was much larger than that of the lateral-medial direction. The effects of nonuniformities in the micro/nano-structure related to bone adaptation on the residual stress should be investigated in further study.

Figure:



Caption: Residual stress along the bone axis at the cortical surface of bovine femurs in three age groups (<1m, 2y, and 8-9y). The values indicate the average of the four positions in the five specimens, excluding the positions that could not be examined due to remained surface soft tissue. The asterisk (*) indicates a statistical difference ($p < 0.05$).

Conclusion: This study shows the differences in residual stress among young, mature, and elder bovine femurs. The results of the study will be of importance in elucidating the mechanism and biomechanical implications of residual stress in bone tissue.

3D FINITE ELEMENT MODEL OF PROGRESSIVE DAMAGE AT MICRO-STRUCTURAL LEVEL OF CORTICAL BONE

Camila Arango [1] [1,*]Eugenio Giner [1]Ana Vercher [1]F. Javier Fuenmayor [1]

[1]Materials and Mechanical Engineering, CIIM Universitat Politècnica de València, Valencia, Spain

Introduction and Objectives: In this work a numerical study of the mechanical behavior of cortical bone tissue under different loads is presented. The 3D model consists in a realistic representation of a portion of tissue containing osteons, cement lines and interstitial tissue between them. The osteon is the basic structural unit of cortical bone (200-500 μm diameter) and it is composed of mineralized collagen fibrils arranged in lamellae (3-7 μm thickness) [1]. Lamellae are concentrically arranged around blood vessels canals (Haversian canals).

The aim of this work is to apply numerical techniques for obtaining elastic anisotropic properties at different hierarchical scales and a damage model using a low computational cost method, evaluating the mechanical state of the system with composite materials failure criteria.

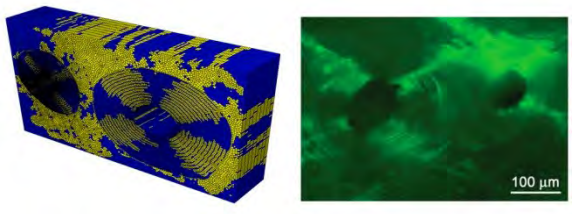
Methods: The material elastic properties of osteons are obtained through a finite element model at mineralized collagen fibril and lamellar levels. For the first level a numerical homogenization model is applied to a fibril configuration of collagen as matrix with hydroxyapatite crystals as reinforcement [2]. At a higher level the elastic properties of mineralized collagen fibrils grouped at different orientations and thicknesses into two types of lamellae: thick and thin.

The 3D model basic components are osteons, cement lines and interstitial tissue with a realistic geometry. The strength properties of the cement line and interstitial tissue are estimated from relations with energetic experimental data from literature. For the damage implementation, user subroutines of the finite element code Abaqus are used, varying the material properties with a stiffness degradation scheme [3]. The failure criteria for osteons correspond to interlaminar (quadratic criteria) and intralaminar stresses. In this work two different compressive load cases are analyzed (radial and axial respect to osteon longitudinal axis) and the damage patterns are compared with experimental results in bibliography [4, 5].

Results: For both load cases, the model predicts the beginning of damage at cement lines, which agrees with experimental evidence. At the same time there is damage propagation on interfaces and inside lamellae.

For the radial compression test, there is a very strong damage zone between 20 and 50 degrees from the applied load axis (Fig. 1) that is found in experimental results as well. For two different cases, thin lamellae (which have most of the fibrils perpendicularly oriented to the Haversian canals), are the less affected by the compressive load.

Figure:



Caption: Fig. 1: Left: Advanced damage state of finite element model with compression load along the radial axis of the osteons. Right: Epifluorescence micrograph for a similar load case test from Ebacher et al. [4].

Conclusion: A 3D numerical procedure is proposed to model the progressive nonlinear damage using the finite element method. The contrast with experimental results allows validating the benefits of the model from the computational point of view. These analyses are a starting point for more complex studies incorporating bigger scale structural cases and realistic load conditions at those levels.

THE OSTEOGENIC INDEX OF FOUR COMMON CONTINUOUS AND INTERMITTENT EXERCISES USED IN OSTEOPOROSIS PREVENTION IN AN AT-RISK POPULATION

Gallin Montgomery [1,*]Will Evans [1]Luca Zoffoli [2]Grant Abt [1]Catherine Dobson [3]Michael Fagan [3]Tina Smith [4]Max Ditroilo [1]

[1]Sport, Health and Exercise Science, University of Hull, Hull, United Kingdom, [2]Department of Biomolecular Science, Universita degli Studi di Urbino, Urbino, Italy, [3]School of Engineering, University of Hull, Hull, [4]Research Centre for Sport, Exercise and Performance, University of Wolverhampton , Wolverhampton, United Kingdom

Introduction and Objectives: Information from studies designed to improve bone health is often poorly reported with regards to intensity of impacts, acceleration slope, muscular activation and stimulus frequency. These are important factors in the osteogenic index (OI) (Turner and Robling, 2003) and bone remodelling. There is a need to analyse and quantify this for a number of reported exercises within the same at-risk population so future interventions can be improved.

Methods: This study quantifies the OI of four exercises using ground reaction force (GRF) and accelerometer (ACC) data to assess which could prove the most beneficial for improving or maintaining bone health within a population of early post-menopausal women (1-5 years).

Six healthy early postmenopausal women 53.1±3.4yrs, 162.4±5.8cm, 66.2±7.5kg were recruited. Participants completed the test barefoot on a force plate recording GRF at 1000Hz. An accelerometer was attached to the sacrum whilst electromyography (EMG) surface electrodes were placed over the rectus femoris (RF) and semitendinosus (ST) muscles in accordance with SENIAM recommendations. EMG and ACC data were synchronously recorded at 1500Hz.

Four exercises were performed both continuously (CON at 15bpm) and intermittently (INT at 4bpm) for 10 cycles of each in a randomised order and included countermovement jumps (CMJ), drop jumps from a 20cm box (DJ), heel drops and unilateral stamps (one foot on the force plate).

EMG was filtered (bi-directional butterworth, 10-500Hz) and processed using a linear envelope (full wave rectification, low-pass cutoff of 8Hz). Baseline EMG was removed from the data. The EMG mean was found across the 10 cycles for each exercise and normalised to the CMJ CON trial. ACC data was filtered optimally using 95% of the signal energy from 1g before and after the 10 highest impact peaks per exercise. Peak GRF and ACC data was converted to g whilst GRF and ACC gradients (Grads) from 1g to peak, were converted to $m.s^{-3}$, all were averaged across the 10 cycles. OI was calculated from the GRF and ACC data using the Turner and Robling (2003) method.

Kruskall-Wallis tests were used for the analysis. Effect Size (ES) and confidence intervals (CI) were performed on percentile rank-transformed data.

Results: All variables displayed no significant differences across all exercises between CON and INT conditions.

EMG data revealed that for the RF mean CMJ was significantly higher than Heel Drops and Stamps ($P<0.001$, ES=3.92, CI 2.48-5.36 and $P=0.012$, ES=2.46, CI 1.41-3.50). DJ was also significantly higher than heel drops ($P=0.043$, ES=2.33, CI 0.32-4.34). The ST mean showed that CMJ, DJ and Stamps were all significantly higher than heel drops ($P=0.002$, ES=2.97, CI 2.25-3.70, $P=0.027$, ES=2.52, CI 1.22-3.82 and $P<0.001$, ES=3.52, CI 2.08-4.96).

Peak GRF data indicated that DJ was significantly higher than stamp with a median of 4.19gvs 2.91g (P=0.005, ES=1.3, CI 0.58-2.02) whilst CMJ and Heel Drop were higher than Stamps (ES=0.8, CI 0.1-1.51 and ES=0.75, CI 0.24-1.25). However the GRF Grads saw the Stamp give higher values than CMJ, DJ and Heel Drops (P<0.001, ES=2.02, CI 1.48-2.55, P<0.001, ES=2.04, CI 1.73-2.35 and P=0.029, ES=1.24, CI 0.73-1.75).

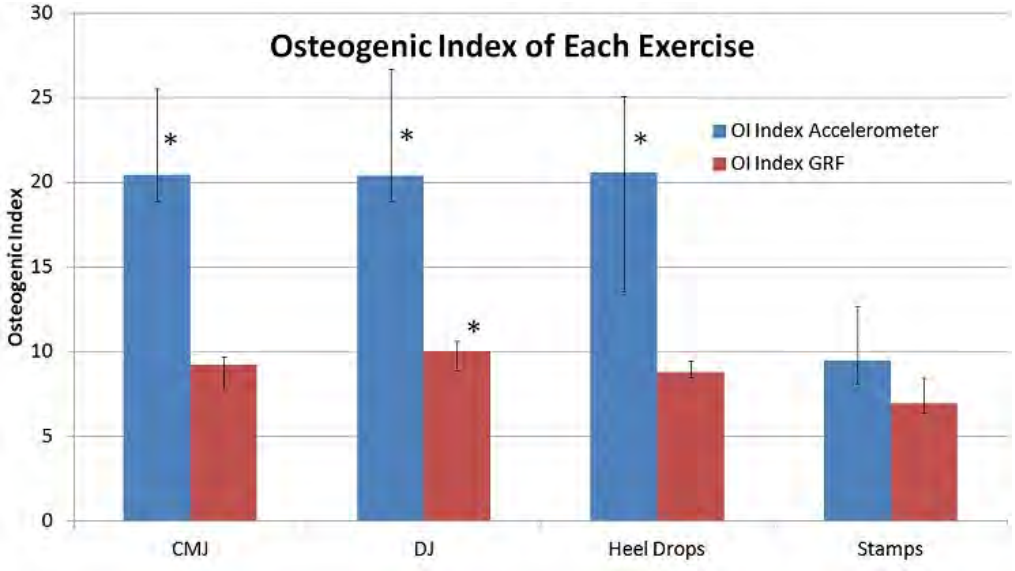
Peak ACC analysis highlighted that CMJ, DJ and Heel Drops were all significantly higher than the Stamp condition (P=0.001, ES=1.62, CI 0.75-2.49, P<0.001, ES=1.71, CI 0.98-2.44, P=0.005, ES=1.44, CI 0.75-2.14).

ACC Grads gave lowest values in the Stamp condition with CMJ and DJ both significantly higher (P=0.007, ES=1.67, CI 0.72-2.61, P=0.002, ES=1.84, CI 0.81-2.88).

The OI Index GRF (figure 1) showed that DJ was significantly higher than stamping (P=0.005, ES=1.3, CI 0.58-2.02) whilst CMJ and Heel Drops showed positive effects when compared to Stamps (ES=0.8, CI 0.1-1.51 and ES=0.75, CI 0.24-1.25).

OI Index SAC data (figure 1) discovered that CMJ, DJ and Heel Drop were significantly higher than stamp (P=0.001, ES=1.62. CI 0.75-2.49, P<0.001, ES=1.71, CI 0.98-2.44 and P=0.005, ES=1.44, CI 0.75-2.14).

Figure:



Caption: (Figure 1. Osteogenic Index.* Denotes a significantly higher value than the Stamp condition)

Conclusion: CMJ, DJ and Heel Drop conditions displayed the highest results for Peak GRF data and Peak ACC data the level of impact experienced around the sacrum. Stamp condition gives the highest acceleration slope, but fails to achieve the same level of impact experienced at the sacrum as the other exercises. For EMG the CMJ condition gave significantly the highest activation for the RF muscle and an equally high ST muscle activation along with DJ and Stamp conditions. This could imply higher concentric stress but is limited eccentrically. All exercises have their own merit for improving bone health in this population but the CMJ and DJ conditions appear to give consistently the highest results across all variables apart from the GRF Grad. The DJ appears to generate the highest OI for GRF and ACC measures combined but gives very similar results to the CMJ and Heel Drops.

A ROBUST METHOD TO IDENTIFY CANCELLOUS BONE BEHAVIOUR:

FROM THE QUASI-STATIC TO INTERMEDIATE AND DYNAMIC STRAIN RATES.

Marianne Prot [1,*] Trevor Cloete [2] Dominique Saletti [3] Sebastien Laporte [1]

[1]Institut de Biomécanique Humaine Georges Charpak, Arts et Métiers Paristech, Paris, France, [2]Blast Impact and Survivability Research Unit , Department of Mechanical Engineering, University of Cape Town , Cape Town, South Africa, [3]3SR, Univ. Grenoble Alpes, Grenoble, France

Introduction and Objectives: Mechanical properties of cancellous bone are required over a large range of strain rate regimes to simulate injuries sustained during a car crash or a sporting accident. The majority of studies have focused on quasi-static compression loading [1], while relatively few have considered the dynamic mechanical characterization [2]. Cancellous bone is known to be strain rate dependent [3]. Recently, a specialized apparatus was developed for bone testing [4] and applied to cancellous bone [5] to address the lack of data between the quasi-static and dynamic regimes. Transient effects tend to obscure the initial phase of a compression test, which is typically recovered via linear extrapolation of apparent modulus to zero stress [6]. However, this approach can be sensitive to operator input.
This paper introduces a robust method with which to determine mechanical parameters that is insensitive to toe region effect, strain rate variation and moderate noise levels.

Methods: Tests

126 cylindrical, non-defatted, bovine cancellous bone specimens were compressed in 3 strain rate regimes: quasi-static, 10^{-3}, 10^{-2}, 10^{-1} /s; intermediate, 1, 10, 100 /s and dynamic, 400 and 600 /s. Three different devices were employed as previously described in [5]. A Zwick testing machine was used for the quasi-static regime, the Split Hopkinson Pressure Bar (SHPB) implemented with a Momentum Trap system and a conical striker for the dynamic strain rates. For the intermediate regime, the behaviour was investigated using two techniques: the wedge bar apparatus for the strain rates of 1 and 10/s and the SHPB previously described for 100/s. All the tests were conducted at near constant strain rates and arrested at approximately 10% strain, so as to facilitate specimen recovery.

Data processing

Stress/strain curves were obtained. In order to consistently compare the behaviour, the following mechanical parameters were selected: the apparent Young's Modulus, E_{app}, the yield stress & strain, ε_y & σ_y, the ultimate stress & strain, ε_u & σ_u. The method used is inspired by the risk curves method. It is based on a 5 parameters logistic curve given below: two horizontal tangents (named P1 for the asymptotic minimum, P2 for the maximum), two slopes (P3, P5) and a value at the inflection point (P4).

$\sigma=P1+P2/(1+f\times g+(1-f)\times h)$

With:

$f=1/(1+e^{(-C\times(\varepsilon-P4))})$

$C=2\times P3\times P5/|P3+P5|$

$g=e^{(P3\times(\varepsilon-P4))}$

h=e^(P5×(ε-P4))

The robust non-linear least square method is illustrated in Figure 1. E_{app} was determined as the slope at the inflexion point. The strain was set up to 0 at the intersection of this slope and the zero stress axes. An automatic process was developed to get ε_u & σ_u while the end of the elastic domain has been defined by minimizing the differences between each point of the modeled curve. The exclusion criterion is a normal distance to the slope greater than the half of the mean distance. To estimate the evaluation errors on each parameter due to the measuring noise, a bootstrap method was also implemented.

Results: The method was applied to three different regimes (illustrated in Figure 1 for quasi-static loading).

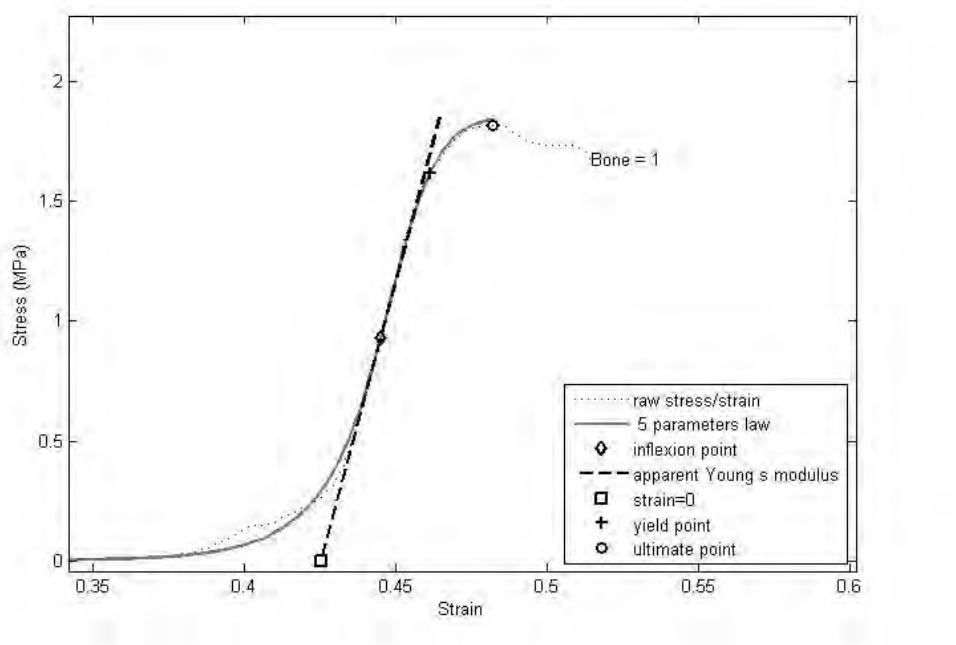
The program provides good results at every strain rate and was not biased by noise. A non-exhaustive list of the resulting data is summarized in table 1.

Data is consistent throughout the strain rates and concurs with published quasi-static data [7]. Maximum estimation errors were observed for 10/s due to load cell noise.

A distinct increase in strength is observed in the intermediate regime, especially at 10 and 100/s, which cannot be attributed to an artefact of a test method since two distinct techniques were used.

The strain rate sensitivity of the apparent Young's modulus needs to be carefully considered as 6 different bones and 3 anatomical orientations were used for sampling. Finally, there is a geometry effect due to the spongy architecture organization.

Figure:



Caption: Method applied at 0.1/s

Conclusion: This study provides a robust method to determine mechanical parameters across different strain rates. The method can effectively deal with the toe region while being insensitive to moderate noise levels and quantifies the error

made on the mechanical parameters estimation. The preliminary results indicate that a distinct transition occurs in the strain rate sensitivity of cancellous bovine bone at intermediate regime.

Ongoing work focused on architectural characterization will allow the role of the porous organization in the fracture process to be investigated.

Table:

Strain Rate (/s)	Mean (MPa)	Standard Deviation	Errors (MPa)
0.001	323	217	1
0.01	365	250	1
0.1	300	192	2
1	286	172	1
10	543	319	16
100	629	480	9
400	471	34	7

VALIDATION OF FINITE ELEMENT MODELS PREDICTING FRACTURE IN THE OSTEOPOROTIC TIBIA

Magnús K. Gíslason [1,*] Sylvie Coupaud [2] [3] Quentin Fogg [4] Stuart McNally [4] Mariel Purcell [3] Keisuke Sasagawa [5] Yuji Tanabe [5] Elizabeth Tanner [6]

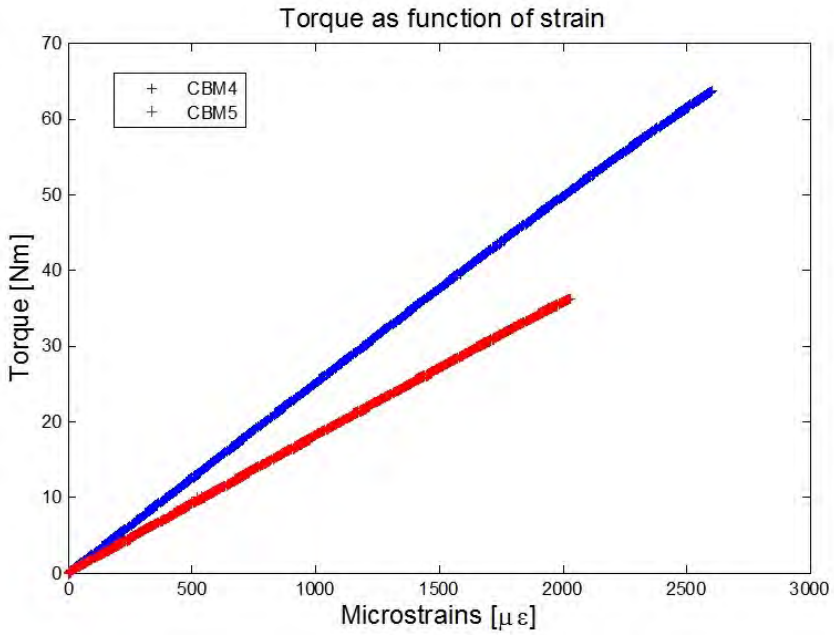
[1]Institute of Biomedical and Neural Engineering, Reykjavik University, Reykjavik, Iceland, [2]Department of Biomedical Engineering, University of Strathclyde, [3]Scottish Centre for Innovation in Spinal Cord Injury, Queen Elizabeth National Spinal Injuries Unit, Southern General Hospital, [4]Laboratory of Human Anatomy, School of Life Sciences, University of Glasgow, Glasgow, United Kingdom, [5]Department of Mechanical and Control Engineering, Niigata Institute of Technology, Niigata, Japan, [6]Department of Biomedical Engineering, University of Glasgow, Glasgow, United Kingdom

Introduction and Objectives: Finite element modelling has been used to calculate the risk of fracture of the osteoporotic bone and compared to healthy bones [1]. However, it is essential to validate the computational models experimentally with real tissue. Finite element models were created using pQCT scans of two cadaveric tibiae, and were loaded in torsion and tested until failure. One specimen, CBM4, showed signs of osteoporosis but the other, CBM5 was otherwise healthy. The mechanical results were compared with the predicted risk of fracture from the FEA model.

Methods: Two fresh frozen cadaveric tibiae were obtained from the Laboratory of Human Anatomy at the University of Glasgow, following ethical approval. The specimens were thawed 24 hours prior to the experiment. Strain gauges (EA-13-062TH-120 from Vishay) designed for torque measurements were mounted 40mm from the proximal end of the specimen. The full-length tibia specimens were mounted in a custom-made square frame and methyl methacrylate (Technovit) resin was used to secure the specimens. Finally the specimens were placed in a testing machine (ElectroPuls E10,000, Instron) where the proximal end was secured to the base and the distal end subjected to rotational loading. The loading protocol was subdivided into two parts: firstly, a 50N compressive load was applied with the rate of 10 N/s for 5 s and held throughout the whole duration of the test. Secondly, the distal end of the tibia was rotated at the rate of 1°/s until failure. The finite element model was solved using Abaqus (v.6-13, Simulia). The geometry was based on multi-slice pQCT (XCT 3000, Stratec) scans of the bones. The in-plane image resolution was 0.5mm x 0.5mm and the bones were segmented using Mimics (v.16, Materialise). The material properties were based on the greyscale values of the pixels and empirical functions used to connect the greyscale values with bone mineral density and a power law connecting the bone mineral density to both Young‘s modulus and ultimate stress values [2].

Results: The two specimens failed at different torque levels, 36.2±0.5 Nm and 63.8±0.5 Nm respectively. Both specimens failed within the diaphysis region and with crack at 54° angle to the horizontal. The measured variables can be seen in Table 1. Figure 1 shows the torque as a function of the measured strain for both specimens. The results were in agreement with the finite element model that predicted distinct fracture in specimen CBM4 under 35Nm loading, whereas no elements exceeded the calculated fracture threshold for each element for specimen CBM5 under 35Nm loading.

Figure:



Caption: Torque as a function of strain

Conclusion: The experiment validated the finite element models and demonstrated the effects that osteoporosis has on the torsional strength of the tibia. Further understanding about the fracture mechanics will provide important information about the biomechanics and clinical relevance of the fragility of osteoporotic bone.

Table:

Specimen	Torque [Nm]	Strain [με]	Rotation [°]
CBM4	36.2±0.5	2029±10	13.6±0.1
CBM5	63.8±0.5	2607±10	13.2±0.1

MORPHOLOGICAL AND MECHANICAL PROPERTIES OF DMD AND TREATED MOUSE BONES

Noor Shafini Mohamad [1,*] Jie Tong [1] Darek Gorecki [2] Matt Guille [3]

[1]School of Engineering, [2]School of Pharmacy and Biomedical Sciences, [3]School of Biological Sciences, University of Portsmouth, Portsmouth, United Kingdom

Introduction and Objectives: Duchenne Muscular Dystrophy (DMD) is caused by mutations in the dystrophin gene that gradually lead to severe muscle malfunction and eventually death [1]. Recent micro-Computed Tomography (μCT) analysis showed an effect of DMD on bone tissue morphology [2], where reduced bone mass and bone resorption was observed in dystrophic (*mdx)* mice compared with wild type. To understand the mechanisms of DMD and to develop its treatments, a receptor, P2X7, was switched off in mice. Bone morphometric and biomechanical properties were evaluated at four-week old using μCT and biomechanical testing.

Aims

To compare the morphometric and the mechanical competence of the mouse bones at 4 week old between the treated bones, the wild type and the *mdx* mouse bones, thereby to establish the role of receptor P2X7 in DMD at this early stage, when muscle function has yet fully developed.

Methods: Four-week old mice tibias (n=24) were imaged using μCT (XT H 225, X-Tek Systems) and data acquisition was performed (V=50-55kV, I=95-110μA). Genotypes included wild type (WT) (n=6), *mdx* (n=6), P2X7-/- knockout (n=6) and *mdx*/P2X7-/- double knockout (n=6). The morphometric parameters were taken at two locations (Figure 1). A three-point-bending arrangement was used to test the whole bone samples at a rate of 0.155 mm/s [3] until failure using a Bose machine (ElectroForce® 3200).

Results: In *mdx* mice, significant bone loss is evident at both proximal and midshaft levels as opposed to WT, as illustrated in Table 1, where values of statistically significant difference ($p<0.05$) from those of *mdx* are highlighted. Knocking out P2X7 in mdx mice appears to have improved the overall morphometric parameters, where most results from *mdx*/P2X7-/- show improvement over those of *mdx*, apart from maximum load at fracture and stiffness, although the differences are only statistically significant in cortical bone density and stiffness. Generally, the results from P2X7-/- are close to those of WT.

Results from mechanical testing show significantly decreased maximum load (by 38%), fracture energy (by 65%) and stiffness (by 41%) in *mdx* compared with those in WT. In P2X7-/-, the maximum load and fracture energy are comparable to those of WT but stiffness is reduced. For *mdx*/P2X7-/-, the maximum load and fracture energy are comparable to those of *mdx*, although the stiffness is reduced significantly.

Figure:

Figure 1: Locations selected for µCT scanning.

Conclusion: Morphometric and mechanical properties of mdx mouse bones differ significantly from those of WT. In treated mouse bones, the morphology analysis showed overall improved bone properties in both proximal and midshaft, although not all statistically significant.

THEORETICAL INFLUENCE OF AGE, RUNNING SPEED, AND RUNNING DISTANCE ON THE PROBABILITY OF SECOND METATARSAL STRESS FRACTURE

Divya Budihal [1] W. Brent Edwards [2,*]

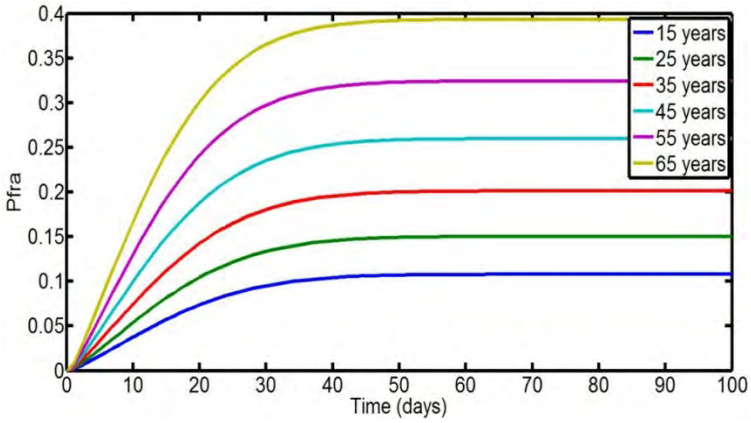
[1]Henry Wise Wood High School, [2]Human Performance Laboratory, University of Calgary, Calgary, Canada

Introduction and Objectives: Stress fractures in long bones account for approximately 15% to 20% of all overuse injuries in runners. These injuries are ultimately caused by the mechanical fatigue of skeletal tissue. Cyclical loads applied to bone during locomotion cause microdamage accumulation, i.e., small cracks in the bony matrix. If this microdamage is not repaired through the action of basic multi-cellular units, stress fractures may occur. Microdamage accumulation varies with bone quality, loading magnitude, and the number of loading cycles. Thus, the likelihood for stress fracture will depend on age, running speed, and running distance. The purpose of this study was to examine the theoretical influence of age, running speed, and running distance on the probability of stress fracture in the second (2^{nd}) metatarsal, a major site for stress fracture development.

Methods: Stride length (SL) and ground reaction force (GRF) as a function of running speed were estimated from the literature [1]. Peak 2^{nd} metatarsal strain for a 170 cm tall, 69 kg male was estimated using the finite element method. The finite element model consisted of 11,560 linear hexahedral elements with different material properties for cortical bone (age-specific according to [2]), trabecular bone (1 GPa), and marrow (0.1 MPa); all materials were assigned a Poisson's ratio of 0.3. The proximal end of the metatarsal was fully constrained and a distributed load equal to 24% GRF was applied to the metatarsal head at a 33° angle relative to the bone's long-axis [3]. The relationship between metatarsal strain and number of cycles to failure (N_f) was determined from a modified standard-fatigue equation, characterizing damage evolution, accumulation, and failure into a single, empirical relationship, which accounted for age-specific bone fatigue [4]. The time to failure (t_f) in days was calculated by dividing N_f by loading cycles/day, where loading cycles/day was a function of SL and running mileage. The t_f values served as inputs to a probabilistic model of bone failure, repair, and adaptation [5] to examine the influence of age (15-65 years), running speed (2.5-4.5 m/s), and running distance (3-7 miles/day) on the likelihood of 2^{nd} metatarsal stress fracture.

Results: The cumulative probability of stress fracture with repair and adaptation (P_{fra}) for a referent scenario (i.e., 25 year old running at 3.5 m/s for 5 miles/day) peaked and plateaued at 0.15 after approximately 40 days of running (Figure). The P_{fra} increased nonlinearly with age (Figure) and running speed. In contrast, P_{fra} increased linearly with running distance. To maintain the same probability of stress fracture as a 25 year old running at 3.5 m/s for 5 miles/day, the results indicated that a 55 year old must run at 2.5 m/s for 3 miles/day (Table).

Figure:



Caption: Pfra for different ages running at 3.5 m/s for 5 miles/day.

Conclusion: The probability of 2nd metatarsal stress fracture was highly dependent on age, running speed, and running distance. Whereas the probability of stress fracture increased nonlinearly with age and running speed, the probability of stress fracture increased linearly with running distance. In accordance with these findings, older runners may want to adopt a slower running speed and a lower running distance when beginning a new running regimen. As the probability of stress fracture is less sensitive to changes in running distance than running speed, new runners may want to reduce running speed rather than distance in order to minimize their likelihood for 2nd metatarsal stress fracture. Bone repair and adaptation are highly dependent on age, and a major limitation of this study was the inability to incorporate this phenomenon into the theoretical model. This study provides a comprehensive theoretical description of stress fracture probability that ultimately may aid in the prevention of this injury. It is unlikely that the theory will be able to accurately predict stress fracture risk on an individual basis, but it should be able to reasonably predict relative changes in stress fracture risk provided that subject-specific training patterns and bone strain are quantified precisely.

STRESS-MICROSTRUCTURE RELATIONSHIP IN HUMERUS OF A GOAT

Ashwij Mayya [1,*] Anuradha Banerjee [1] R Rajesh [2]

[1]Indian Institute of Technology - Madras, [2]The Institute of Mathematical Sciences, Chennai, India

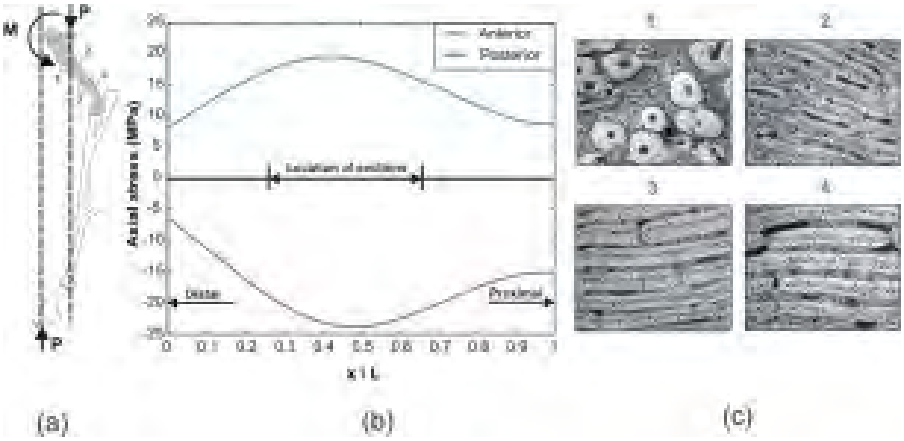
Introduction and Objectives: The adaptive response of cortical bone to high mechanical stresses, depending on the anatomical site, leads to bone material having significant differences in its microstructure and mechanical properties. Haversian bone, thought to be the bone adapted to high stresses by secondary remodelling, however, has been known to have inferior tensile strength and fracture toughness [1,2]. This apparent contradiction in the understanding of bone adaptation has been the focus of a recent investigation on goat femur which presents evidence of typical Haversian adaptation only at sites under high compression [3]. It is of significance to further examine the import of these findings at anatomical sites where the stress distribution that develops within a cross-section of the bone is remarkably different from that of femur. In the present study, the humerus of a goat is chosen for characterizing the stress-microstructure relationship along the length of bone to test if Haversian bone is indeed an adaptation to high mechanical stresses that are only compressive in nature.

Methods: Humerus is primarily a load bearing bone with prominent angulation and curvature in the sagittal plane. The stress field in the humeral diaphysis is determined by applying beam theory to a simplified 2D biomechanical model of the fore leg. In the stance phase of gait cycle, the contact point with the ground is shown to be offset from the humeral head. To ensure static equilibrium, a counter clock-wise moment acts at the proximal end of the humerus as shown in Fig. 1(a). The effect of muscle forces is assumed to be restricted to contact points at the joint centres which would scale down the stress distribution of the bone. The cross-sectional area, moment of inertia, offsets from the neutral axis at the anterior and posterior regions are determined using smooth interpolation polynomials obtained from processing the binary images of cross sections. To correlate the stress field with microstructure, the sections cut along the length are polished with successively finer grit particles and observed under an optical microscope. Also, the mineral content of the microstructures is qualitatively analysed using EDS analyses by placing multiple samples on the specimen stage.

Results: At the stance phase of the gait cycle, the humerus is shown to develop significant bending stresses in sagittal plane, such that the anterior and posterior cortices are in compression and tension respectively as shown in Fig. 1(b). Maximum stresses in the bone occur at the proximal end of the diaphysis.

Microstructural examination of several sections of the bone along its length using optical microscope showed distinct variations as presented in Fig. 1(c). The authors' hypothesis that the microstructure correlates with the stress field is confirmed as Haversian systems are observed at regions of high compressive stresses while regions with low stresses have typical fibro-lamellar/plexiform structure. The regions of high tensile stress exhibit a microstructure which appears as compact layering of bone material and distinctly non-Haversian. The compact form of microstructure is shown to be significantly different from plexiform bone in the extent of calcification established from EDS line scans.

Figure:



Caption: (a) Free body diagram of fore leg during the three legged stance (b) Variation of axial stresses in anterior and posterior cortices along the length (c) variation of microstructure at the anterior and posterior cortices of proximal and distal regions of diaphysis.

Conclusion: These findings support the hypothesis that Haversian remodeling is sensitive to the nature of stresses as it is an adaptive response to compressive stresses only.

THE EFFECT OF MALALIGNMENT ON KNEE JOINT CONTACT LOADING

Franziska Reisse [1,*] Howard Hillstrom [2] Rob Walker [1] Diagarajen Carpanen [1] Mark Lenhoff [2] Carl Imhauser [3] Robert Rozbruch [4] Austin Fragomen [4] Matt Koff [5] John Dowell [1 6] Rajshree Mootanah [1]

[1]Engineering and Built Environment, Anglia Ruskin University, Chelmsford, United Kingdom, [2]Leon Root MD, Motion Analysis Laboratory, [3]Department of Biomechanics, [4]Limb Lengthening and Complex Reconstruction Services, [5]Department of Radiology and Imaging – MRI, Hospital for Special Surgery, New York, United States, [6]Department of Orthopaedics, Ramsay Springfield Hospital, Chelmsford, United Kingdom

Introduction and Objectives: Osteoarthritis (OA) is a debilitating disease of the joint that leads to significant pain, loss of mobility and quality of life. The total annual cost of OA is estimated at $185.5 billion to the United States [1]. Lower extremity malalignment is postulated to present excessive compartment stress to the cartilage matrix and has therefore been associated with knee OA [2]. There is no known cure for OA and current therapeutic approaches cannot arrest disease progression. Malalignment correction is a surgical procedure to redistribute load in the knee joint, reduce peak pressure and delay OA progression. This is carried out by either removing or adding a wedge of bone to the proximal tibia such that the mechanical axis deviation is restored to 0 mm. The mechanical axis deviation (MAD) is the horizontal distance between the knee joint center and the line passing through the hip and ankle joint centres. However, clinical outcomes have been unpredictable. Therefore, the aim of this study is to perform virtual osteotomies on a validated knee model [3] to predict the resulting contact loading for different knee alignments. We hypothesise that the alignment correction associated with an MAD of zero does not correspond to minimum contact loading and that there is a strong correlation between MAD and knee joint contact mechanics.

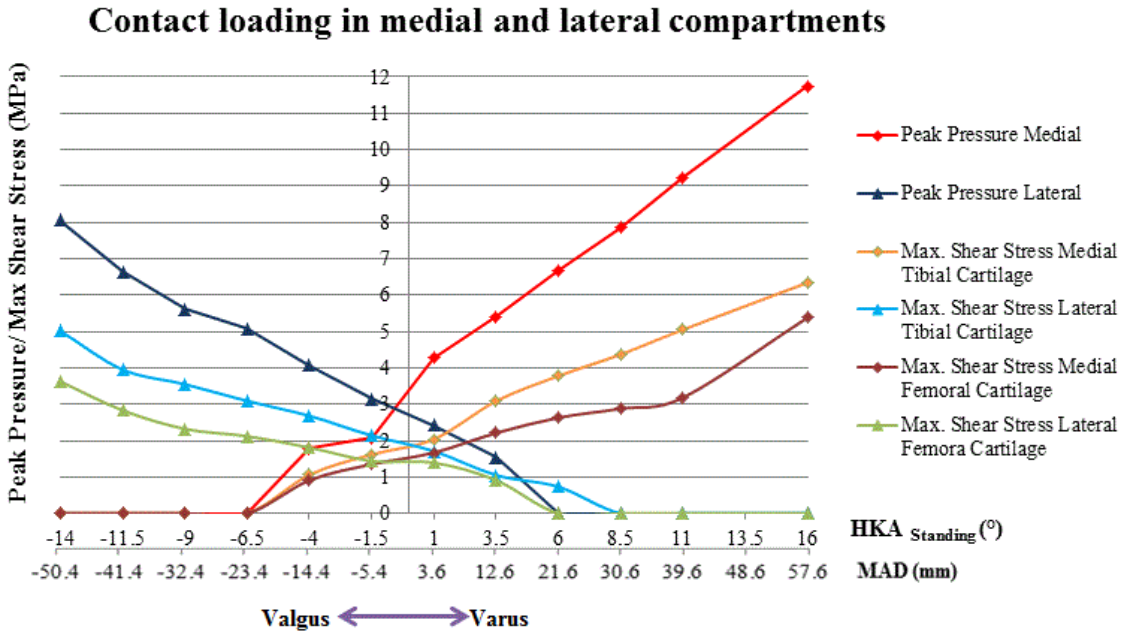
Methods: Three-dimensional (3D) SPGR and 3D CUBE magnetic resonance images of a cadaveric knee joint were acquired and segmented in Mimics imaging package (Materialise, Belgium) to create accurate 3D representations of the bones, cartilage, menisci and ligaments. The solid 3D knee joint assembly model was then exported to ABAQUS V6.11-2 (HKS, USA). Bones were meshed with tetrahedral elements and all remaining parts were meshed, using hexahedral elements. Material properties of bones and cartilage were set as homogenous, isotropic structures with linear elastic behaviour; Meniscus material properties were set as transversely isotropic. Material properties of each ligament were tuned until the kinematics of the FE model matched those of the cadaveric specimen, positioned in a load-controlled robot, in 5 degrees of freedom along a 0° to 65° flexion pathway [3]. Each meniscal horn was attached to the tibial plateau by using 1D linear springs with a stiffness of 2000N/mm [4]. To evaluate the effect of alignment, the distal femur was mechanically grounded and the tibia was fixed at 18° of flexion. An axial load of 811 N, an anterior load of 100 N and a lateral load of 77 N were applied to simulate the end of weight acceptance as per normative data from the Leon Root, MD Motion Analysis Laboratory at the Hospital for Special Surgery. Different wedge geometries were then virtually removed to simulate malalignments from 14° valgus to 16° varus.

Results: The native alignment of the cadaveric knee (1° varus) gave a medial:lateral load ratio of 70%:30%. The medial and lateral peak pressure for the native aligned knee was 4.28 MPa and 2.42 MPa, respectively. Medial peak shear stress

was 2.04 MPa in the tibial cartilage and 1.67 MPa in the femoral cartilage. The lateral peak shear stress was 1.71 MPa in the tibial and 1.32 MPa in the femoral cartilage.

An increase in varus alignment substantially increased medial knee contact loading while an increase of valgus angulation substantially increased the contact loading in the lateral compartment (Figure 1). An MAD of 0 mm resulted in a medial:lateral load ratio of 60%:40%. The minimum peak pressure occurred at an angle of 0.5° valgus, which corresponds to an MAD of -1.4 mm. The lowest peak shear stress for the tibial cartilage occurred at an alignment of 0.25°, which corresponds to an MAD of 0.7 mm. For the femoral cartilage the lowest peak shear stress occurred at an alignment of -1.2°, which corresponds to an MAD of -4.25 mm. There is a very strong correlation between surgical realignment geometry, MAD and knee joint contact loading (R>0.94).

Figure:



Caption: Peak contact pressure and maximum shear stress in the medial and lateral compartments

Conclusion: This study used a validated subject-specific 3D FE knee model to predict how different varus and valgus alignments influence knee joint contact loading. The hypothesis that the HTO geometry associated with an MAD of zero does not correspond to minimum contact loading was confirmed. In addition, results showed a very strong correlations (R>0.94) between knee geometry and joint contact loading. The ability of a subject-specific model to predict changes in the magnitude and location of peak contact loading within the knee as a function of alignment was demonstrated. This study serves as a foundation for the development of a surgical tool that could help surgeons make informed decisions on the degree of realignment required to minimise peak pressure, thereby delaying OA progression.

CONTRIBUTION OF INDIVIDUAL SOURCES OF ERROR IN GYROSCOPE SIGNAL INTEGRATION FOR BODY SEGMENT ORIENTATION ESTIMATE DURING GAIT

Ilaria Pasciuto [1 2,*] Elena Bergamini [1 2] Gabriele Ligorio [3] Angelo Maria Sabatini [3] Aurelio Cappozzo [1 2]

[1]Department of Movement, Human and Health Sciences, [2]Interuniversity Centre of Bioengineering of the Human Neuromusculoskeletal System, Università degli Studi di Roma Foro Italico, Roma, [3]The BioRobotics Institute, Scuola Superiore Sant'Anna, Pisa, Italy

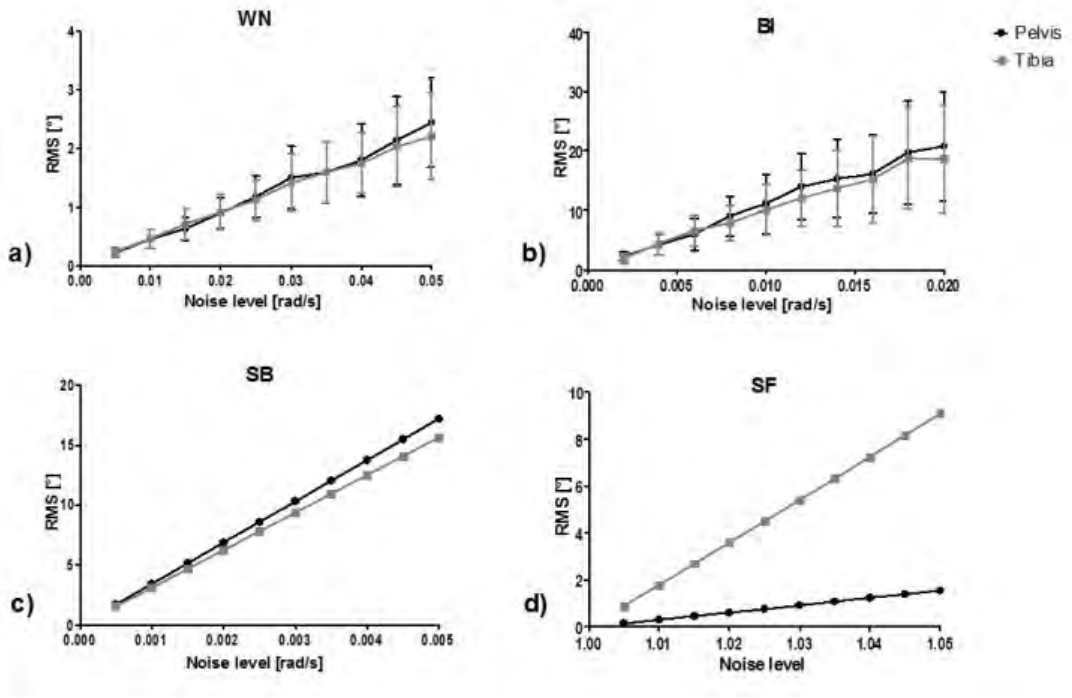
Introduction and Objectives: Accurate 3D orientation of body segments is a crucial aspect in human movement analysis. Among motion capture technologies employed for its estimation, inertial measurement units based on micro electro-mechanical systems (MEMS) are gaining momentum due to their easy set-up and reduced dimensions. In this context, body orientation estimation is based on the integration of the gyroscope signals, which however are affected by several sources of error that cannot always be effectively compensated for through sensor fusion approaches [1]. These gyroscope errors mainly include white noise, static bias, bias instability and miscalibration scale factors [2]. The aim of this work is to assess the contribution of these individual sources of error on the orientation estimation as obtained by numerical integration. For this purpose, a simulation approach was used, based on typical gyroscope signals associated to pelvis and tibia during walking. These sites are commonly used in human motion analysis as the former is close to the body center of mass and the latter provides robust detection of gait events and favorable conditions for sensor fusion approaches.

Methods: The simulation approach was based on modeling both the ideal gyroscope signals and the typical MEMS error sources. To obtain ideal signals representative of healthy gait, two tri-axial gyroscopes were attached to the pelvis and to the distal part of the right tibia of a healthy subject (26 years, 1.75 m, 70 kg) who walked along a 30 m straight pathway. The frequency spectra of the recorded signals, calculated over each available stride [3], were truncated at 15 Hz and averaged to produce ideal gyroscope signals of selected duration (1 minute). Mathematical models of white noise (WN), bias instability (BI), static bias (SB), and scale factor (SF) were then used to corrupt the ideal signals. In order to cover the range of typical values of commercially available sensors, ten levels were assigned to each noise source: the levels of both WN and BI differed in terms of standard deviation; SB levels were defined by the value of the offset; and SF by the gain representing miscalibration. As both WN and BI are defined stochastically, fifty simulations were performed for each level. In order to obtain the orientations corresponding to the ideal and noisy signals for each sensor, the kinematic equations [4] were integrated with an integration step representative of typical sampling frequencies (128 Hz). The difference between the ideal and each noisy orientation was then evaluated in terms of the Root Mean Square (RMS) of the orientation error defined in [4]. Finally, for each level of the two stochastic noise sources, the mean (μ) and standard deviation (σ) of the RMS over the 50 simulations was obtained.

Results: The mean errors associated to WN (Fig. a) increase with the values of the noise levels following a linear trend (R^2=0.99), and, in agreement with [2], a linear trend (R^2=0.98) is also observed for the σ of these errors. Regarding SF (Fig. d), the errors grow proportionally (R^2>0.99) to the gain values [2]. The slope of the curve is different for the two

sensors, as it depends on the angular velocity values. Since the tibia experiences angular velocities (μ=101.05 °/s) that are greater than those of the pelvis (μ=30.44 °/s), the former body segment is more sensitive to the SF noise. For what concerns SB (Fig. c), it presents a linear trend (R^2>0.99) in accordance with [2]. However, the two sensors present different slopes, indicating that the same offset applied to different angular velocity curves yields different variations in orientation. This result stresses the non-linear relationship between angular velocity and orientation [4] whose effects have not yet been thoroughly investigated. As suggested in [1], the cause for the difference in slopes could be related not only to the angular velocity values *per se*, but also to their distribution about the three sensor axes, which during gait was found to be much smaller in the pelvis (σ=16.11 °/s) than in the tibia (σ=106.47 °/s). Finally, the orientation error associated to BI (Fig. b) has been found to increase linearly with the noise levels (R^2=0.99) for the considered duration.

Figure:



Caption: Mean RMS of the orientation error in pelvis and tibia as a function of noise source levels. The vertical bars in a) and b) represent the standard deviation of the orientation error. The noise levels in d) are dimensionless.

Conclusion: This work shows that the influence of the non-linear relationship between angular velocity and orientation is evident in the SB error and that the effect of the distribution of the angular velocities about the three sensor axes in this respect must be taken into account.

THE ROLE OF ALTERED PROXIMAL FEMORAL GEOMETRY IN IMPAIRED PELVIS STABILITY AND HIP CONTROL DURING CP GAIT: A SIMULATION STUDY

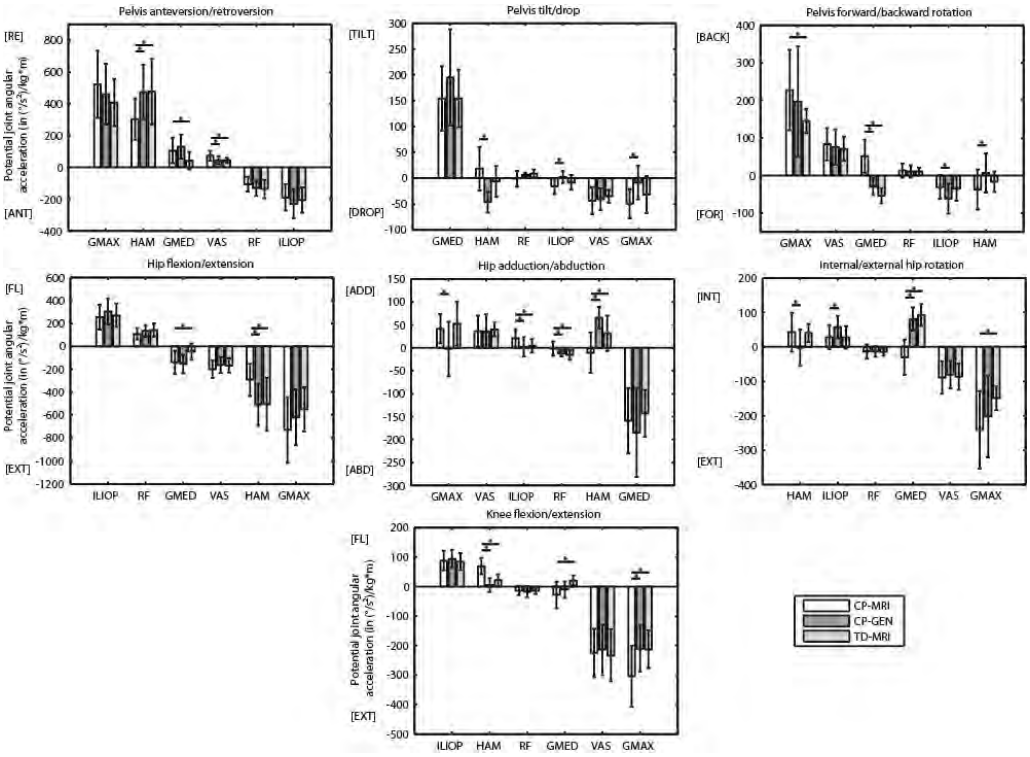
Lode Bosmans [1]Karen Jansen [1]Mariska Wesseling [1]Guy Molenaers [2]Lennart Scheys [2]Kaat Desloovere [3]Ilse Jonkers [1,*]

[1]Kinesiology department, [2]Department of development and regeneration, [3]Department of rehabilitation sciences, KU Leuven, Leuven, Belgium

Introduction and Objectives: Children with cerebral palsy (CP) often present aberrant hip geometry, more specifically increased femoral anteversion (FA) and neck-shaft angle (NSA). Furthermore, altered gait patterns are present within this population, amongst which crouch gait is one of the most common. This study aimed to identify the extent to which aberrant musculoskeletal geometry on the one hand and CP gait characteristics on the other hand modify muscular control of pelvis, hip and knee kinematics. We hypothesize that the presence of proximal femoral deformities will reduce the hip and knee muscles' potentials, but that the aberrant gait characteristics themselves will also affect muscle control.
Methods: Eight subjects with diplegic CP (8-12 yrs) and one control subject were included in this study. For each subject, a clinical gait analysis was performed and magnetic resonance images (MRI) of the lower extremities were captured. For each subject, a scaled generic (based on the Gait2392_Simbody model) [1] and a personalized MRI-based musculoskeletal model with personalized bone and muscle geometry [2] were created. For each subject with CP, dynamic simulations of gait were generated in OpenSim [1] for the following kinematics-model combinations: (i) CP-MRI, (ii) CP-GEN and (iii) TD-MRI. For CP-MRI and CP-GEN, pathological kinematics were applied to the MRI-based and generic model respectively. For TD-MRI, , typically developing (TD) gait characteristics of the control subject were used and applied to the MRI-based models. For all model types and kinematics, an induced acceleration analysis [3] was used to calculate the cumulative potential of individual muscles to accelerate pelvis orientation, hip and knee joint angles during the single stance phase of gait. A Wilcoxon signed-ranks test compared the potential accelerations based on the scaled generic and personalized model (CP-MRI and CP-GEN) to identify the influence of aberrant femoral geometry during CP gait. A Mann-Whitney U-test compared the potential accelerations between the two gait patterns for the personalized models (CP-MRI and TD-MRI) to identify the additional effect of the CP gait pattern in the presence of proximal femoral deformity.
Results: As presented in figure 1, femoral deformity as well as CP-specific gait pattern have a distinct effect on muscle control. The overall muscle potential was most affected in the sagittal plane (potential difference of 894 (°/s²)/kg*m between CP-MRI and CP-GEN and 993 (°/s²)/kg*m between CP-MRI and TD-MRI), followed by transverse (432 and 460 (°/s²)/kg*m) and frontal plane (398 and 199 (°/s²)/kg*m). For specific muscles, the CP gait pattern beneficially countered the loss of muscle potential induced by the proximal femoral deformity. This was found for GMAX/GMED in the sagittal (strengthening the potential to increase pelvis retroversion, hip and knee extension) and transversal plane (increased potential to induce external hip rotation), for VAS in the sagittal plane (strengthening its potential to increase pelvis retroversion) and HAM in the frontal plane (strengthening its potential to increase pelvis tilt and decrease hip adduction). In contrast, CP gait further compromised the muscle potential of GMAX/GMED transverse plane control (increased

backward pelvis rotation), ILIOP/RF frontal plane control (increased hip adduction) and HAM sagittal plane (decreased pelvis retroversion, hip extension and increased knee flexion). Proximal femoral deformity and CP gait were found to have a contradictory effect on the potential of the hip extensors: The mono-articular GMAX (and GMED) potentials as hip extensor were augmented, whereas the potential of HAM to extend the hip decreased and the potential to flex the knee increased.

Figure:



Caption: Fig 1. Potential joint angular accelerations (in (°/s²)/kg*m for iliopsoas (ILIOP), rectus femoris (RF), gluteus medius (GMED), vasti (VAS), hamstrings (HAM) and gluteus maximus (GMAX). * indicates statistically significant differences ($p<0.05$).

Conclusion: Both the presence of proximal femoral deformities and the CP gait pattern substantially affect muscle control. For individual muscles, negative as well as positive effects are reported depending on the analyzed degree of freedom, indicating a complex, muscle-specific effect of the deformity. In general, CP gait affects the overall muscle potentials more than the proximal femoral deformity. The hypothesis that the muscles' potentials to control pelvis orientation and hip and knee joint kinematics were to be reduced can only be partially accepted, as muscle contributions to joint angular accelerations both increased and decreased depending on the analyzed degree of freedom. CP gait in the presence of proximal deformity appears to be a well-balanced situation optimizing muscular control in the different planes.

SOFT TISSUE COMPONENTS INCREASE STABILITY AND EFFECT THE KINEMATICS OF A BIPEDAL PASSIVE-DYNAMIC WALKER

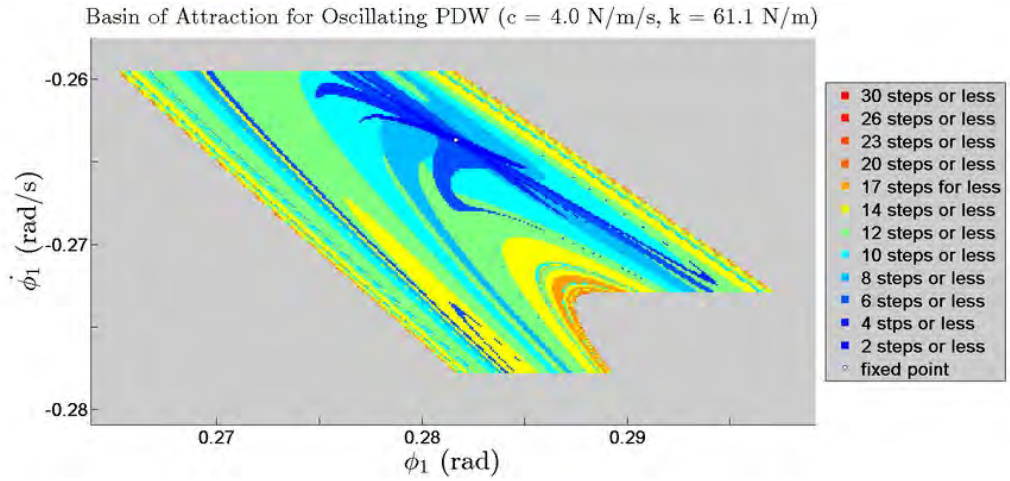
Samuel Masters [1,*] John Challis [1]

[1]Kinesiology, The Pennsylvania State University, State College, United States

Introduction and Objectives: The human body is composed primarily of soft tissue which oscillates during locomotion. As a result, ignoring soft tissue oscillation in models of human ambulation may affect the accuracy of the measurements made by said model (e.g., joint loads or muscle forces). Simulations that contain an oscillatory component may expose the benefits and impediments of soft tissue oscillation. Typically, non-rigid models are more strenuous to simulate computationally, but allow for a larger arsenal of mechanisms that increase stability (e.g., energy damper systems). Passive-dynamic walkers (PDWs) are tools for studying the underlying dynamics of human gait. A bipedal PDW with massless, rigid legs and point masses located at the hip and each foot can ambulate on an incline solely due to the energy from gravity *in silico* [1]. These systems, which capture many components of human gait, can be modified to study the dynamics of biologically inspired mechanisms (e.g., tendon energy storage and release or arm swing). A simple, bipedal PDW was modified to study the dynamical effects of a spring-damper system.
The objectives of the study were: (1) to outline the kinematic differences between a PDW with and without an oscillatory mechanism and (2) to quantify the dynamical effect of an oscillatory mass on the stability of a bipedal PDW.
Methods: A bipedal PDW with rigid, massless legs and a point mass at the hip and each foot was simulated to ambulate on an incline. There were two models: a control walker that did not contain an oscillating mass (CPDW) and a walker with an oscillating mass located at the hip (OPDW). The oscillating mass was connected to the hip via a spring-damper system. Stable gait cycles were found by keeping the damping coefficient at a constant value and incrementing the spring stiffness by 0.1 N/m until the walker failed. This was repeated for damping coefficients between 0 and 10 N/m/s in increments of 0.25 N/m/s. The conditions for foot-ground contact were such that each step was mathematically dependent upon the angular position of the stance leg exclusively. Therefore, the initial state conditions of the stance leg were perturbed to analyze the stability of the CPDW and the OPDW for varying spring-damper parameters. Furthermore, the kinematics of the CPDW and OPDWs were compared. All stable gait cycles analyzed were period-one (P1) gait cycles. That is, each step was kinematically identical and, therefore, the PDW could ambulate indefinitely if unperturbed.
Results: All results discussed were obtained for an incline of 0.009 radians. For an OPDW without damping, stable walking cycles were found for spring stiffness values between zero and 8.6 N/m. As the damping coefficient increased, the range of spring stiffness values that resulted in stable walking increased exponentially. For example, at damping coefficients of 2 N/m/s and 4 N/m/s, stable gait cycles were found for spring stiffness values up to 11.5 N/m and 673 N/m, respectively. Compared to the CPDW, an OPDW with a spring stiffness of 61.1 N/m and damping coefficient of 4.0 N/m/s, resulted in a 2.89% decrease in step time and a 37.83% increase in step length. As a result, the average walking velocity increased by 41.87%. In general, the PDW walking velocity increased as the spring stiffness increased. Furthermore, the basin of attraction for the same OPDW (Figure 1) was 161.45% greater than the CPDW. As

the spring stiffness increased, stable gait cycles bifurcated one or more times (i.e., P1 gait cycles transitioned to period-two (P2) gait cycles, then P2 gait cycles transitioned to P4 gait cycles, etc.). Period-n gait cycles occur when the initial conditions of a step repeat every n-th step. Furthermore, this period-doubling region transitioned into a period-halving region until the gait cycles returned to stable P1 gaits.

Figure:



Caption: Figure 1: The basin of attraction of the OPDW (spring stiffness of 61.1 N/m, damping coefficient of 4.0 N/m/s). The initial states of the stance leg for which the OPDW returns to the period-one gait cycle (fixed point-attractor).

Conclusion: Insights into human locomotion have been obtained from PDW, here these models were extended to examine the potential role of soft tissue oscillations. The two models simulated produced gait with kinematic differences between the rigid model and the model containing soft-tissue like components. Importantly the gaits simulated with the model containing soft tissue components was much more stable than the rigid model, suggesting that in humans these soft tissue damped oscillations may, in addition to their other roles, act to make gait more stable.

HYBRID FORWARD INVERSE DYNAMICS FRAMEWORK FOR HUMAN MUSCULOSKELETAL SIMULATIONS

Mohammad S. Shourijeh [1,*] Daniel L. Benoit [1 2]

[1]Faculty of Health Sciences, [2]Faculty of Engineering, University of Ottawa, Ottawa, Canada

Introduction and Objectives: Different approaches have been used in musculoskeletal simulation studies to solve the muscle redundancy problem. Inverse dynamics, forward dynamics, and hybrid (inverse-forward [1] or forward-inverse [2]) dynamics have been applied with different optimal control techniques in static, partially dynamic, or fully dynamic approach. Focusing on the knee joint, the ideal framework would predict biomechanical quantities, such as muscle activations and joint loads, in a biofidelic manner. The goal of this research is to introduce a simulation framework that can predict knee joint biomechanical quantities, based on knee joint stability criteria, while taking advantage of the strengths of both static and dynamic optimization techniques, while maximizing the use of in vivo data to produce physiologically relevant simulations.

Methods: The workflow was developed using OpenSim-MATLAB scripting to run simulations on a variety of movements and can be used in: 1) an inverse dynamics manner (i.e. from measured kinematic data and force platform data to muscle forces/activations); 2) forward dynamics (i.e. from muscle excitations to kinematic estimations); and 3) hybrid dynamics (i.e., a combination of forward and inverse dynamics) and is shown in Fig. 1.

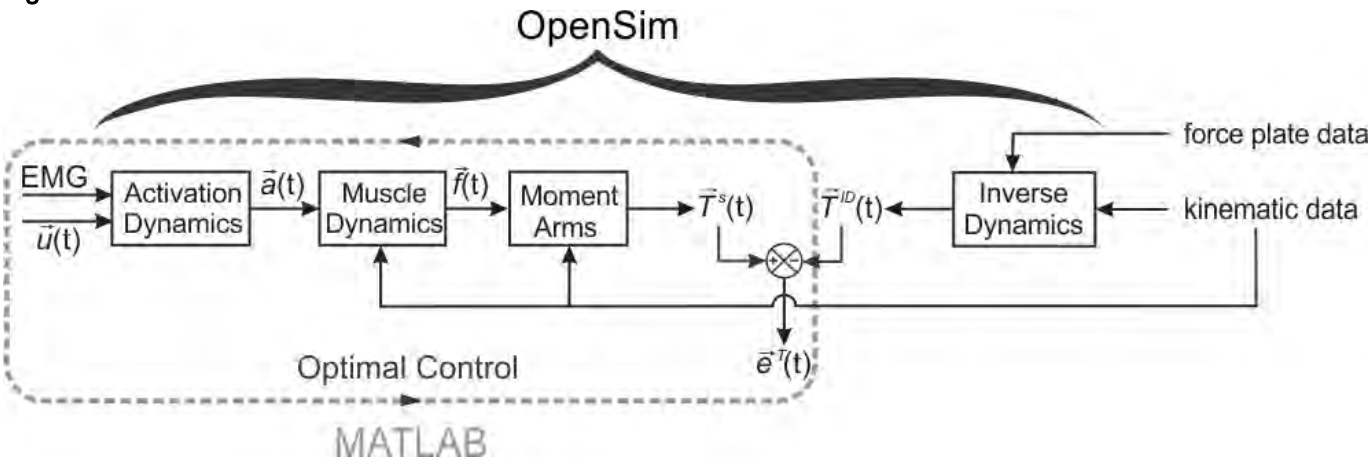
Several steps are included in the framework such as scaling, inverse kinematics, inverse dynamics (and residual reduction algorithm, RRA, and static optimization). These are followed by a forward inverse dynamics phase, which provides a computationally cheaper simulation compared to fully forward dynamics simulations. MATLAB optimization is used for the optimal control part, whereas other optimizations are done in OpenSim 3.2 within the specifically defined tasks, such as scaling and RRA.

The framework provides several features, including parameter identification, static or dynamic predictive simulations, noise rejection, EMG-driven simulations, partially predictive simulations, joint load calculation, and objective function alteration.

Hybrid dynamics could be used for subject-specific model tuning where the torque error between the forward and inverse dynamics sides is minimized and model parameters such as muscle-related parameters will be optimally identified, for which a dynamic optimization should be solved. This requires EMG data for all muscles in the model. Hybrid dynamics can also be used for muscle excitation optimization where the framework searches for the best muscle excitations that minimize the error as well as a physiological cost, e.g. muscle fatigue. Note that the framework starts from excitations and ends with joint torque, i.e. it does not integrate the multibody equations of the system and therefore it is more efficient than a fully forward dynamics that tracks body motion such as [3]. Finally, when some EMGs are measured, but some of the muscle signals are still unknown, hybrid simulations can be useful, in which situation optimization will be performed to find optimal values of the unknown muscle activities. As EMG measurements are prone to noise and crosstalk, minor tweaks on the known EMGs could also be done for convergence to a possibly better optimal point.

Results: The hybrid framework has simulated level walking trials using Gait2392 and Gait1018 models from the OpenSim repository. The results of using the Gait1018 along with comparison with those of static optimizations and experimental EMGs will be presented in [4].

Figure:



Caption: Schematic of the hybrid forward inverse dynamics musculoskeletal simulation framework. u and a are muscle excitation and activation, respectively; f represents tendon-muscle force; T is joint torque; superscripts s and ID refer to simulation and inverse dynamics; and e designates error.

Conclusion: A framework for efficiently simulating musculoskeletal models was introduced. This framework has features that use the advantages of both SO and DO, can integrate known in vivo subject characteristics making it more bio-fidelic than existing alternatives, and converges to optimal solutions within reasonable computation time. As such, it is an ideal framework to investigate the effects of population-based differences due to injury or disease. To study rehabilitation-related quantities of the knee joint, such as ACL injury, one future work will be to use a more bio-fidelic knee model that considers ligaments at the knee such as [5].

TIBIOFEMORAL CONTACT LOADING IN ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTED INDIVIDUALS AND HEALTHY CONTROLS DURING A RANGE OF GAIT TASKS.

David J. Saxby [1,*] Pauline Gerus [2] Bryce Killen [1] Luca Modenese [1] Tim Wrigley [3] Adam Bryant [3] Karine Fortin [3] Kim Bennell [3] Flavia Cicuttini [4] David Lloyd [1]

[1]Centre for Musculoskeletal Research, Griffith Health Institute, Griffith University, Gold Coast, Australia, [2]Laboratory of Human Motion, Education and Health, University of Nice Sophia-Antipolis, Nice, France, [3]Centre for Health, Exercise and Sports Medicine, University of Melbourne, [4]Department of Epidemiology and Preventive Medicine, Monash University, Melbourne, Australia

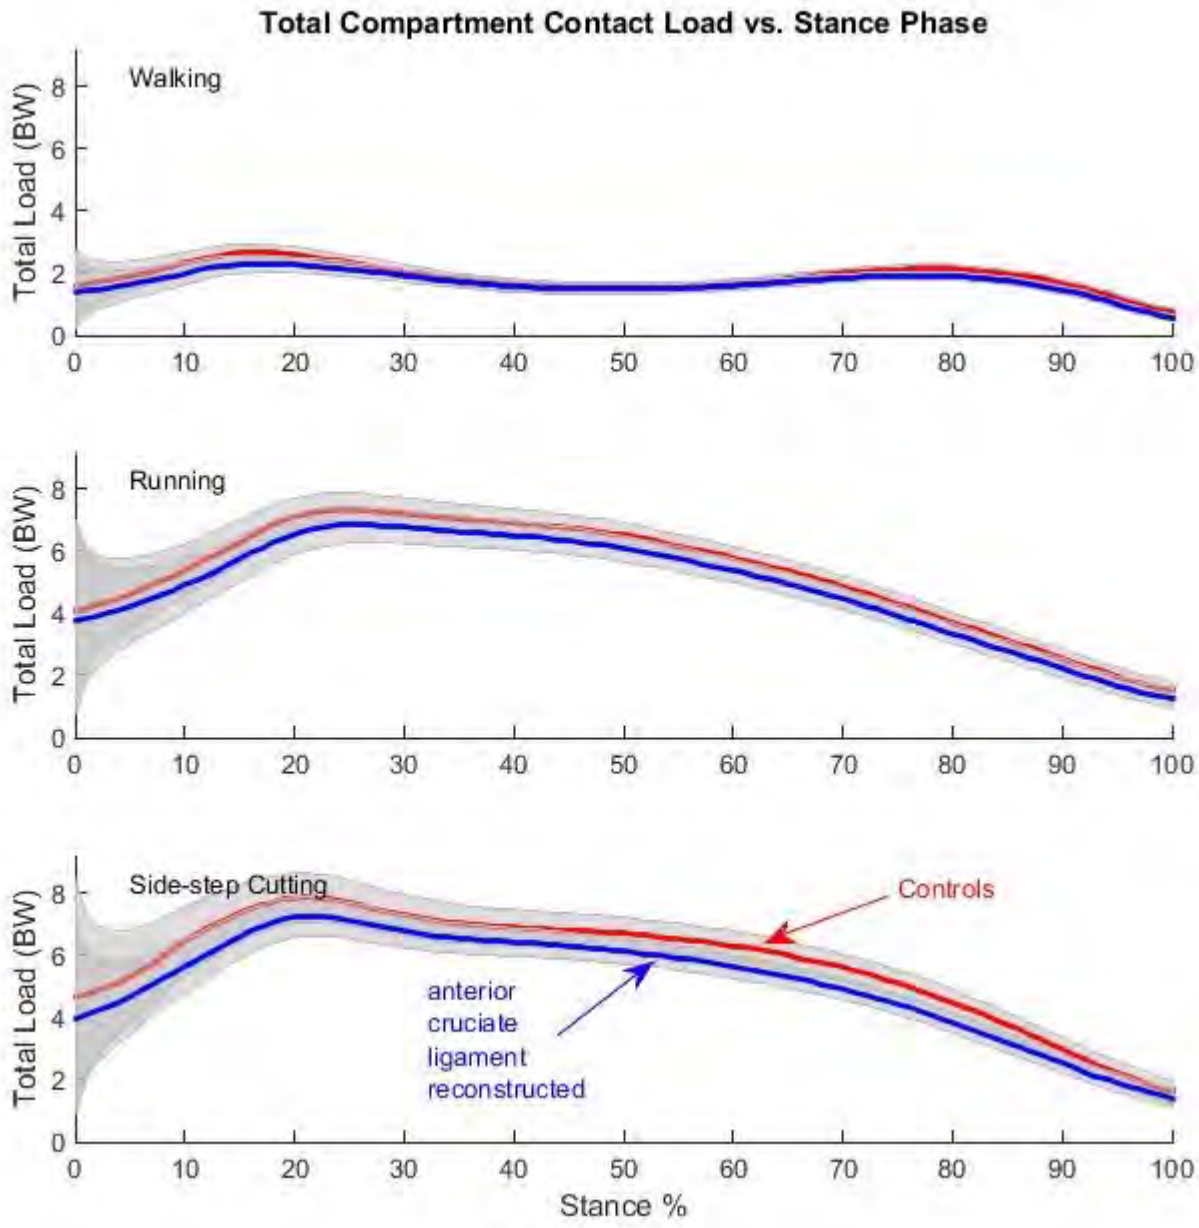
Introduction and Objectives: The tibiofemoral joint receives frequent high-magnitude contact loads (TCLs) during activities of daily living [1]. TCLs can cause tibiofemoral osteoarthritis (OA) in animal studies, and are implicated in human OA development [2]. Human studies have identified anterior cruciate ligament rupture and reconstruction (ACLr) as a powerful risk factor for OA. ACLr modifies joint mechanics, muscle strength and daily activity. The effect of ACLr on tibiofemoral contact loads in unknown. Instrumented prosthetic implants (IPs) allow direct measurement of tibiofemoral contact loads (TCLs), but due to cost and their invasive nature are inappropriate for most study designs. As a result, surrogate or proxy measures of *in vivo* joint contact loads are used such as the external knee adduction moment (KAM). KAM shows equivocal associations with joint health and disease, and this ambiguous nature of the KAM may arise from KAM not being an appropriate measure of medial tibiofemoral contact load (MTCL). In lieu of surrogates such as KAM, electromyogram-driven neuromusculoskeletal (EMGd NMS) models provide an alternative approach to predicting joint contact loads. EMGd NMS models incorporate experimentally measured muscle recruitment (EMGs) and external gait mechanics to estimate *in vivo* muscle forces and TCLs.

While IP studies have provided profiles of standardized net tibiofemoral contact loads during selected gait modes, healthy and disease risk (ACLr) populations perform a wide range of motions, and little is known about tibiofemoral joint contact loads across walking and sporting movements. The purpose of this study was to model TCLs in ALCr and healthy controls during walking, running and side-step cutting gait using an EMGd NMS model. We hypothesized that differences in TCLs exist across between ACLr and controls and across gait tasks, specifically that ACLr will display lower TCLs across gait tasks.

Methods: Participants (Controls n=60, ACLr = 105, age range 18-40) performed walking (W), running (R) and side-step cutting (SSc) while 3-dimensional motion capture (Vicon, UK), ground reaction forces (Kistler, Switzerland), and electromyograms (EMGs)(Zero Wire, Milan, Italy) were acquired. EMGs were acquired from 8 major knee muscles, and conditioned by band-pass filter (30-450 Hz Butterworth), linear envelope (6 Hz LP Butterworth) and scaling to functional maximum. OpenSim [3] and CEINMS [3] were used to estimate medial, lateral and total tibiofemoral contact loads (TCLs) during W, R and SSc. Repeated measures ANOVA was performed to determine differences across gait task and between groups.

Results: TCLs were significantly different between gait modes (Fig 1), with mean and peak TCLs (medial, lateral and total compartments) increasing from W to R to SSc. Lateral compartment was never unloaded, despite the presence of substantial positive external adduction moments during W and R. Similarly, medial compartment remain substantially loaded during SSc despite the presence of a positive KAM. The increase in TCLs as gait task speed and external loads increased was of no surprise although SSc which was slower than R displayed larger total TCLs. An interaction of knee injury group (ACLr or healthy) with total compartment load revealed that ACLr individuals have lower peak tibiofemoral contact loads during R and SSc, but not during walking gait.

Figure:



Caption: Fig 1. Total compartment load +/- 95% confidence intervals for ACLR (blue) and controls (red) during stance phase of walking, running and side-step cutting. Load is scaled to body-weight and time to 100% of stance phase.

Conclusion: Medial and lateral tibiofemoral compartments experienced substantial contact loading during walking, running and side-step cutting. Despite the presence of large positive or negative external frontal plane moments, both medial and lateral compartments experienced substantial contact forces with no periods of zero loads. Total TCLs were different across walking, running and side-step cutting gait, with a general trend of increased gait velocity resulting in increased TLCs in both compartments. For movements of similar velocities (such as running and side-stepping) TCLs were found to be larger in side-step cutting, despite running being performed at higher velocity. ACLr individuals exhibited lower TCLs during sporting tasks such as running and side-step cutting. During walking gait ACLr and controls exhibit similar TCLs. It is possible that chronic under-loading of the tibiofemoral compartment in ACLr populations could be related to their increased risk of OA development.

AS-0297

A SIMULATION MODEL OF ROTATIONAL FALLS IN EQUINE EVENTING

Martin G. C. Lewis [1,*] Lauren Birkbeck [2] Cleveland Barnett [1]

[1]School of Science and Technology, [2]School of Animal, Rural and Environmental Sciences, Nottingham Trent University, Nottingham, United Kingdom

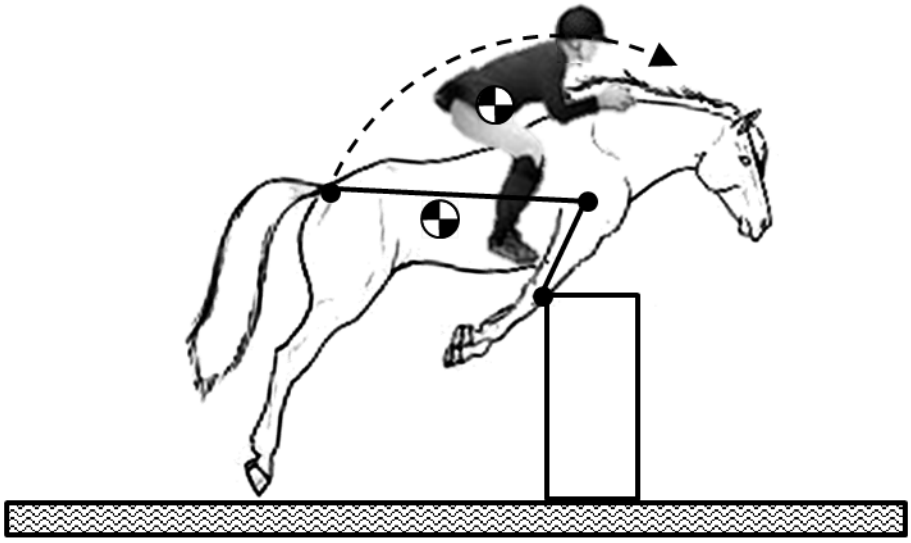
Introduction and Objectives: Rotational falls in equestrian eventing involve the horse contacting a solid fence before rotating over the fence in a somersault like action. Rotational falls present the greatest risk of death or serious injury to the rider, with nine deaths reported between 2004 and 2013, among other serious injuries such as paralysis and internal organ damage [1]. Limited research into the biomechanics of the horse and rider during jumps has attempted to understand the execution of horse jumping performance [2] and the loads imparted on fences during collisions [3]. In addition research on the mechanical conditions of a rider and horse system which result in a rotational fall does not currently exist. An investigation into the causes of rotational falls is paramount to enable investigation into methods for reducing the number of rotational falls and subsequent fall-related death or serious injury.

Methods: A rotational fall was simulated using a rigid two-dimensional, three-segment model of a horse and rider rotating about a pin joint fixed at the top near most corner of a standard dimension fence (Figure 1). One segment represented the combined properties of lower forelimb, metacarpals and digits, another segment represented the remaining forelimbs, trunk and hindlimbs and a final segment representing the rider. The rider mass centre location was given a fixed position relative to the horse trunk for each simulation. Rider whole-body mass centre location and moment of inertia were calculated from Dempster [4] according to mean digitised rider kinematics measured during competition. The segmental mass centre locations and moments of inertia of the two horse segments were calculated using data from Buchner et al. [5]. The point of contact of the horse with the fence was varied to occur between the knee (distal most end) and the elbow (proximal most end) of the antebrachium.

The effect of perturbing a number of variables was investigated including: rider position upon horse, angle between forelimb segment of the horse and trunk, angle of the horse trunk relative to the horizontal and initial rotational energy in the system. A range of initial conditions for each variable were investigated by perturbing combinations of mean kinematics for nineteen horse and rider combinations filmed successfully executing a jump for intermediate sections at a British Eventing competition.

Results: Varying the contact point of the horse with fence along the line of the antebrachium acts to change the orientation of the horse and rider where the system has sufficient energy to rotate beyond the global vertical. The orientation of the horse's trunk at this breakpoint ranges from 135˚ when the forelimbs are maximally flexed beneath the trunk and the contact point of horse with fence is at the knee joint, and 95˚ when contacting more proximal to the trunk at the elbow. This represents an angle of the horse's back relative to the horizontal of 10 ˚ and 50 ˚ respectively. Increased kinetic energy and potential energy at impact will all act to reduce the energetic requirements for a rotational fall, and increase the chance that a rotational fall may occur.

Figure:



Caption: A three-segment, rigid body model of a rotational fall; segment 1 (Antebrachium) from axis of rotation at distal end at the knee to the proximal end at elbow, segment 2 (Trunk) from elbow to croup, segment 3 (Rider) with fixed mass and whole-body moment of inertia at a position relative to segment 1.

Conclusion: The effect of large initial energy in a rider and horse system makes it more likely that sufficient energy is present to cause a rotational fall. The energy requirement for a rotational fall are smallest when the forelimbs are maximally flexed and the contact point is at the most distal aspect of the antebrachium.

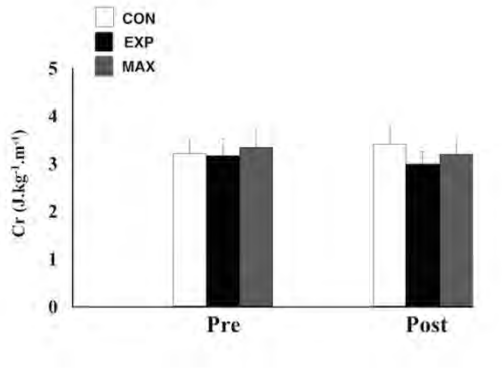
EFFECTS OF DIFFERENT STRENGTH TRAINING PROGRAMS ON BIOMECHANICAL AND ENERGETIC PARAMETERS OF RUNNING IN TWO DIFFERENT INTENSITIES

Jorge L. Storniolo [1 2,*] Alberto E. Minetti [2] Leonardo A. Peyré-Tartaruga [1]

[1]Laboratory of Research and Exercise, Federal University of Rio Grande do Sul, Porto Alegre, Brazil, [2]Pathophysiology and Transplantation, University of Milan, Milan, Italy

Introduction and Objectives: Adding of strength to endurance training is recognized to improve the metabolic cost of running (Cr) through neuromuscular adaptations (i.e. motor unit recruitment, intra/intermuscular coordination and musculotendinous stiffness) [1, 2]. Vertical stiffness (K_{vert}) is an important variable for running because it estimates the amount of elastic energy which could be stored and released for this movement. It is known that K_{vert} is velocity-dependent and might be related to Cr due to elastic properties [3] and increase after strength training [4, 5]. However, it is unknown the response of Cr and K_{vert} after two different strength training programs. Thus, this study aims at compare the effects of maximal and explosive strength training on Cr and K_{vert} in submaximal and supramaximal intensity of running. **Methods:** A total of 24 recreational runners took part in the research (mean±SD - age: 26.3±5.2 years; height: 1.75±0.9 m; weight: 75.4±15.4 kg). The subjects were assessed pre and post-training for the biomechanical and energetic variables. Indirect calorimetry data were evaluated with MEDGRAPHICS analyzer to calculate maximal oxygen consumed (VO_{2max}) and Cr on treadmill. Cr was analyzed on 60% of velocity associated to the VO_{2max}. Biomechanical data were recorded and analyzed with 6 cameras of VICON motion system with a sampling frequency of 120 Hz for 60 and 110% velocity of VO_{2max}. Video records were obtained to analyze biomechanical variables during running. K_{vert} and F_{max} were estimated from Morin et al. [5] equation. Neuromuscular parameters were evaluated such as one repetition maximal (1RM) in squat exercise and height of counter movement jump (hCMJ). The subjects were divided into tree groups: maximal and explosive strength training (MAX, n=8 and EXP, n=9) and control group (CON, n=7). MAX and EXP performed simultaneously the strength and endurance training, while CON group performed only endurance training during 8 weeks. MAX group performed exercises between 85-95% of 1RM, while EXP group performed exercises between 30-40% of 1RM in maximal velocity. A two-way ANOVA (group x time) with repeated measures was used to test for differences in K_{vert}, F_{max}, Cr, aerial time (AT), contact time (CT), velocity in 60 and 110% of velocity associated to VO_{2max} (vVO_2), 1RM and hCMJ. Paired t-test was used to compare the variables pre- and post-training. The alpha adopted was 0.05. **Results:** K_{vert}, F_{max}, AT, CT and Cr did not show significant differences between the groups after 8 weeks of training ($p > 0.05$) at any of the measured intensities (table 1). However, vVO_2 on 60 and 110% of intensity associated to the VO_{2max} have increased for MAX group ($p = 0.02$; $p = 0.04$, respectively). Neuromuscular variables as 1RM and hCMJ increased for MAX group and was higher than CON group ($p < 0.001$; $p = 0.01$, respectively) (table 1).

Figure:



Caption: Cost of running (Cr) before and after 8 weeks of training. Where CON (white bars), control group; EXP (black bars), explosive strength group; MAX (grey bars), maximal strength group.

Conclusion: Strength training groups did not show significative differences between the biomechanical variables after 8 weeks of training at any of the measured intensities. MAX group increased the vVO_2 on both intensities and decreased the Cr, although not significant. This result, associated to maintenance of K_{vert} and F_{max} might indicate a lower energy expenditure for MAX group. Therefore, the maximal strength training through increase of force, presented at improves of 1RM and hCMJ, seems to be more beneficial to recreational runners at submaximal and supramaximal intensities.

Table:

		CON (n = 7)		EXP (n = 9)		MAX (n = 8)	
	%VO2max	Pre	Post	Pre	Post	Pre	Post

PERFORMANCE OF VARIOUS NCAA FIELD HOCKEY BALLS

J.J. Trey Crisco [1,*] Kathryn Yates [1] Bethany Wilcox [2]

[1]Orthopaedics, [2]Brown University, Providence, United States

Introduction and Objectives: At the collegiate level in the United States, there is a wide range in the character of field hockey balls approved play. Colors include white and orange with smooth or dimpled surfaces. To the best of our knowledge the performance of field hockey balls has not been previously studied. We used a motion analysis approach that we developed previously for baseball bats to examine the performance of various field hockey when hit by female colligative field hockey players.

Methods: Seven members of the Brown University women's field hockey team (NCAA Division I – Ivy League) who swung right handed were recruited. All players used the same TK Synergy 1 composite 36.5" stick which had four infrared markers attached. Markers were attached halfway down the grip (between the shooter's hands), where the grip meets the rest of the stick, halfway between the end of the grip and the end of the stick, and on the rounded end of the stick. Eleven different ball models (labeled A to K) were used in testing. Each ball tested had six square pieces of tape placed symmetrical about the ball. Ball A was defined as the reference ball as it is marketed as the NCAA approved championship ball. Four high-speed cameras (Qualisys Oqus system) were used to track the 3-D motion of the stick and ball. For each player, the eleven ball models were randomized. Each player hit ten shots with each ball. The ball began in a stationary position, however many of the players taped the ball forward before shooting. In total, 770 total shots on goal were recorded (7 players hitting 10 shots each with 11 different balls). The tracked data was analyzed to compute ball speed, stick linear (at point of ball contact) and rotational speed and ball performance factor. Ball performance factor was defined as ball speed divided by linear stick speed. The significance of the difference in mean speeds and performance factor among the ball models was examined with an ordinary one-way ANOVA. Differences among the various models were assessed using Dunnett's multiple comparisons test with ball model A as the reference. Mechanical testing was also performed on each ball by compressing the balls between to flat plates to a value of 6.35 mm and recording the peak compression load.

Results: Ball model A speeds averaged 46.8 m/s, with a maximum of 63.9 m/s. The linear stick speed for shooting ball model A were a mean of 47.3 m/s, with a maximum of 57.5 m/s. The rotational speeds for shooting ball model A were a mean of 40.6 radians/s, with a maximum of 57.2 radians/s. There was no difference in the mean ball or stick speeds between ball model A and any of the other ball models.

Ball performance factor of model was a mean of 1.00 for ball model A and this factor was significantly higher than ball model F (0.93) and ball model J (0.93).

The load at maximum compression did not correlate with ball performance factor (P = 0.520). However, there were substantial differences in the load at maximum compression among the various ball models. Ball model A had a mean compression load of 1274 N (SD: 70 N), while ball model F had the highest mean compression load of 2462 N (SD: 290 N) and ball model D had the lowest mean compression load of 462 N (SD: 40 N).

Conclusion: In this study the ball and stick speeds we measured were unexpectedly higher than speeds measured in baseball bat impacts or in lacrosse shooting at the collegiate level. However, we do not that the study setup was ideal, allowing the women to maximize their efforts. Across the various models we found little difference in ball performance, with ball model A only slightly outperformed the other ball models. Despite this vary narrow range of ball performance, we found a very large range, almost a factor of 5, in ball compression values. This laboratory study suggest that balls with lower compression, and thus theoretically lower injury potential, can be used in play with no significant difference in performance. However, it should be noted that what level of injury reduction this would provide is not known, nor is it known if other factors affect true field performance of the balls.

IMPACT OF BOXING PUNCHES ASSESSED WITH WEARABLE INERTIA SENSOR AND MOTION CAPTURING

Akinori Nagano [1,*] Shoma Kudo [2] Ryosuke Akaguma [2]

[1]Faculty of Sport and Health Science, [2]Department of Sport and Health Science, Ritsumeikan University, Shiga, Japan

Introduction and Objectives: Boxing is an Olympic sport that has a long history. Because of the nature of boxing, in which a primary objective is to land punches on the head and stomach of the opponent, measures to ensure safety in boxing practice and matches are crucially required. There have been several preceding studies that pursued this goal [1] [2]. Recently with the development of high resolution, light weight and wearable sensors, biomechanical measurements have become more reliable, less restrictive and easier to conduct. We applied these latest sensing techniques to evaluate the impact of boxing punches. Specifically we utilized wearable inertia sensors, with which we measured three components of acceleration and three components of angular velocity data. We also utilized the technique of motion capturing, with which we obtained a wider variety of kinetic / kinematic data such as forces, position, velocity and acceleration of body landmarks very accurately.

Methods: Protocol: We collected punching data from right-handed experienced boxers. The punching motions were (1) jab, (2) one-two, (3) one-two-three and (4) one-two-hook. The boxers threw punches into either punching mitts held by an experienced trainer, or into a sand bag. (a) Acceleration and angular velocity of landmark points, (b) motion of the boxer, trainer who held the mitts, and sand bag, and (c) ground reaction forces were recorded. We also recorded and analyzed sparring sessions in normal boxing practice routine.

Inertia measurements: We used high resolution, wearable and light weight inertial sensors (ATR-Promotions, Japan). We attached the sensors at the wrist of boxers (Figure), at the wrist of trainer who received punches with punching mitts, and the sand back. Three components of acceleration and three components of angular velocity data were obtained at 500Hz. The sensor was quite small (slightly larger than a coin used in Japan) and light weight. The data were transferred to a mobile personal computer via Bluetooth. Restriction on the motion of boxers were minimal.

Motion Capturing: We used a system composed of 16 optical cameras (Motion Analysis Corporation, USA) and 15 force plates (Tec Gihan, Japan). Boxers threw punches in the calibrated space into punching mitts held by a trainer, or into a sand bag. Reflective markers were attached to the neck, shoulder, elbow, wrist, and fist of boxers (Figure). Position, velocity and acceleration of the landmarks were obtained. We calculated the momentum and kinetic energy of the fist/forearm.

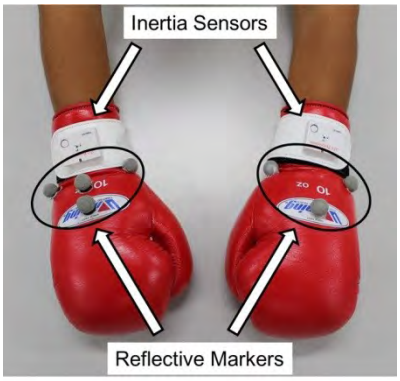
Sparring Recording: We recorded sparring sessions in normal boxing practice with a high-speed camera (nac Image Technology, Japan). We also attached an inertial sensor on the back side of the headgear of boxers. This enabled us to directly measure the acceleration of the head component imposed by punches.

Results: Punches thrown into the mitts: Based on the data from motion capture system and force plates, the momentum of a punch was calculated as 10.00 - 19.87 kg m/s (Table). The results suggested that the impacts can be reasonably assessed in activities that include strong collisions such as boxing. The measured values from the accelerometers were found to exceed 16G.

Punches thrown into the sand bag: Acceleration of the sand bag varied according to punch type. The acceleration also varied according to the size of boxing gloves. When comparing the impulse received by the sand bag and the momentum of wrist and forearm, there was a good matching between the values. This confirmed the validity of utilizing inertial sensors for our purpose.

Sparring: In routine boxing sparring sessions, “clean hit” of punches are rare. This is because boxers usually focus on improving techniques and skills rather than knocking out the partner during sparring. Therefore in this study the inertial sensors rarely gave high acceleration values. On the other hand, even when punches were defended (blocked) by a boxer, the sensors occasionally gave moderate magnitude of acceleration values.

Figure:



Caption: Inertia sensors and reflective markers attached on the gloves.

Conclusion: (1) We assessed the impact of boxing punches with wearable accelerometers and motion capturing. (2) We obtained consistent measures from inertia sensors and motion capture system, validating the assessment of impact using the small, light-weight and wearable sensors. (3) The momentum of punches ranged between 10.00 - 19.87 kg m/s.

Table:

	PunchSpeed (m/s)	Momentum (kgm/s)
LeftJab	7.431	13.75
OneTwo_LeftJab	6.630	12.26
OneTwo_RightStraight	8.724	16.14
OneTwoThree_LeftJab	6.213	11.49
OneTwoThree_RightStraight	8.423	15.58
OneTwoThree_LeftStraight	6.860	12.69
OneTwoHook_LeftJab	5.658	10.47
OneTwoHook_RightStraight	7.564	13.99
OneTwoHook_LeftHook	8.120	15.02

USING POSTURE TO BOOST TILT PRODUCTION WITH ASYMMETRIC ARM ACTIONS

Joanne Mikl [1,*]

[1]ACFR, University of Sydney, Sydney, Australia

Introduction and Objectives: Tilt of the principal longitudinal axis of the body towards the angular momentum vector will produce left twist in a somersault; the twist-to-somersault ratio increases as tilt increases [1,3]. Asymmetrical arm actions may be used to produce tilt [2]. When the arms move in a plane (Fp) which is perpendicular to the principal medial axis of the body and contains the shoulder, the actions may be modelled in 2D. In a layout (L) posture, Fp will also be aligned with the frontal plane of the chest (Fc) and so coaches may use the easily understood instruction to move the arms in Fc. However, in an Entry Pike (EP) or Arch (A) posture, Fp and Fc are not aligned. EP and A may be used to increase tilt production [2], provided the arm action is still performed in Fp.

This paper seeks to describe the position of Fp to improve instruction regarding the plane in which to move the arms. Further it determines the orientation change when performing the asymmetrical arm actions “Raise”, “DiverS” and “Drop” [2] and compares results between Fp and Fc in an attempt to determine if EP and A may still be used to boost tilt when using Fc.

Methods: Due to left-right symmetry in L, EP or A the transverse principal axis of the body and the transverse axis of each segment of the body are parallel. Hence the location of Fp may be described by the angle of rotation needed for the longitudinal axis of the segment of interest to reach the principal longitudinal axis of the body. A forward rotation will be positive. This angle was determined for the pelvis, abdomen, chest, upper- and lower legs.

The tilt produced by each arm action, Raise, DiverS, and Drop was determined using the conservation of angular momentum. Tilt was calculated in Fp for L, EP and A, and in Fc, for EP and A. In Fp only tilt resulted and in Fc the orientation change was split into tilt, twist, and somersault; somersault being negligible since Fc has no component perpendicular to the principal transverse axis of the body.

To determine the above values the fifteen inertial property data sets from the literature collated by Mikl [2] were applied.

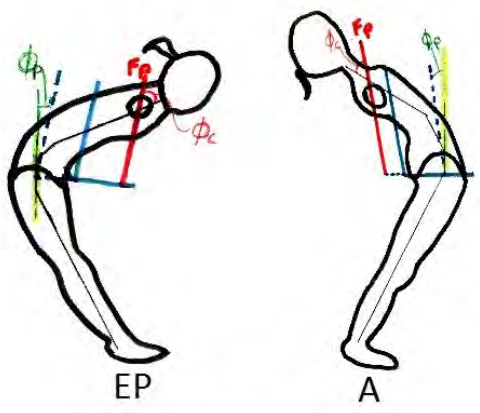
Results: The pelvis’ longitudinal axis was the closest of any segment to the principal longitudinal axis of the body; the median angle (Φp) was 2.1° (EP), -2.6° (A). Φp is small and since the frontal plane of the pelvis may be observed by eye it is helpful to use the frontal plane of the pelvis as an approximation of Fp. The angle between the longitudinal axis of the chest and the longitudinal axis of the body (Φc) had a median of -57.2° (EP) and 27.4° (A). Not being small angles, moving the arms in Fc rather than Fp will reduce tilt considerably, while adding twist. Attached is a sketch of EP and A with the principal axes (blue), the longitudinal axis of Fp (red), and the angles ϕp and ϕc marked.

Moving the arms in Fc rather than Fp, both EP and A show a reduction in tilt and result in less tilt than L. The reduction in tilt in EP is greater than A presumably because of a greater magnitude of ϕc. The table gives the tilt produced when the arms move in Fp for L, EP and A, and Fc for EP and A (for L, Fc and Fp are the same). Positive tilt produces a left (positive) twist.

EP and A produce opposite twist, since each Φc has opposite sign. For A the twist is in the wrong direction, putting the athlete behind in twist. Even though in EP the twist is in the desired direction it is essentially a one off bonus; the reduction in tilt will ultimately produce a lower twist rate and so twist completed will progressively fall behind.

Ranking actions in order of tilt gives Raise, DiverS, Drop in Fp and DiverS, Raise, Drop in Fc. Further DiverS produced less twist than Raise in Fc. Thus, moving both arms rather than one appears to reduce the negative effect of using Fc over Fp. Never-the-less there is still a large reduction in tilt.

Figure:



Conclusion: Using EP or A will boost tilt production if the asymmetrical arm actions used are in Fp. The location of this plane depends on the inertial properties of the body making its location difficult to explain to an athlete. It was found that the frontal plane of the pelvis was the closest anatomical plane and since this can be seen by eye, it is useful when explaining in which plane to move the arms. Moving the arms in Fc produces tilt considerably below that for L, and so using EP and A are no longer of benefit in boosting tilt. A was particularly poor since the secondary twist rotation was in the wrong direction.

Table:

Quartile			4	3	2	1	0	
Diver S	**Fp**	L	9.2	7.8	7.2	5.2	3.3	
		EP	12.6	10.0	9.9	6.3	4.1

PERFORMANCE ON THE FUNCTIONAL MOVEMENT SCREENTM IS RELATED TO HOP PERFORMANCE, BUT NOT TO HIP OR KNEE STRENGTH IN ATHLETES

Nienke Willigenburg [1,*] Timothy Hewett [2]

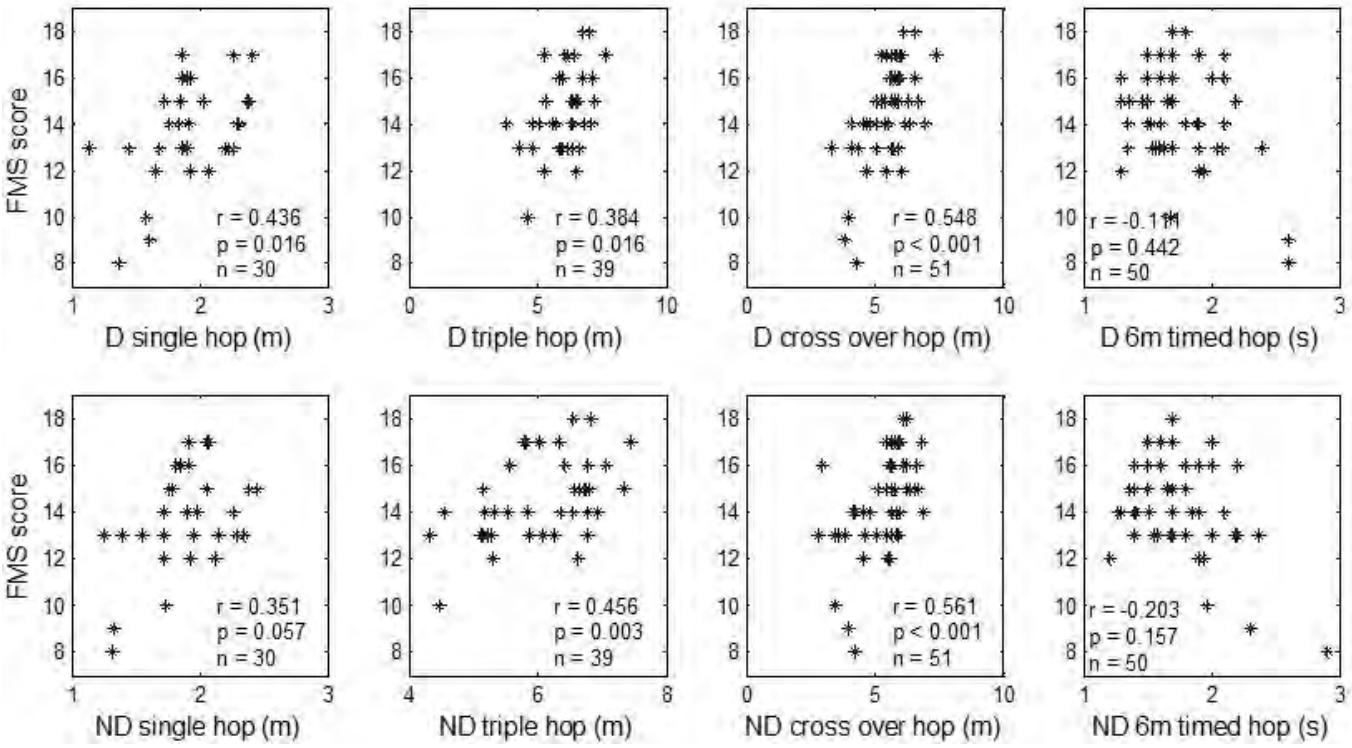
[1]OSU Sports Medicine, Sports Health and Performance Institute, [2]OSU Sports Medicine, Sports Health and Performance Institute, Departments of Physiology and Cell Biology, Orthopaedic Surgery, Family Medicine, and Biomedical Engineering, The Ohio State University, Columbus, United States

Introduction and Objectives: Pre-participation physical examinations have become common practice to screen athletes, and often include anthropometric, flexibility, and strength measures, with the aim to predict injury risk. Recently, interest has grown in screenings that reflect neuromuscular control during basic motor skills. One method to quantify fundamental movements in athletes is the Functional Movement Screen (FMS™) [1]. The FMS™ aims to 'pinpoint deficient areas of mobility and stability that may be overlooked in the asymptomatic active population' [2]. The FMS™ consists of seven tasks which are scored on a range from 0-3, based on execution criteria, including aspects of mobility, stability, and compensatory movements. The FMS™ is currently used as screening instrument in major sport leagues, as it may be associated with the risk of athletic injuries [3]. However, from a biomechanical perspective, it can be questioned whether the selected movement tasks adequately reflect actual measures of interest, especially with respect to injury prediction. Also, the different FMS™ tasks do not appear to represent unitary constructs, which brings the use of the summed score into question [4]. Moreover, the FMS™ score depends on the subject's knowledge of the grading criteria [5]. Given these potential flaws, it may be preferable to quantify athletic performance by maximum-effort based tests that assess isolated outcome measures of interest. This study defines the relationship between FMS™ scores and hop performance, hip strength, and knee strength in a population of collegiate football players. We hypothesized that FMS™ scores would positively correlate to hop performance, but not to hip and knee strength. Our secondary hypothesis was that limb asymmetries in hip strength, knee strength and hop performance would correlate with asymmetries in FMS™ tasks.

Methods: Fifty-nine freshmen of a division I collegiate American football team (age=18±0.6 years, height=1.86 ± 0.06m, mass=106±20.2kg) participated in this study. The athletes performed the FMS™, as well as a variety of maximum-effort hop tests, isokinetic knee strength and isometric hip strength tasks. We recorded total FMS™ score, peak strength and hop performance, and calculated asymmetries between legs on the different tasks. Spearman's correlation coefficients quantified the relationships between FMS™ scores and the other measures of strength and performance, and a chi-square analysis compared the number of athletes with asymmetries on the different tasks.

Results: We observed significant correlations ($r=0.38$-0.56, $p\leq0.02$) between FMS™ scores and hop distance, but not between FMS™ scores and hip or knee strength (all $p\geq0.21$). The amount of asymmetry on the FMS™ test was significantly correlated to the amount of asymmetry on the timed 6m hop ($r=0.44$, $p<0.01$), but not to hip or knee strength asymmetries between limbs (all $p\geq0.34$).

Figure:



Caption: Correlations between FMS(TM) scores and the different hop tests. The upper and lower panels represent the hop performance on the dominant (D) and non-dominant (ND) limbs, respectively.

Conclusion: FMS™ total score was positively correlated to hop distance, and limb asymmetry in FMS™ tasks was correlated to limb asymmetry in 6m hop time in football players. No significant correlations were observed between FMS™ score and hip and knee strength, or between FMS™ asymmetry and asymmetries in hip and knee strength between limbs. These results indicate that a simple hop test may be a time and cost efficient alternative to FMS™ testing in athletes, and that functional asymmetries between limbs do not coincide with strength asymmetries between limbs.

WHICH JOINT TO ASSIST? SIMULATION-BASED GUIDELINES FOR REDUCING THE METABOLIC COST OF WALKING WITH HEAVY LOADS

Christopher L. Dembia [1,*] Amy Silder [2] Thomas Uchida [2] Jennifer Hicks [2] Scott Delp [1 2]

[1]Mechanical Engineering, [2]Bioengineering, Stanford University, Stanford, United States

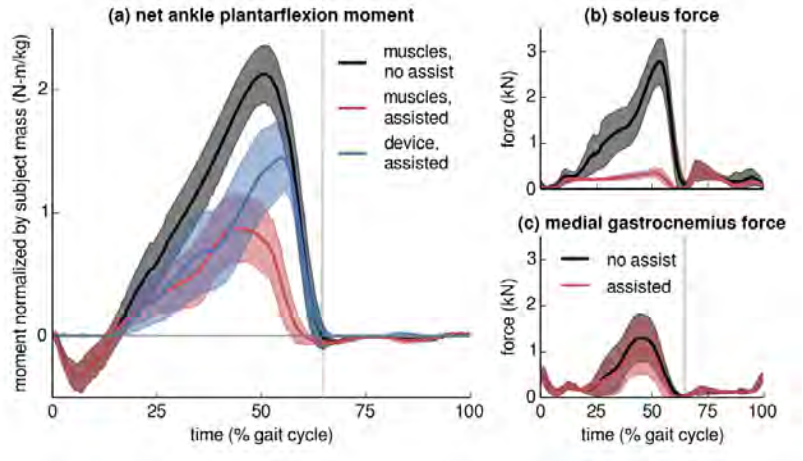
Introduction and Objectives: Soldiers often carry over 40 kg while on duty. These loads significantly increase metabolic cost and limit the soldiers' ability to perform their duties [1]. To alleviate this burden, engineers are designing devices to decrease the metabolic cost of walking with heavy loads (“loaded walking”) [2], [3]. Many existing devices are designed to assist ankle plantarflexion, based on the rationale that the ankle typically provides half of the net positive mechanical joint work during loaded walking [3]–[6]. Alternatively, a device explicitly optimized to reduce muscle activity might lead to greater reductions in metabolic cost. Computer models of the musculoskeletal system that incorporate energy expenditure enable a systematic exploration of a range of assistance strategies (e.g., varying the joint being assisted and the timing and magnitude of actuation), without the need for time-consuming device prototyping and human testing. The aim in this work was to use musculoskeletal simulation to discover which type of joint assistance has the greatest potential to decrease the metabolic cost of loaded walking. We considered 6 types of joint assistance: ankle plantarflexion, knee flexion, knee extension, hip flexion, hip extension, and hip abduction.

Methods: We collected motion capture data for 6 individuals walking at a freely selected speed while carrying 40 kg on their torso. We generated simulations of each walking trial using OpenSim’s Computed Muscle Control (CMC) algorithm [7] (the “no assist” condition). Next, we tested the 6 types of joint assistance by creating new CMC simulations in which the model could be assisted by a virtual massless torque actuator that acted at one joint and in only one direction. The kinematics of the motion remained the same, as did the objective to minimize the sum of squared muscle activations. However, CMC was free to use the virtual actuator to replace muscle actuation (the “assisted” conditions).

To estimate the metabolic cost of walking in each simulation, we used the CMC results as inputs to a modified version of the muscle metabolics model developed by Umberger et al. [8]. We used this metabolics model to compute the relative decrease in cost of transport (COT; energy required to transport a unit weight by a unit distance) that resulted from the use of each virtual actuator.

Results: All 6 types of joint assistance led to a decrease in COT (see table). Assisting hip flexion showed the greatest potential to reduce metabolic cost, with a 16% decrease in COT compared to normal walking. Assisting ankle plantarflexion reduced COT by 7.9%, which is in the same range as has been achieved experimentally [3]. Assisting knee extension had the smallest effect on COT. The torques supplied by some virtual actuators resembled the corresponding net joint moments, while others differed substantially. One reason for these differences is the fact that motion is generated by a complex coordination of both uni- and bi-articular muscles. For example, the ankle plantarflexion actuator took over the role of the uni-articular soleus muscle, but did not affect the activity of the bi-articular medial gastrocnemius (see figure).

Figure:



Caption: Effects of ankle plantarflexion assistance. Net ankle plantarflexion moment normalized by subject mass for the "no assist" condition (black) along with the net moment from muscles (red) and the ankle plantarflexion device (blue) in the "assisted" condition (a). Force generated by the (b) soleus and (c) medial gastrocnemius muscles, both with (red) and without (black) assistance. (solid: mean; shading: ± 1 standard deviation; vertical gray line: toe-off)

Conclusion: Assisting hip flexion, rather than ankle plantarflexion, led to the greatest potential savings in the metabolic cost of transport. Non-intuitively, some of the virtual actuator torque profiles were substantially different from the corresponding net joint moments. Both of these findings support the use of muscle-driven simulations to help design assistive devices. Our results do not account for possible kinematic adaptation—a limitation we hope to address through future work via predictive simulation.

Table:

Type of Assistance	Relative Decrease in COT ± 1 s.d.
hip flexion	16 ± 2.0 %
knee flexion	12 ± 3.7 %
hip abduction	9.0 ± 4.8 %
hip extension	8.2 ± 2.8 %
ankle plantarflexion	7.9 ± 1.7 %
knee extension	3.7 ± 1.8 %

RUPTURE OF THE MUSCLE-TENDON COMPLEX IN TENSILE TEST USING DISCRETE ELEMENT MODELING

Anthony Roux [1 2,*] Jennyfer Lecompte [1] Laure-Lise Gras [1] Sébastien Laporte [1] Ivan Iordanoff [2]

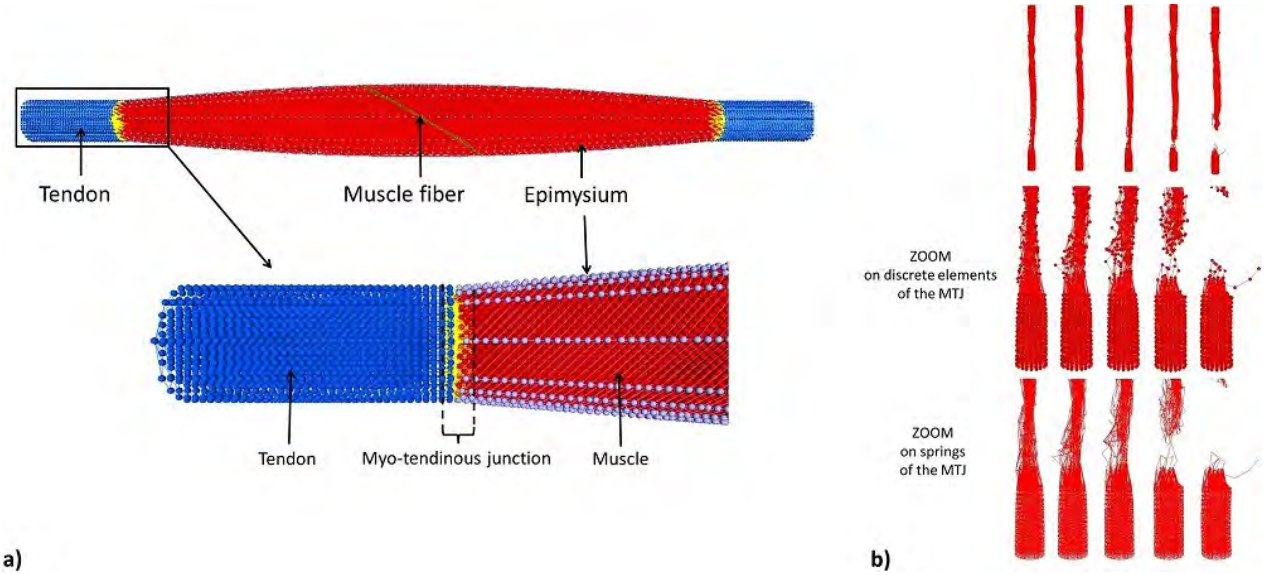
[1]Arts et Metiers ParisTech, Institut de Biomécanique Humaine Georges Charpak, Paris, [2]Arts et Metiers ParisTech, Institut de Mécanique et d'Ingénierie, Talence, France

Introduction and Objectives: Tear of the muscle-tendon complex (MTC) is one of the main causes of sport injuries but its mechanisms are still unclear [1]. The MTC is a multi-scale, non-isotropic and non-continuous structure that is composed of numerous fascicles gathered together in a conjunctive sheath (epimysium). Many MTC models use the Finite Element Method to simulate MTC's behavior as a hyperviscoelastic material. The Discrete Element Method (DEM) used for modeling composite materials could be adapted to fibrous materials as the MTC and to model the rupture. Before modeling the tear of the MTC, the aim of the study was to model its behavior and its rupture in tensile test.

Methods: The MTC model was developed in DEM (Figure 1-a) with GranOO software (I2M, France, www.granoo.org). Mechanical properties of MTC were addressed thanks to literature values [2], [3]. Stiffness of each element was related to discrete elements' cross-sectional area, initial length of links and corresponding elastic modulus (EM). Fibers were built with spherical discrete elements linked with springs (EM=37.44 kPa). The extra cellular matrix was computed using springs between fibers. Tendon's fibers were built with respect to muscle fibers architecture (EM=800 MPa). The myotendinous junction (MTJ) was represented by multi-links between tendon and muscle. Force vs. displacement evolution was obtained during a computed tensile test. MTC was fixed on its lower extremity and the upper extremity was subjected to a linear displacement. Thus, stretch-dependent evolutions of muscle volume and pennation angle were calculated. Elongation was chosen as rupture's criterion: spring's length over 30% strain [4] leads to a break and a separation from the MTC.

Results: The computed Force-Displacement displayed a classical hyper-elastic behavior, its shape was in agreement with *in vitro* experimental data of Gras et al. [5] over the SternoCleidoMastoideus (SCM) muscle. Values of mechanical properties of extracellular matrix (EM=100 kPa) (one of the main components of the MTC) and MTJ (EM=400MPa) had to be adjusted in order to fit with experimental data due to the lack of data in the literature. Furthermore, we used elastic modulus from patellar tendon [3] which could be not directly applied to SCM tendon. The use of linear springs, added to the MTC's structural effect, leads to a hyper-elastic behavior for the MTC's response in tensile test. The decrease of pennation angle during the tensile test was in agreement with *in vivo* assessments. The variation of the volume of the MTC, calculated during the simulation, was less than 1%, as previously described in the literature. This confirms the incompressibility property of MTC thanks to springs' properties in DEM. Rupture was located in the MTJ's area of the MTC, as described in the literature [6]. Indeed, MTJ was at the interface between the stiff tendon and the soft muscle, leading to a stress concentration. MTC was broken by fibers' delamination, in agreement with in vitro data [7] (Figure 1-b).

Figure:



Caption: a) MTC's geometry in DEM b) Rupture in the Myo-Tendinous Junction of the MTC in tensile test with DEM

Conclusion: The DEM seems to be a promising method to model the hyper-elastic macroscopic response of MTC with simple elastic microscopic elements. In order to model the tear of the MTC, the muscle's contraction will be implemented.

DYNAMIC PATIENT SPECIFIC FINITE ELEMENT BREAST MODEL FOR NODULE TRACKING DURING MAMMOGRAPHY

Silvia Pianigiani [1,*] Ngan Nghiem Bich [2] Bernardo Innocenti [2]

[1]IRCCS, Istituto Ortopedico Galeazzi, Milano, Italy, [2]BEAMS Department, Université Libre de Bruxelles, Bruxelles, Belgium

Introduction and Objectives: Mammograms are commonly used to screen the breast in order to detect eventual pathologies, such as nodules. These images show a compressed breast in different deformed shapes. However, the comprehensive use of these images during surgery, when breasts are under different boundary conditions, is problematic. For example, surgeons experience difficulties not only in the identification, but also in the removal of nodules by needle aspiration. Misidentification of the nodule position could affect the patient health. Therefore, the purpose of this project is to develop and validate a patient-specific finite element model of the breast to accurately localize the position of potential breast nodules under different conditions.

Methods: First, a parametric three-dimensional breast model has been designed. By the use of this model, the patient specific breast can be obtained measuring 10 external parameters directly on the standing patient. The breast model consists of several parts, such as the fat, the glandular area and the duct. The model does not include the nipple and it is considered fully constrained to the chest. Once the patient specific model is obtained, that can be used for a finite element analysis in which several positions are considered: standing with undeformed breast, standing with deformed breast during cranio-caudal (CC) mammography, standing with deformed breast during 45° oblique mammography (MLO) and supine with undeformed breast simulating surgery conditions. Moreover, in order to track a possible nodule position from one of the deformed configurations to the surgical condition, spheres with different dimensions and positions have been inserted in the model. Different approaches to model the different materials of the breast have been used, as very few is reported in the literature. To understand which was the best modelling choice, a validation of the model is performed by comparing breast deformations in the numerical model and the mammograms. For the best matching, the tracking of the nodule has been analysed.

Results: Linear, Neo-Hookean and Mooney-Rivlin models used in this study show different outputs, in terms of shape, simulation time and displacements of the nodules. Comparing the numerical deformed shape with the ones obtained form images, the two most accurate models are the Neo-Hookean and the Mooney-Rivlin (Figure 1). The use of both models presents similar computational time. For the two models, different magnitude and trend of displacement has been shown for nodules of different dimensions and located in different part of the breast to simulate a ductal carcinoma in situ and an invasive ductal carcinoma. Generally bigger nodes move less than the smaller ones. Moreoever, the Mooney-Rivlin model shows higher displacement values, but with similar trend and position compared to the Neo-Hookean model.

Figure:

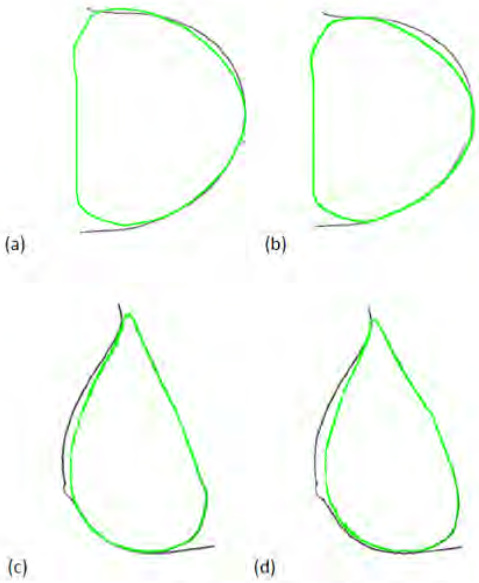

Figure 1: comparison between border deformed breast from image (black) and obtained after numerical simulation for: (a) CC view, Neo-Hookean model; (b) CC view, Money-Rivlin model.; (c) MLO view, Neo-Hookean model; (d) MLO view, Money-Rivlin model.

Conclusion: The aim of this work is to simulate breast deformation by means of finite element modeling. The use of this model has been coupled with nodule tracking information, useful during surgery to completly recover patient's health. From the obtained results, nonlinear methods provide more realistic outputs than linear methods, replicating better the hyperelastic materials behavior of the breast. There are minor differences in the outputs obtained from the two used nonlinear models.

The presented breast model presents some limitations, such as simplify geometries and the inclusion of the skin layer only throughout the friction coefficient between the breast and the mammograms plates. Although the proposed breast model presents minor limitations, it provides a valuable surgical tool to assist breast surgery.

The authors have nothing to disclose.

A MODIFIED VERSION OF THE THREE-COMPARTMENT MODEL TO PREDICT FATIGUE DURING SUBMAXIMAL TASKS WITH COMPLEX FORCE-TIME HISTORIES

Michael Sonne [1,*] Jim Potvin [1]

[1]Kinesiology, McMaster University, Hamilton, Canada

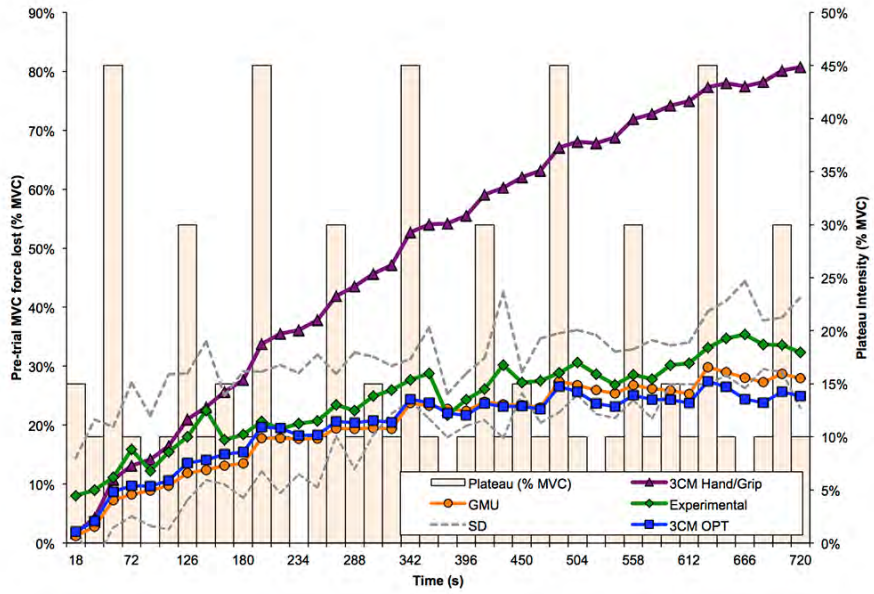
Introduction and Objectives: There has been extensive research on the inclusion of fatigue models into proactive tools for the purpose of ergonomic analysis with digital human models (DHM). The end goal of this line of research is to allow for an accurate prediction of muscle fatigue during complex and/or combined industrial tasks, thus proactively reducing the risk factors related to musculoskeletal injuries before the job(s) physically exists on the assembly line.

The three-compartment model of muscle fatigue[1] ($3CM_{XFL}$) has been validated, for the prediction of endurance times for various joints in the human body, by simply modifying the fatigue and recovery rates in the model [2]. However, it is not known how well the $3CM_{XFL}$ predicts fatigue levels during intermittent tasks, consisting of repeated efforts “on” to a single force level, then “off” to complete rest. As most work tasks are more complex than on/off [3], it is not clear if the current $3CM_{XFL}$ can be used for the ergonomics analysis of the full range of occupational tasks. The purpose of this research was to validate the existing $3CM_{XFL}$, against experimental fatigue levels resulting from a variety of submaximal force patterns, and provide modifications to the $3CM_{XFL}$ to increase the accuracy of fatigue predictions in these industrially relevant tasks.

Methods: We collected 9 experimental conditions of repeated sequences of submaximal plateaus of either 12 - 15 seconds in length, varying between 0 - 45% of MVC, followed by complete rest. Fatigue was determined by comparing an MVC after each plateau to a pre-trial plateau - with the decrease representing the fatigue level. These force profiles were completed using either isometric contraction of the distal aspect of the thumb, or isometric handgrip. Changes were made to the $3CM_{XFL}$, such that: 1) the fatigue rate was scaled to the current activation level and 2) the recovery rate was scaled based on a gradient that depended on both the current activation level and current fatigue level (termed the graded motor unit 3CM, or $3CM_{GMU}$). The $3CM_{XFL}$ was also optimized ($3CM_{OPT}$), by modifying the model’s fatigue (F) and recovery (R) coefficients, to predict fatigue throughout the experimental trials. We used the data from 7 of the conditions to determine the optimal F and R coefficients for the $3CM_{GMU}$ and $3CM_{OPT}$, and then tested the optimized model with data from the remaining 2 conditions. In all 9 conditions, the RMSD and R^2 between predicted and experimental fatigue was calculated, as was the error between the final experimental and predicted fatigue. The optimized models ($3CM_{GMU}$ and $3CM_{OPT}$) were also used to predict endurance times between 10% and 100% MVC, in increments of 10% MVC.

Results: The results can be found in Table 1. In general, the $3CM_{OPT}$ and $3CM_{GMU}$ were better at predicting fatigue in complex submaximal force patterns. The $3CM_{XFL}$ produced an asymptote at 6.1% MVC. Conversely, the $3CM_{GMU}$ predicted an asymptote and 29% MVC, compared to the $3CM_{OPT}$ which predicted an asymptote at 45.4% MVC.

Figure:



Caption: Figure 1. The mean experimental fatigue data (± SD) are plotted with the fatigue predicted with the 3CM-GMU, OPT and XFL for one of the test conditions (n = 8).

Conclusion: The $3CM_{GMU}$ model builds on the theoretical basis of the three-compartment model of Xia and Frey-Law (2008), and aims to improve its physiological fidelity. Optimizing the *F* and *R* coefficients, for both the $3CM_{GMU}$ and $3CM_{OPT}$, results in strong predictions of fatigue levels during complex, submaximal force patterns. The $3CM_{GMU}$ was able to predict muscle fatigue levels within approximately 4.1% MVC. The modifications made to the original 3CM allowed the $3CM_{GMU}$ to provide accurate predictions of fatigue accumulation and recovery during complex, intermittent force patterns. The discrepancy between the $3CM_{GMU}$ and $3CM_{OPT}$ and the $3CM_{XFL}$ in predicting endurance times indicates there are factors not accounted for between intermittent and sustained tasks. Additional research should aim to: 1) apply the findings of this model to other body parts, and 2) improve the model to allow for accurate fatigue predictions during sustained isotonic, intermittent and complex contraction patterns.

Table:

	Optimization			Test			All		
	RMSD	Mean Error	R^2	RMSD	Mean Error	R^2	RMSD	Mean Error	R^2
GMU	4.1	-0.9	0.824	4.4	-2.9	0.937	4.2	-1.3	0.849
OP	4.	-1.4	0.786	4.5	-6.0	0.916	4.1	-2.4	0.815

T	0								
XFL	29.4	45.6	0.833	31.0	49.9	0.901	29.7	46.6	0.848

Caption: Summary of results from optimization and test conditions. The GMU and OPT performed better in the submaximal complex force patterns than the XFL. There were no significant differences between the OPT or the GMU.

A THEORETICAL AND COMPUTATIONAL FRAMEWORK FOR MODELING AND SIMULATING MUSCULOSKELETAL STIFFNESS DURING LOCOMOTION

Massimo Sartori [1,*] Marco Maculan [2] Claudio Pizzolato [3] Monica Reggiani [2] Dario Farina [1]

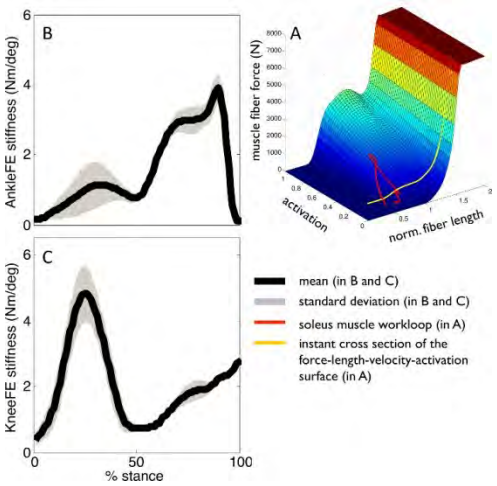
[1]Department of Neurorehabilitation Engineering, University Medical Center Goettingen, Goettingen, Germany, [2]University of Padova, Vicenza, Italy, [3]Griffith University, Gold Coast, Australia

Introduction and Objectives: Human locomotion emerges from the coordinated recruitment of musculotendon units (MTUs), which actuate multiple joints and degrees of freedom (DOFs). This underlies the continuous modulation of MTU viscoelasticity for best adapting to the mechanical demand of the performed motor task and external environment. Understanding the mechanisms regulating musculoskeletal viscoelasticity is crucial for understanding normal/abnormal locomotion. Musculoskeletal viscoelasticity can be investigated at the stiffness and damping levels. This contribution focusses on the stiffness level. Quasi-stiffness (QS) is used to derive joint elastic characteristics that are representative of entire phases of the gait cycle. However, QS may provide estimates that are biased by force responses that are not strictly associated to changes in joint kinematics. Alternatively, musculoskeletal modeling allows characterizing the elastic force response in individual MTUs/DOFs. Modelling has been used to reconstruct single-DOF stiffness from individual MTUs' stiffness in isometric conditions [1, 2]. These studies modelled the muscle elastic properties using the short-range stiffness (SRS) formulation and solved for the musculoskeletal redundancy using static optimization techniques. These factors prevent current modeling methods to be translated to the study of dynamic movement. In this context, muscle fibers would operate outside the SRS range and would underlie neuromuscular control strategies (i.e. co-contraction, reflex-based excitation) that could not be explained by a single optimization criterion chosen *a priori*. This work proposes, for the first time, a theoretical and computational framework for investigating musculoskeletal stiffness during locomotion and describes how this differs from QS and SRS.

Methods: Movement data were collected from five healthy subjects (age: 26.6±1.3years, weight: 73.9±11.8Kg, height: 1.77±0.1m) who performed 7.8±0.8 ground level walking trials (speed: 1.9±0.25m/s). Collected data included EMG signals from 13 leg muscles, whole-body stereophotogrammetry data, and foot-ground reaction forces. Data were used to create and calibrate a subject-specific musculoskeletal leg model that matched each individual's anthropometry and EMG-to-force generating properties. The subject-specific EMG-driven model was validated on its ability of blindly predict experimental joint moments measured from a set of validation trials that were not used for the model calibration [3, 4]. The subject-specific model was employed to create a multi-dimensional cubic B-spline function per MTU. This described how muscle fiber force changed with respect to its states including: activation, normalized fiber length and velocity (Fig. 1A). Muscle fiber stiffness was then computed as the directional derivative from the force-length-velocity-activation surface (Fig. 1A) along the normalized fiber length directional axis, for given instantaneous states and corresponding force level. Muscle fibers stiffness was then combined with the interacting series-elastic tendon stiffness. The resulting stiffness from all MTUs in the model was then projected onto the knee flexion-extension (KneeFE) and ankle planar-dorsi flexion (AnkleFE) DOFs.

Results: Fig. 1A shows how the soleus fibers force slope at 57.6% stance can substantially differ when estimated directly from the force-length profile (i.e. see the workloop profile typically used for deriving QS) or from the instantaneous force-length-velocity-activation surface cross section (i.e. see the surface cross section used in our methods). Figs 1B-C show the instantaneous KneeFE and AnkleFE stiffness reconstructed from the individual MTUs' stiffness. Human locomotion is characterized by stiffness bursts of impulsive nature. The knee produced a stiffness peak (4.8±0.8Nm/deg) at 25±1.3% stance, followed by a minimally overlapped ankle stiffness peak (3.8±0.4 Nm/deg) at 88±2.3% stance.

Figure:



Caption: (A) Instantaneous force-length-activation surface of the soleus muscle for a given value of contraction velocity, with projected force-length work loop for one single walkig trial. (B) Ankle plantar-dorsi flexion stiffness and (C) knee flexion-extension stiffness averaged across all trials performed by one subject.

Conclusion: We proposed a subject-specific model for predicting musculoskeletal stiffness that explains both experimental EMGs and joint moments during locomotion. This provides a framework for describing how stiffness modulates as a function of muscle activation, fiber contraction, and interacting tendon dynamics as well as how this differs from QS and SRS. This could be used, in the future, to understand abnormal stiffness strategies in patients with neurological and orthopedic conditions and deliver personalized rehabilitation treatments.

APPROXIMATION TO THE MATHEMATICAL MODELING OF ARTICULAR CONTACT BY APPLYING THE DIFFERENTIAL GEOMETRY /KINEMATIC (DG/K) METHOD.

David L. Maldonado Guzman [1,*] Carlos Julio Cortes Rodriguez [1]

[1]Mechanical Engineering and Mechatronics, Universidad Nacional de Colombia/Biomechanics Research Group, Bogota, Colombia

Introduction and Objectives: The understanding of the physiological incongruence of the joint surface, which allows an optimal distribution of strain, it is still be a challenge for engineers, designers and health professionals whose field of work is the development of individualized joint implants. The complexity lies in the development of models capable of considering the tribological behaviour. This work presents a theoretical mathematical model of contact, which can make an approach of the kinematic behavior of a human joint. As case study is analyzed the radio cubital- proximal joint of elbow, which is a geometry entity known as trochoid. The modeling is based on the application of the method for both curves and surfaces. The method is based on the application of methods of differential geometry for the apprehension and geometrical study of identities, and basically the study of the geometry of movement or kinematics. For the study case is applied the fundamental theorem of the curves, in which it is evaluated the rigid movement joint as a control parameter of the point of instant contact, as an initial phase and are then applied the concepts of the first and second fundamental forms for the characterization of surfaces.

Methods: *Fundamental theorem or uniqueness of the curves: analysis of the instant contact.*

There is a single curve oriented to which the curvature K(s) and the torsion τ(s) a point corresponding to an arc of court with length(s). If a curve with the curvature and torsion oriented exists, then the Frenet formulas are satisfied[Toponogov, 2006]; thus the curve is parameterized in mobile reference system that moves along the same, constituting the control point of contact between the surfaces. By applying the theorem of uniqueness to the curve generated by the plane of contact between the trochlea and the olecranon, which embraces in a 50% to the trochlea and has an inclination of approximately 45 degrees,

The trochoid type is parameterized, for case between angles of 30 to 145 degrees:

$$x = bt - c \sin t \quad (1)$$

$$y = b - c \cos t \quad (2)$$

Where t is the angle variable that describes the circle of radius b, and the distance from the center to the point of contact is c.

Results: Similarly, a surface is unequivocally determined by certain values local invariants defined as first second fundamental forms. The procedure below is based on the geometric modeling of surfaces apply the following procedure gives the characterization of the contact:

1) Definition of the first fundamental form for the concave cylindrical surface (P).

In particular, the *first fundamental form of a surface* is defined as

$I(\lambda) = I(\lambda,\lambda) = E(\lambda^1)^2 + 2F\lambda^1\lambda^2 + G(\lambda^2)^2$ (3)

2) Definition of the metric from the first fundamental form.

$L(\gamma) = \int \sqrt{(E\,du^2 + F\,du\,dv + G\,dv^2)}$ (4)

3) Definition of the second fundamental form for the concave cylindrical surface (P)

In particular, the *second fundamental form of a surface* is defined as

$II(\lambda,\mu) = L\lambda^1\mu^1 + M(\lambda^1\mu^2 + \lambda^2\mu^1) + N\lambda^2\mu^2$ (5)

4) Definition of the fundamental factors of the second fundamental form (L, M , N) Equ (5).

Sometimes, for calculating L, M, and N it is more convenient to use the following Formulas:

$L = -\langle r_u, n_u\rangle, M = -\langle r_u, n_v\rangle, N = -\langle r_v, n_v\rangle,$

which are obtained from the previous formulas by differentiation of the identities

$\langle r_u, n\rangle = 0$, $\langle r_v, n\rangle = 0$.

For the cylindrical surface:

$X = r\cos v$; $Y = r\sin v$; $Z = u$

Thus , the second fundamental form :

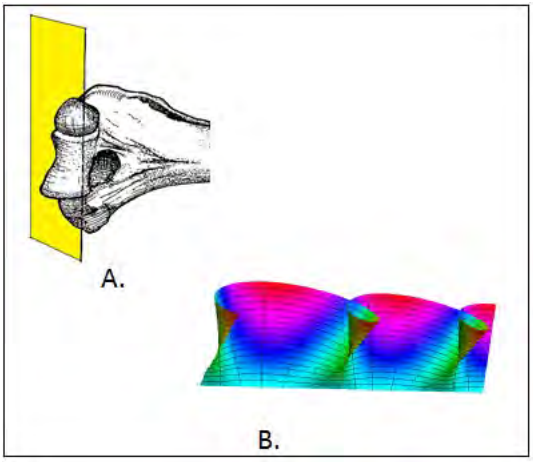
$II(\lambda) = (1/r)(\lambda^1)^2$ (6)

5) Identification of the natural surface

$P = p(I(\lambda), II(\lambda))$ (7)

6) Control of the point of instant contact coordinate transformation. Homogeneous coordinates. Apply to theorem of Rodriguez.

Figure:



Caption: A. radio cubital- proximal joint; B. Trochoid, t =35° set the parameters defined by flat Frenet.

Conclusion: As an initial step in the process of mathematical modeling of the articular contact based on differential geometry shown to be an approximate method for the characterization and versatile, suitable for the analysis and evaluation of contact and motion geometry. In principle the DG/K method has been focused on the synthesis of machining processes, this could also be considered as a tool of synthesis and manufacturing of individualized implants.

In addition, it may be considered as instrument to support the methodology of analysis by the finite element method, likewise as implicit procedure in the development and characterization of custom implants. [Yongtae, 2010].

CERVICAL SPINE LOADING DURING RUGBY MACHINE SCRUMMAGING

Grant Trewartha [1,*] Ezio Preatoni [1] Timothy Holsgrove [2] Dario Cazzola [1]

[1]Department for Health, [2]Department of Mechanical Engineering, University of Bath, BATH, United Kingdom

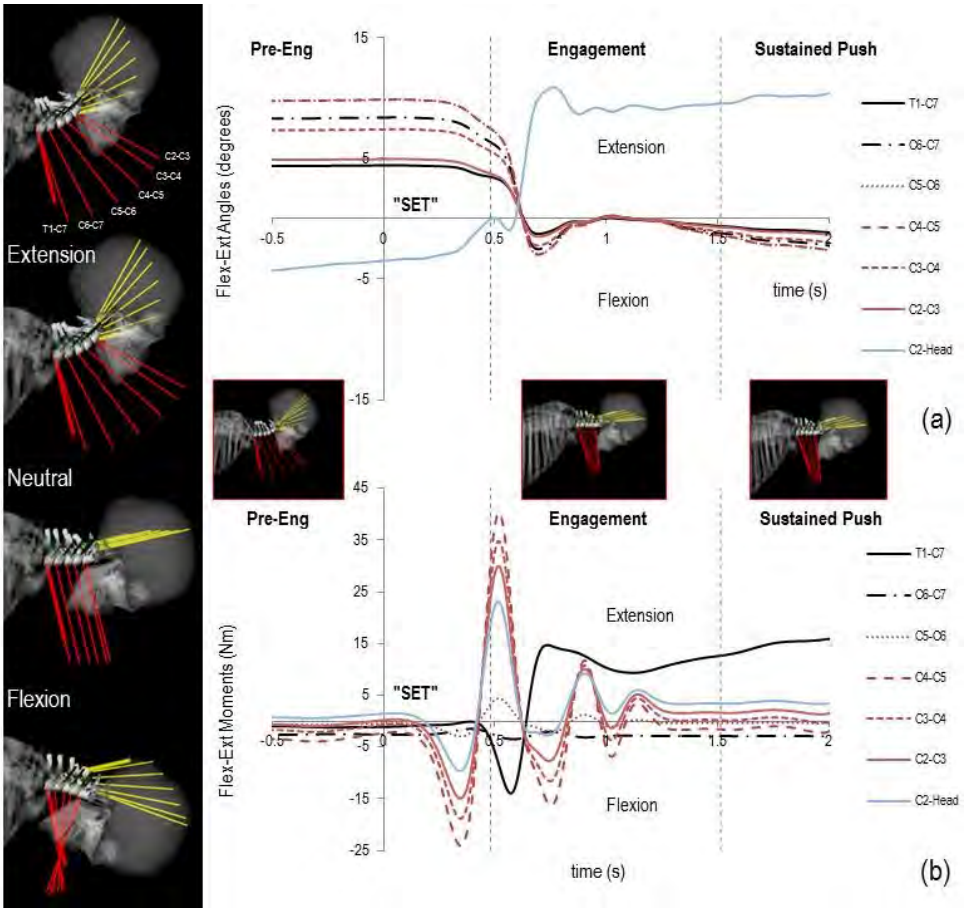
Introduction and Objectives: Recent changes to the scrummaging laws in Rugby Union have been made to reduce the scrum engagement forces experienced by front row players [1], with the motivation of improving player welfare. However, information on the internal anatomical loading experienced by rugby players under different scrum conditions and a representation of the injury mechanisms which may act during this activity is still lacking. The purpose of the present study was to use a computational musculoskeletal modelling approach to characterise the cervical spine loading during machine-based rugby scrummaging, as an initial step in understanding more about injury mechanisms.

Methods: The 'Rugby Model', a customised OpenSim musculoskeletal model (OpenSim 3.2, SimTK) was developed, principally by merging a full body model ('OpenSim 2354') with an existing head and neck model [2]. Adjustments included providing the head and neck segments with inertia parameters from DEXA imaging to allow dynamic analyses and adding a scapulo-clavicular joint with constrained motion to permit a better representation of external loading (via the shoulders onto the spine) during scrummaging. Verification of the model for kinematic and dynamic variables was completed via referencing of residual values to literature. Nine front row rugby players (mass=102.3±14.0 kg, height=1.81±0.07 m) performed individual scrummaging trials against an instrumented scrum machine collecting external 'shoulder' forces at 500 Hz and with feet positioned on individual force plates (Kistler 9287BA, 2500 Hz). During scrum trials, a total of 52 reflective markers were positioned on the player and tracked by a motion analysis system (Qualisys Oqus, 250 Hz) and all data streams were time-synchronised.The model was scaled to the anthropometric characteristics of the participant, the Inverse Kinematics routine reconstructed the joint angles of the linked 13-segment kinematic model during the movement, the ground reaction forces and scrum machine forces were fed into OpenSim and the inverse dynamics routine was processed with kinetic and kinematic data filtered through a 3rd-order low-pass bidirectional Butterworth filter at 12 Hz.

Results: The engagement phase is the most dynamic phase of the scrum due to external load application. The OpenSim model permitted the recovery of the joint kinematics/kinetics at each individual cervical motion segment as well as between C7-T1 and C2-Head segments.The cervical spine was in an extended position from T1-C7 to C2-C3 joints prior to contact but then underwent a flexion motion during impact, whereas the C2-Head joint was initially slightly flexed but showed an extension motion throughout the engagement phase (Figure 1a). During the engagement phase, a pattern of separation between upper and lower cervical vertebrae was observed: upper vertebrae (C5 to C2) showed a high extension moment (e.g. 27.2±2.4 Nm for C4-C5 joint), whilst T1-C7 (-6.9±2.8 Nm) and C6-C7 joints showed a flexion moment (Figure 1b). These moments represent an internal load on the cervical spine that tends to straighten the neck and flatten the physiological spine curvature. Although no direct evidence of injury mechanisms can be drawn from such measures, these findings seem in line with the patterns of injury that previous authors have described in relation with scrum-related neck traumas [3]. The cervical vertebrae were all highly loaded, with magnitudes only 40% less than the

ones reported for whiplash (~40 Nm) or head compression injuries (~50 Nm). The values were considerably lower than those observed during head first impact (~100 Nm).

Figure:



Caption: Figure 1. Cervical spine flexion/extension joint angles (a) and joint moments (b) during a single scrummaging trial.

Conclusion: This study describes the internal loading of cervical spine structures during one-player machine rugby scrummaging. This was the first '*in-vivo*' study that aimed to associate the external load applied onto the player's shoulders with the internal mechanical conditions at the cervical and scapuloclavicular level. Peak magnitudes for cervical joint moments were in the region of those suggested to result in neck injuries in other contexts. During the scrummaging action there was a separation point in the loading pattern around C5 vertebra, the region known to be most at risk for catastrophic and degenerative injuries from rugby. Future work will improve the accuracy of the model representation and the ultimate goal is to perform sensitivity analyses to assess the influence of misdirected forces on cervical spine loading and to evaluate technique-based interventions for injury prevention in scrummaging.

EFFICACY OF ISOLATED ANKLE STRENGTHENING AND FUNCTIONAL BALANCE TRAINING FOR REDUCING RUNNING INJURY RISK FACTORS IN NOVICE RUNNERS: A RANDOMIZED CONTROLLED TRIAL

Jennifer Baltich [1,*] Carolyn Emery [1] Darren Stefanyshyn [1] Benno Nigg [1]

[1] Faculty of Kinesiology, University of Calgary, Calgary, Canada

Introduction and Objectives: Risk factors have been proposed for running injuries including (a) reduced muscular strength, (b) excessive joint movements and (c) excessive joint moments[1,2]. To date, many running injury prevention programs have focused on a "top down" approach to strengthen the hip musculature in the attempt to reduce movements and moments at the hip, knee, and/or ankle joints[3]. However, running mechanics did not change when hip muscle strength increased[4]. It could be speculated that emphasis should be placed on increasing the strength of the ankle joint for a "ground up" approach. Ankle strengthening techniques include isolated strengthening or movement-related strengthening such as functional balance training. There is little knowledge about the efficacy of ankle strengthening programs on gait and strength alteration or injury reduction. Therefore, the primary objectives of this study were to compare changes in ankle isokinetic strength and lower extremity running mechanics for novice runners participating in an isolated ankle strength program and a functional balance training program to an activity-matched control group. An exploratory analysis was completed to compare injury rates.

Methods: This is a randomized controlled trial. Novice runners (<2 years experience, 18-60 years) were randomized to one of three groups: an isolated ankle strengthening group (strength, n=29), a functional balance training group (balance, n=25) or an activity-matched control group (control, n=21)[4]. The isolated strengthening consisted of Thera-Band exercises at the ankle joint while the functional balance training incorporated lunges, squats, and hops using a BOSU ball. The control group completed static and dynamic stretching. All groups trained 25 minutes a day, 5 times a week for 8 weeks. Ankle strength was assessed as the peak isokinetic torque (Nm) measured using a Biodex System 3 dynamometer. Over ground running kinematics and kinetics were assessed using 3D motion analysis and a force platform. The difference in the dependent variables pre- and post-training were compared. Injuries were tracked for 6 months and defined as any physical complaint causing a restriction in running.

Results: Fifty-three participants (21 balance, 19 strength, 13 control) completed both the baseline and 8-week follow up assessment. The balance group had the fewest drop outs with 4 participants (16%) compared to the strength group with 10 drop outs (34%) and the control group with 8 drop outs (38%). Descriptive statistics are summarized in Table 1. Peak isokinetic ankle plantar flexion torque increased following training in the strength group. Both the strength group and the control group demonstrated increased ankle eversion and inversion torque. The balance group reduced the peak ankle eversion angle during over ground running. Both the balance group and the strength group reduced peak ankle inversion moments and knee adduction moments. The running injury incidence rate was 0.97 injuries/1000 hours of running exposure (95%CI: 0.48-1.74) for the balance group, 0.76 injuries/1000 hours of running exposure (95%CI: 0.28-1.66) for the strength group and 0.51 injuries/1000 hours of running exposure (95% CI: 0.14-1.3) for the control group.

Conclusion: Preliminary findings suggest that isolated ankle strength training leads to larger increases in strength at the ankle joint than functional balance training. While functional balance training was successful at reducing joint movement and moments at the ankle, both isolated ankle strengthening and functional balance training reduced joint moments at the knee. There was no significant difference in injury incidence rates between the groups. An additional 45 participants will be collected and analyzed by June 2015, bringing the final sample size to 120 runners. The results from this increased sample size will confirm whether isolated ankle strength training or functional balance training is more effective for increasing ankle strength and reducing joint movements and moments.

Table:

Outcome	Balance n=21	Strength n=19	Control n=13
Peak Plantar Flexion Torque [Nm]	2.8 [-3.7, 9.3]	17.6 [7.2, 28.4]*	8.3 [-0.78, 17.4]
Peak Eversion Torque [Nm]	0.2 [-1.2, 1.6]	2.7 [0.5, 4.9]*	2.3 [0.3, 4.3]*
Peak Inversion Torque [Nm]	0.7 [-0.17, 3.2]	6.1 [3.1, 9.2]*	5.0 [1.4, 8.6]*
Peak Ankle Eversion Angle [°]	-1.4 [-0.5, -2.3]*	0.4 [-0.7, 1.5]	0.2 [-1.0, 1.5]
Peak Ankle Inversion Moment [BWm]	-0.009 [-0.002, -0.016]*	-0.008 [-0.001, -0.016]*	-0.005 [-0.015, 0.004]
Peak Knee Adduction Moment [BWm]	-0.012 [-0.004, -0.021]*	-0.008 [-0.002, -0.014]*	-0.002 [-0.012, 0.007]

AS-0311

THE KINETIC IMPULSE ASYMMETRY INDEX IN THE VERTICAL JUMP PREDICTS LOWER BODY INJURY IN ELITE ATHLETES

M J Jordan [1,*] J Barnert [2] P Aagaard [3] W Herzog [1]

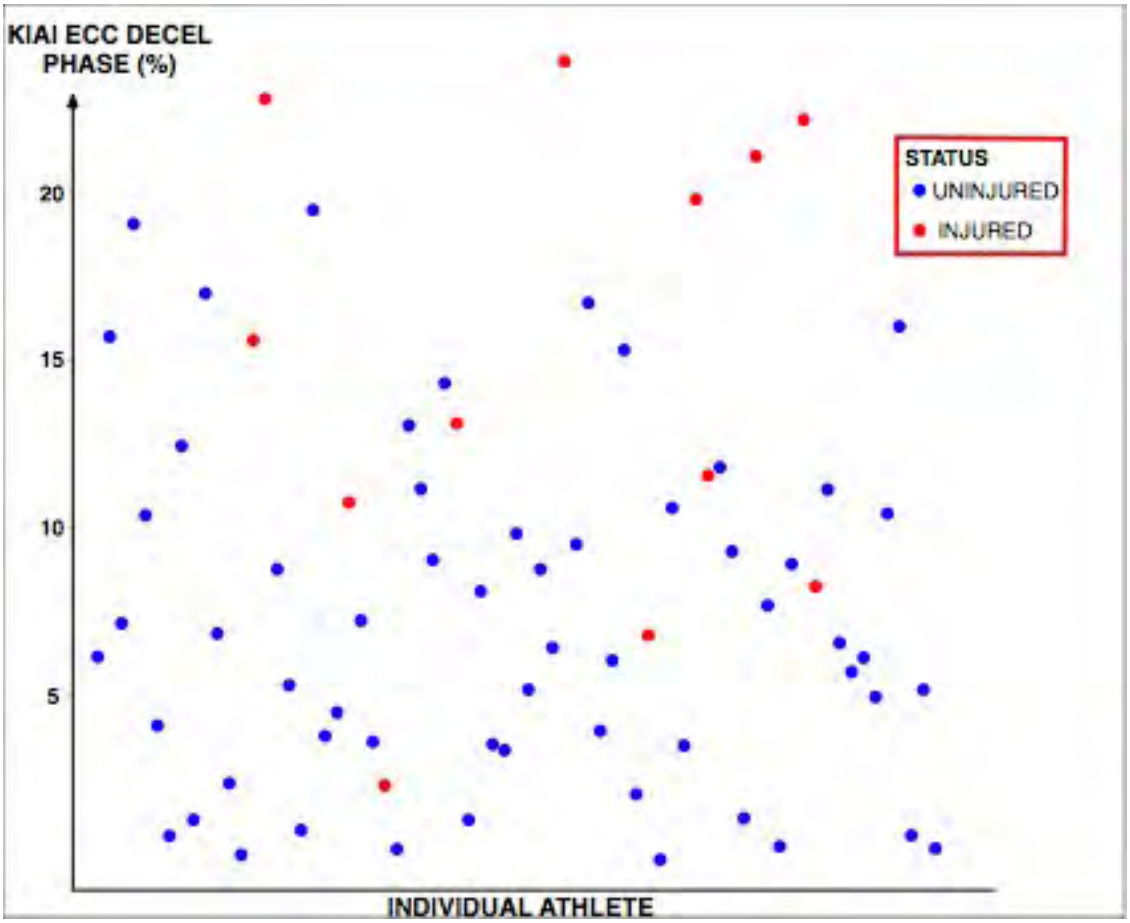
[1]University of Calgary, [2]Canadian Sports Institute - Calgary, Calgary, Canada, [3]University of Southern Denmark, Odense, Denmark

Introduction and Objectives: Lower body injury, including anterior cruciate ligament (ACL) rupture, occurs frequently in sport [1]. To prevent injuries, functional assessments may be useful to identify at-risk athletes [2]. The kinetic impulse asymmetry index (KIAI) obtained during countermovement (CMJ) and squat (SJ) jumping was proposed to differentiate between non-injured and ACL-reconstructed athletes [3]. However, to date, no prospective study has evaluated this approach for identifying athletes at-risk for lower body injury. Our purpose was to evaluate the use of the KIAI to predict lower body injury in competitive athletes.

Methods: Seventy-one athletes (Females: n=51, Age=20.6±2.3 years, Mass=67.8±11.5 kg; Males: n=20, Age=20.1±1.7 years, Mass=78.7±16.5 kg) from five sports (alpine skiing, luge, soccer, rugby, wrestling) were assessed at the start of the off-season preparatory period. Dual force plate analysis of the vertical ground reaction force from each limb was used to evaluate lower limb asymmetry during five bilateral CMJs and five SJs by analysis of vertical kinetic impulse in terms of phase-specific KIAI [3]. Subjects were retested weekly throughout the observation period. The closest data point prior to injury was used for the injured athletes (INJ) while baseline test values were used in the analysis of non-injured athletes (N-INJ). Injuries were classified as: muscle, bone, joint. One-way ANOVA was used to compare KIAIs between INJ and N-INJ and the absolute value of the KIAI was used in a logistic regression model for injury (α=0.05).

Results: In the follow-up period, 12 athletes suffered lower body injury (Females: n=8; Males: n=4; Muscle: n=4; Joint: n=8). Injured athletes displayed increased asymmetry in the eccentric deceleration phase of the CMJ (N-INJ = -1.1%±8.9; INJ = -11.1%±12.5, P<0.01). KIAI tended (P=0.06) to differ in the concentric phase of the CMJ (N-INJ = -1.3%±4.6; INJ = -6.2%±8.2) while no group difference was found in the late phase of the SJ (N-INJ = -3.3%±8.1; INJ = -6.3%±13.7, P=0.48). Logistic regression analysis revealed the CMJ concentric phase (Odds Ratio = 1.4, 95% CI = 1.1-1.7), and eccentric deceleration phase (Odds Ratio = 1.2, 95% CI = 1.1-1.4) to be predictors of injury (P<0.01). Retrospective injury prediction was highest using the eccentric deceleration phase of the CMJ (87.3%) followed by the concentric phase of the CMJ (84.5%), and the late phase of the SJ (84.5%).

Figure:



Conclusion: The present results suggest that the KIAI is an effective tool for identifying athletes at-risk for lower body joint and muscle injury. KIAI obtained for the eccentric deceleration phase of the CMJ was the strongest predictor of injury. Since the ability to decelerate the body centre of mass during many athletic movements, such as landing from jumps, is important for ACL injury prevention [2], the approach used in this study may be relevant for athletes in a variety of sports (e.g. alpine ski racing, field sports). Additionally, the KIAI can be obtained using a straightforward biomechanical approach. Combined with its high predictability for injury, the KIAI seems ideal for use in high performance sport environments. Future research will be aimed at increasing the sample size and evaluate the relationship between the KIAI and specific injury types, such as ACL rupture.

AS-0312

UTILITY OF A SHORT DURATION HIGH-INTENSITY EXERCISE PROTOCOL TO PROSPECTIVELY ASSESS BIOMECHANICAL AND MUSCULAR MARKERS OF ACL INJURY IN DYNAMIC SPORTS

Fransiska Bossuyt [1,*] Felipe Garcia-Pinillos [2] Raja Azidin RMF [1] Jos Vanrenterghem [1] Mark A Robinson [1]

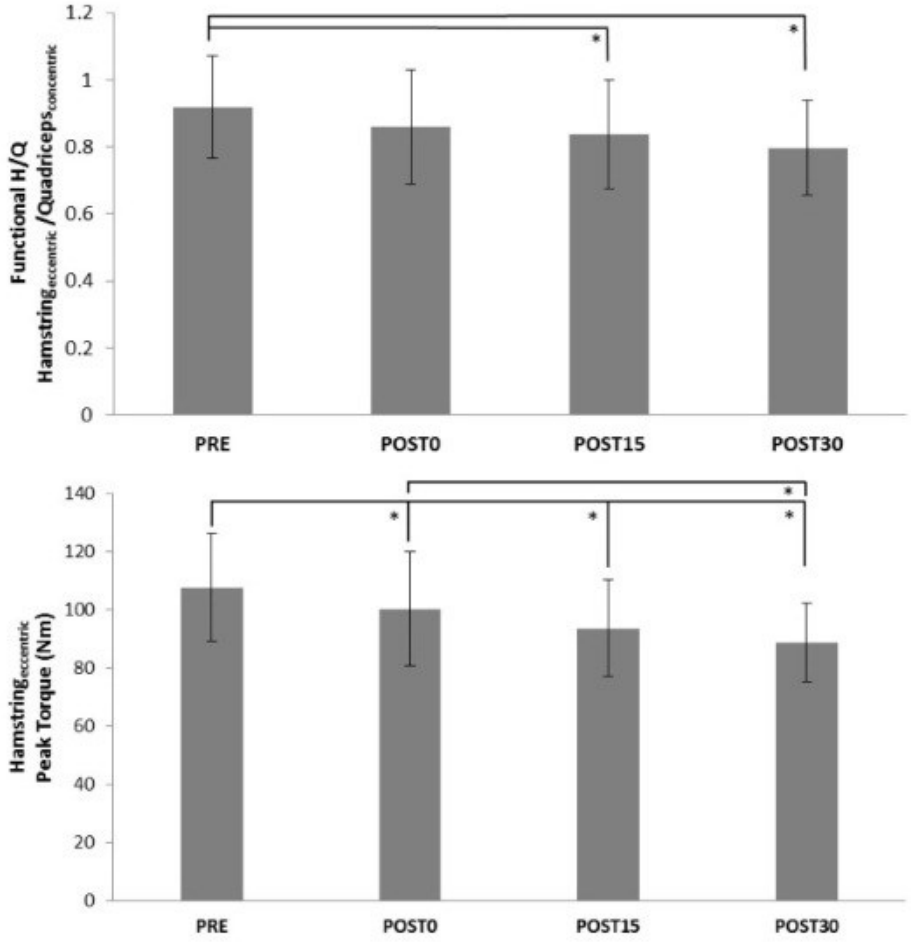
[1]School of Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom, [2]Corporal expression, University of Jaen, Jaen, Spain

Introduction and Objectives: Fatigue is suggested to play a crucial role in the mechanism of anterior cruciate ligament (ACL) injury [1]. This highlights the need for the inclusion of exercise-induced fatigue in prospective studies. Prospective studies give the highest level of evidence, but due to requiring large cohorts it is difficult to include a time consuming fatigue protocol as part of prospective screening. Therefore, the aim of this study was to investigate the effect a 5-min high intensity exercise protocol (SAFT^{5}) has on biomechanical and muscular markers of ACL injury risk.

Methods: Fifteen recreationally active females completed SAFT^{5} which was modified from a long duration match-play simulation (SAFT^{90})[2]. Participants' non-dominant leg was analysed before SAFT^{5} (PRE), immediately after (POST0), 15 min after (POST15) and 30 min after (POST30). Kinematics and kinetics were measured at these time points during the landing phase of a single leg hop (SLH) (70% body height) and a 30 cm drop vertical jump (DVJ). Maximum contractions of concentric quadriceps (Q_{con}) and concentric and eccentric hamstrings (H_{con} and H_{ecc}) were measured with an isokinetic dynamometer. A one-way repeated measures ANOVA was used to assess the dependent variables (α=0.05).

Results: In response to SAFT^{5} eccentric hamstring peak torque was significantly reduced at POST0 (7%), POST15 (13%) and POST30 (18%) compared to PRE. Functional H/Q ratio (H_{ecc}/Q_{con}) was significantly reduced at POST15 (9%) and POST30 (13%) ($p<.05$) (Figure 1). Additionally, at initial contact of a SLH, participants landed with a significantly more extended knee (2.2 ± 2.6°) at POST30 ($p<.05$) and a significantly increased knee internal rotation angle (4.1 ± 4.5°) at POST0 and POST15 (4.5 ± 3.8°, $p<.05$). There were no significant effects on conventional H/Q ratio (H_{con}/Q_{con}) and landing patterns during DVJ ($p > .05$). SAFT^{5} induced detrimental effects on biomechanical and muscular markers of ACL injury risk in recreationally active females. The selective occurrence of fatigue in H_{ecc} is in agreement with previous findings of SAFT^{90} in males and has been related to increased injury risk [2]. Despite the significant reduction in H_{ecc} between pre and every post-test, the functional H/Q ratio was only significantly reduced POST15 and POST30. This could be explained by the delay in peripheral fatigue (i.e. fatigue within the muscle itself) as a recent study concluded that central fatigue (i.e. alteration in the nervous system) manifests prior to reductions in knee flexor maximal torque in response to SAFT^{90} [3]. The altered landing strategies in a SLH in response to SAFT^{5} are thought to be associated with increased ACL injury risk [1]. Knee flexion angle was, however, only significantly reduced after 30 min passive rest. Nevertheless, this evidence supports the use of a functional exercise protocol such as SAFT^{5} to identify at risk individuals in prospective screening.

Figure:



Conclusion: In conclusion, SAFT[5] altered biomechanical and muscular landing strategies that have been associated with increased ACL injury risk and are similar to observations from match simulations. Our findings therefore support the utility of such exercise protocol in the context of prospective cohort studies where time constraints apply.

CHRONIC ANKLE INSTABILITY ALTERS THE RELATIONSHIP BETWEEN EMG AMPLITUDE AND EVERSION PEAK FORCE OF THE FIBULARIS MUSCLES

Jay Hertel [1,*] Luke Donovan [1] Lindsy Donnelly [1]

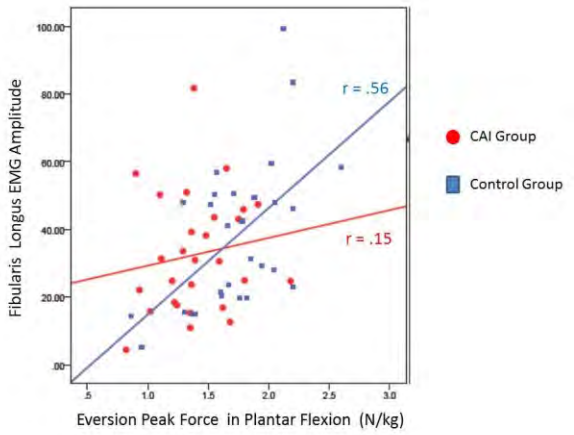
[1] Department of Kinesiology, University of Virginia, Charlottesville, United States

Introduction and Objectives: Chronic ankle instability (CAI) occurs in approximately 40 percent of patients incurring first time ankle sprains and is characterized by persistent symptoms lasting more than 12 months after sprain, repetitive episodes of the ankle giving way, and recurrent ankle sprains.[1] Altered sensorimotor function of the fibularis muscles demonstrated in CAI patients include diminished eversion strength[2], delayed EMG activation in response to inversion perturbation[3], and arthrogenic muscle inhibition[4]. To date, the relationships between the EMG activity of the fibularis muscles and eversion force production have not been examined. Our purpose was to investigate the correlation between eversion peak force and surface EMG amplitude of the fibularis longus and brevis muscles during isometric contractions taken in neutral and plantar flexed (PF) positions in young adults with and without CAI.

Methods: Twenty-eight young adults with CAI (19 females, 9 males, age=21±3.1 years) and 28 healthy young adults without history of ankle sprain (19 females, 9 males, age=22±4.1 years) participated. Peak force was assessed with a handheld dynamometer during 5-second maximum voluntary isometric eversion contractions in two testing positions (neutral, 30° PF) while sEMG amplitudes of the fibularis longus and brevis were simultaneously recorded. Peak force was normalized to body mass. EMG signals were filtered and smoothed using a 50-sample moving window root mean square. EMG amplitude was defined as the area under the middle 3 seconds of the RMS curve. The amplitude values for each corresponding muscle were then normalized to a time-matched epoch collected during a quiet resting period. For each dependent variable, means and 95% confidence intervals were calculated for each group in each condition. Pearson correlation coefficients were calculated between the respective peak force and EMG amplitude measures within each group.

Results: The CAI group produced less eversion peak force than the control group in both the neutral and PF positions, however there were no group differences identified in any of the EMG amplitude measures (see Table). For the CAI group, there were no significant correlations between peak force and EMG amplitude for the fibularis longus (neutral: r = 0.23, P = 0.24; PF: r = 0.15, P = 0.44) or fibularis brevis (neutral: r = -0.02, P = 0.94; PF: r = -0.04, P = 0.82). In contrast, the control group had significant correlations between peak force and EMG amplitude for both the fibularis longus (neutral: r = 0.42, P = 0.03; PF: r = 0.56, P = 0.002) and fibularis brevis (neutral: r = 0.38, P = 0.05; PF: r = 0.40, P = 0.04).

Figure:



Caption: Scatter plot illustrating correlation between eversion peak force and fibularis longus EMG amplitude in the CAI and control groups.

Conclusion: The CAI group generated less isometric eversion peak force in both the neutral and PF positions relative to the control group, however there were no group differences in the EMG amplitudes of the fibularis longus or brevis muscles. The lack of EMG amplitude differences between groups could indicate that the CAI patients were able to generate adequate activity of the muscles in the leg but that activation was not translated into force acting on the ankle. An explanation for this could be lesions to the fibularis tendons or retinaculum. Unfortunately, we did not evaluate our participants for such lesions. The relationship between EMG amplitude and force production has been studied for decades[5], however this relationship has not been previously examined in CAI patients. We identified significant correlations of moderate magnitude between isometric eversion peak force and fibularis longus and brevis EMG amplitude in the healthy, but not the CAI, group. This discrepancy provides added evidence of the sensorimotor alterations associated with CAI. Further research is necessary to identify the physiological mechanisms driving the decoupling of fibularis muscle activation and eversion force output of CAI patients as well as interventions to help restore this relationship.

Table:

	Peak Eversion Force in Neutral (N/kg)	Fibularis Longus EMG Amplitude in Neutral	Fibularis Brevis EMG Amplitude in Neutral	Peak Eversion Force in Plantar Flexion (N/kg)	Fibularis Longus EMG Amplitude in Plantar Flexion	Fibularis Brevis EMG Amplitude in Plantar Flexion
CAI Group	**1.64* [1.46–1.81]**	27.1 [21.5-32.6]	38.3 [27.9-48.8]	**1.40* [1.27–1.54]**	32.7 [25.9-39.4]	38.4 [28.6-48.3]
Control Group	**2.10 [1.93–2.28]**	27.9 [22.5-33.3]	32.9 [27.0-38.8]	**1.73 [1.60–1.87]**	38.0 [29.5-46.5]	41.1 [33.0-42.3]

CHARACTERIZATION OF FUNCTIONAL CHANGES IN THE APONEUROSES OF THE RABBIT MEDIAL GASTROCNEMIUS DURING CONTRACTION IN-SITU

Christine Waters-Banker [1,*] Andrew Sawatsky [1] Azim Jinha [1] Timothy Leonard [1] Walter Herzog [1]

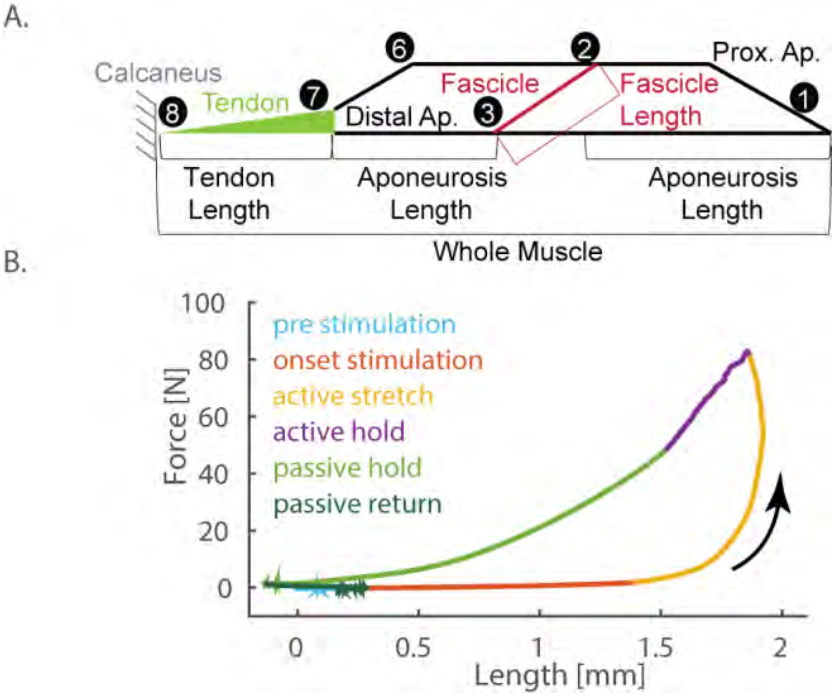
[1] Kinesiology, University of Calgary, Calgary, Canada

Introduction and Objectives: Previous attempts have been made to predict the stiffness of the aponeurosis in skeletal muscle by modeling the structure in-series with the tendon and fascicles. Predictions of mechanical properties of muscle elements (fascicles and aponeuroses) have been derived from force and length measurements *in vivo* using various techniques such as tendon buckle transducers, and ultrasound imaging. When aponeuroses and fascicles have been considered 'in-series', experimental and theoretical research showed a net gain of work produced by aponeuroses during full activation/deactivation cycles: a thermodynamically impossible result [1]. Therefore, the objective of this study was to record functional length changes of the aponeuroses in relation to tendon, fascicle, and whole muscle/tendon length changes during isometric and dynamic contractions *in situ*.

Methods: The right medial gastrocnemius muscles (MG) of six New Zealand White Rabbits were isolated and instrumented with 8 piezoelectric ultrasound sonomicrometry crystals while the animal was anesthetized (Figure 1a). Fascicles were isolated using a point-contact micro-stimulator and the two ends of the fascicle were marked with methylene blue dye for crystal placement. A cuff electrode was placed on the tibial nerve for electrical stimulation. A stereotaxic frame stabilized the limb at the hip, knee, and shank. The calcaneus was detached and fixed to a horizontally mounted muscle puller (MTS Inc.). The muscle was passively pulled to various predetermined lengths along the force-length relationship and then contracted either isometrically, concentrically, or eccentrically. Supramaximal stimulation was performed at 70Hz for all experiments. During contraction, total length changes for the tendon, both distal and proximal aponeuroses, fascicle, and whole muscle/tendon unit were recorded. Individual length changes of each structure were summed and compared to the absolute muscle/tendon length change during each contraction.

Results: During isometric contractions taking place at optimal length (L_0): the distal aponeurosis lengthened substantially (1.77mm ± 0.32mm (SD)) while the proximal aponeurosis lengthened slightly (0.15mm ± 0.35mm). Fascicles always shortened substantially (-3.58mm ± 1.55mm). For concentric contractions starting at L_0 and shortening onto the ascending limb: at the onset of stimulation the distal and proximal aponeuroses briefly lengthened and shortened respectively (distal: 1.4mm ± 0.06mm; proximal: -0.19 mm ± 0.23), and then shortened during the shortening phase (distal: -0.23mm ± 0.39mm; proximal: -0.37mm ± 0.36mm), while fascicles shortened throughout (-3.82mm ± 0.98mm). Eccentric contractions, traveling on the ascending limb to L_0, resulted in lengthening of the aponeuroses at the onset of stimulation (distal: 1.19mm ± 0.42mm; proximal: 0.20mm ± 0.17mm) and throughout the stretch (distal: 0.38mm ± 0.14mm; proximal: 0.21mm ± 0.16mm), while the fascicles shortened at onset (-2.06mm ± 0.76mm) and lengthened throughout the stretch (1.31mm ± 0.10mm). A counter-clockwise positive work loop (45.6 mJoules) was generated when changes in distal aponeurosis length were plotted against force production for a complete eccentric contraction from 0N force to 0N force (loading area: 47.76 Nmm, unloading area 2.12 Nmm) (Figure 1b).

Figure:



Caption: Figure 1: (A) Schematic representation of the MG muscle (side) with sonomicrometry crystal placement. (4 and 5 not pictured). (B) Counter-clockwise work loop of distal aponeurosis length vs. force production showing a creation of 45.6 mJoules energy.

Conclusion: At a first glance, changes in aponeuroses length are consistent with an in-series arrangement of aponeuroses with tendon and fascicles. However, when changes in aponeurosis length were plotted against MG forces (measured at the end of the distal tendon) during an eccentric contraction, a counter-clockwise work loop was generated indicating a net gain in mechanical work. At the onset of activation a large elongation of the aponeurosis takes place with little force, and upon stretch aponeurosis length stays virtually constant despite a great increase in force. Viscoelastic structures, such as aponeuroses, display negative hystereses with a net loss of mechanical energy. The creation of energy that results from assuming force measured at the tendon is in-series with the aponeurosis violates the Second Law of Thermodynamics, rendering the result impossible. Therefore, the force measured at the tendon is not the same force experienced across the aponeurosis, and as such it would be incorrect to model the aponeurosis as an in-series component with the tendon. Any such assumption could lead to vastly incorrect interpretations of the role of aponeuroses in the storage and release of energy in stretch-shortening cycles.

REGIONAL VARIATION IN FASCICLE STRAIN IS JOINT DEPENDENT IN A BI-ARTICULAR MUSCLE

Emma Hodson-Tole [1,*] James Wakeling [2] Taylor Dick [2]

[1]Cognitive Motor Function Research Group, Manchester Metropolitan University, Manchester, United Kingdom, [2]Neuromuscular Mechanics Lab, Simon Fraser University, Burnaby, Canada

Introduction and Objectives: It is well documented that fascicle length changes can be uncoupled from those of the whole muscle tendon unit (MTU), within a gearing process which enables muscle fibres to operate at strain rates which are favourable for force production or mechanical power output. The strain and strain rates fibres operate at have however been reported to show regional variation within a muscle, with such variation suggested to be the result of regional differences in fascicle geometric properties, arrangement of internal connective tissue and/or neural activation patterns. In a bi-articular muscle, whether the relationship between MTU and fascicle length change can be differentially influenced by the joint moved has not been fully investigated. In addition, the potential for variation in any such relationship in different parts of the same muscle has also received limited attention. The human medial gastrocnemius muscle (MG) is a bi-articular muscle, which can contribute to ankle joint plantar flexion and knee joint flexion. Fascicles in MG are pennate, with a tendency for those in the proximal region to be shorter and more pennate than those in the distal muscle region. We therefore investigated the relationship between MTU and muscle fascicle length changes in proximal and distal regions of MG during passive rotation of the ankle or knee joint.

Methods: B-mode ultrasound images were simultaneously collected from proximal and distal regions of the right MG of eight participants (Mean±SD Height: 1.78±0.08m, Weight: 73.07±10.61kg), whilst they laid prone on an isokinetic dynamometer. Each probe was aligned to provide a clear view of complete fascicles and secured in place, for the duration of the experiment, using elasticated bandage. The dynamometer was set-up to enable passive rotation of either the ankle joint (-15^{o} dorsiflexion to +30^{o} plantar flexion) or the knee joint (180^{o} extension to 90^{o} flexion). During knee joint rotation the ankle joint was fixed at 90^{o} using a customised brace. The ranges of motion used ensured the MTU underwent similar changes in length in each condition (knee: 0.45-0.426m; ankle: 0.45-0.42m, calculated using OpenSim v3.2).
Muscle fascicle lengths were determined from analysis of collected images, with images from the proximal portion analysed using an automated computational approach and those from the distal region assessed manually. MTU lengths for each participant were calculated, using angle data recorded from the dynamometer in each trial and participant specific knee and ankle moment arms determined from recorded MR images.

Results: The results revealed a striking and significant effect of both joint and muscle region, with differences also occurring between the MTU lengthening and shortening phase of the rotation cycle. The highest fascicle strains in both proximal and distal muscle regions occurred during ankle joint rotation, despite similar MTU lengths occurring between conditions. MTU shortening, caused by ankle joint rotation, led to the largest fascicle strains recorded in the distal muscle region while little difference occurred between proximal and distal muscle regions during the MTU lengthening phase. During knee joint rotation fascicle strains were largest in the proximal muscle region during both MTU shortening and lengthening phases of the joint rotation.

Conclusion: Knee and ankle joint rotations lead to different responses in muscle fascicles of human MG, with different responses also occurring in proximal and distal muscle fascicles. Such differences may reflect different properties in elastic structures in proximal/distal regions of MG (e.g. length of free tendon) and the association of a given joint with other muscles (e.g. soleus will have been influenced by ankle joint rotation but not knee joint rotation). These regional and joint specific differences could have implications for sensory feedback during postural control and indicate that fascicle length changes in bi-articular muscles may be influenced by the kinematics of either the joints spanned.

THE BIOMECHANICAL DEMANDS OF PROLONGED SITTING: AN EVALUATIVE ERGONOMIC COMPARISON OF TRUCK SEATS

Michelle Rae [1,*]Colin McKinnon [2]Dan Viggiani [3]Jack Callaghan [3]Wayne Albert [1]

[1]Kinesiology, University of New Brunswick, Fredericton, [2]University of Waterloo, Waterloo, Canada, [3]Kinesiology, University of Waterloo, Waterloo, Canada

Introduction and Objectives: The trucking industry has one of the highest claims rates for work-related injury and illness in terms of prevalence and cost. The objective of the research project was to evaluate discomfort, sitting posture and muscle activity during a prolonged driving task between a new truck seat prototype (Force-3) and an industry standard seat. **Methods:** Twenty participants were recruited from a student population (10M,10F) to perform two 2-hour simulated driving sessions. Two truck seats were evaluated: Force-3's seat prototype and current market popular product "Low Ride Pro Back-Knoedler". An 8-channel surface electromyography system was used to monitor neuromuscular activity of the following bilateral muscles: Cervitis Capitis (C4), Erector Spinae (T9,L3) and the External Obliques. EMG was normalized through maximum voluntary contractions (MVCs), which included; an abdominal crunch/twist, back and neck extensions. The data was analyzed by determining the amplitude percentage change from the MVC trials. Lumbar spine flexion and lateral bend angles were measured by placing three tri-axial accelerometers on the skin over T1, L1 and S1. Angles computed from the accelerometers were expressed as a percentage of each participant's maximal range of motion. To monitor the participants perceived discomfort, ratings of perceived discomfort (RPD) and the automotive seating discomfort questionnaire (ASDQ) were given systematically (using a 100mm scale, e-VAS), every 15 minutes, throughout the simulated driving task. Following the second session, an exit survey was given to quantify which chair was preferred. **Between**. Two way repeated measure with a pairwise comparison **Within.** A one-way repeated measure with a pairwise comparison.

Results: RPD Questionnaire. *Between Chairs Comparisons (BCC)*: Participants significantly experienced more neck (Time (T)=75,90,105minutes(m)), right gluteus (T=45,105m) and right upper leg (T=45m) discomfort in the Knoedler chair compared to the prototype. *Within Comparison (WC),Knoedler:* Neck, right upper back, right/left gluteus and right/left low back significantly increased pre/post driving task (T=120m) as well as the right upper thigh(T=105m). *WC, Prototype:* Participants experienced discomfort in the low back post-driving task (T=120m). **ASDQ Questionnaire.** *BCC*: Discomfort related to seat cushion firmness was experienced in both seats, however discomfort scores were significantly greater in the Knoedler seat in comparison to the prototype (T=60m). *WC, Knoedler:* Five components of the chair were perceived as uncomfortable: Discomfort scores significantly increased in seat cushion firmness, lumbar stiffness and overall discomfort scores pre and post driving task. Discomfort scores were also found in firmness of the backrest (T=90m) and overall lumbar support (T=60,75,90m). *WC, Prototype:* Two components of the chair were perceived as uncomfortable: discomfort scores related to seat cushion firmness and lumbar stiffness significantly increase pre/post-driving task. **Exit Survey**. 90% of the participants preferred the prototype. **Accelerometers.** *BCC*: No significant differences were found between seats in flexion/extension, lateral bend lumbar angles (between L1 and S1) or thorax lateral bend (T1 and L1).

However significant increases were found in trunk (T1/L1) flexion angles when using the Knoedler seat from T=0 until T=75m. *WC, Knoedler:* Lumbar lateral bend angles (T=20, 30m) significantly increased overtime. *WC, Prototype:* A significant increase in thorax flexion/extension angles was found until T=45m. Participants also experienced more lateral bend between T=5-35m and then reverted back to baseline values throughout the rest of the driving protocol. **EMG.** *BCC*: No statistical difference was found in the comparison of neuromuscular activity between truck seats. *WC, Knoedler:* Right and left Cervitis Capitis values significantly increased overtime as well as the left Erector Spinae activity (T9) from T=5-115m and right External Obliques (T-5, 45m). *WC, Prototype:* A bilateral increase was found in the Cervitis Capitis, External Obliques and Erector Spinae(L3) activity.

Conclusion: Discomfort scores attributed to body parts and the chair was greater when using the Knoedler seat. According to the exit survey, participants preferred the Force-3 prototype. During the first 75minutes of driving, trunk kyphosis was greater when using the Knoedler seat. EMG scores did not significantly change in between chairs however neuromuscular activity did increase overtime in both seats. Biomechanical changes may be portrayed in the postural kinematic evaluation and passive lumbar flexion that has yet to be evaluated. The unsystematic patterns found in the results could be a product of compiling both genders. The Knoedler chair is designed for the 50th percentile male, which could affect female sitting patterns. Gender comparison will be analyzed and also be a pivotal focus for our future research.

AS-0317

HOW COMPLEX SHOULD LOWER-LIMB JOINT MODELS BE FOR SUBJECT-SPECIFIC SIMULATIONS OF MOVEMENT?

Lorenzo Pitto [1] Giordano Valente [1,*] Rita Stagni [2] Fulvia Taddei [1]

[1]Medical Technology Laboratory, Rizzoli Orthopaedic Institute, [2]DEI, University of Bologna, Bologna, Italy

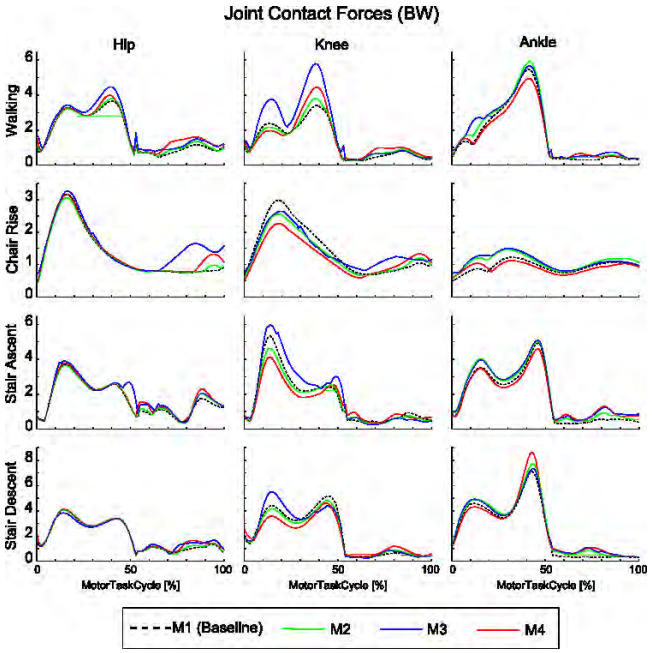
Introduction and Objectives: Subject-specific musculoskeletal modelling can be applied to study musculoskeletal disorders, providing a valuable approach to muscle and joint loading analysis during movement. The choice of the lower-limb joint models can significantly affect force predictions [1]. However, it is not clear how different joint models affect musculoskeletal forces calculated during different motor tasks using models based on clinical imaging. Particularly, the behavior of the knee and ankle joint can be markedly variable when simulating different motor tasks, which introduce different joint ranges of motion. In addition, the identification of image-based joints is unavoidably affected by uncertainty due to the imaging quality available and operator variability. This can lead to error propagation, potentially decreasing the benefits of increased model complexity. The aim of this study is twofold: first, to evaluate the effect of different knee and ankle joint models on muscle and joint contact forces predicted during four common motor tasks, by using musculoskeletal models created from lower-body MRI; second, to analyze the sensitivity of muscle and joint contact forces to the uncertainty in the identification of subject-specific kinematics constraints.

Methods: Experimental data were collected on a healthy subject, including lower-body MRI and gait data (marker trajectories, ground reaction forces and EMG recordings) during walking, chair rise, stair ascent and descent. A baseline musculoskeletal model (M1) was created previously [2], which included a 7-segment articulated linkage with spherical joints at the hips, hinge joints at both knees and ankles, and 84 musculotendon actuators. More complex knee and ankle models were built upon the baseline model as follows: planar hinge and universal joint [3] (M2), modified spherical and universal joint [4] (M3), and anatomical 4-bar-linkage knee and ankle [5,6] (M4). To test the sensitivity to parameter identification, five operators virtually palpated the anatomical landmarks necessary to create M4 joints. The joint parameters were statistically sampled according to inter-operator palpation variability, and a set of perturbed models was then created. Simulations of movement solving a typical inverse dynamics and static optimization problem were performed using OpenSim [7]. To assess variability in model outcomes, joint contact forces from the three modified models were compared against the baseline model (absolute differences, Pearson correlation coefficients). To qualitatively assess validity of the models, predicted muscle activations predicted were compared against measured EMG. To analyze the sensitivity to the uncertainties in identifying 4-bar linkage mechanisms, standard deviations of joint contact forces predicted through the perturbed M4 models were calculated for each simulated motor task.

Results: Overall, differences in joint contact forces between the modified models and the baseline were dependent on the motor task analyzed, although they were not substantial (Figure). M2 and M4 showed mild differences and a tendency to underestimate knee loads. M3 showed the most marked differences and a tendency to overestimate loads.
Predicted muscle activations were generally consistent with EMG recordings. M3 presented discrepancies in the activations of gastrocnemius and biceps femoris in stair descent and walking.

In walking, chair rise and stair ascent, the uncertainties in the identification of M4 did not have a substantial effect on joint contact forces, showing mean standard deviations over the motor task cycles below 0.26 BW. Conversely, in stair descent, there was a marked effect on knee and ankle forces, showing a mean standard deviation of 0.4 BW and a maximum of 2.66 BW at the ankle.

Figure:



Caption: Joint contact forces (in body-weight) during the four motor tasks predicted by using the baseline model (M1) and the three modified models (M2, M3, M4) including different knee and ankle joint models

Conclusion: The models predicted different joint loads, and behaved differently in different motor tasks. In the absence of direct validation methods of the predicted forces, the implementation of complex subject-specific joints should be justified only when the predictions are robust to the uncertainties in parameter identification. Therefore, before implementing image-based kinematic constraints, it is advisable to analyze the sensitivity of predictions over the joint range of motion and, if this choice appears weak (as in the stair descent task), opting for less complex, but more robust and reproducible joint models.

FASTER VS SLOWER RUNNING REDUCES TOTAL LOADS SUMMED ACROSS ALL STEPS USED TO RUN A STANDARD DISTANCE

Paul Devita [1,*] Kayla Murphy [1] Patrick Rider [1]

[1]Kinesiology, East Carolina University, Greenville, United States

Introduction and Objectives: Running is popular because it has many health benefits protecting against disability and early mortality (1,2). Running is also associated with a high rate of overuse injuries, reportedly between 19 to 79% per annum (3). Injuries occur throughout much of the musculoskeletal system but have particularly high rates in the ankle and knee regions and include achilles tendinitis, anterior knee pain, and patellar tendinitis (4). Running patterns can be modified to reduce lower extremity loads which are presumed to cause running injuries. Altering foot-strike (rear vs fore-foot strike) changes achilles tendon and ankle and knee joint loads (5,6). Shorter step length lowers patellofemoral joint forces (7-8) and running speed itself is directly correlated with the magnitude of ground forces and joint loads (9). These analyses were based entirly on individual foot steps. Alternatively, recent data supports the idea that longer steps and faster speeds reduce total lower extremity loads per unit distance (e.g. 1 km) because these gaits have fewer steps and ground contact phases per unit distance. Miller et al (10) showed that total knee joint loads summed over all steps were reduced per unit distance in running compared to walking despite having much larger per-step loads. It follows that the reduced number of steps per unit distance at faster vs slower running may also offset the larger per step loads associated with faster running. We now hypothesize that running at faster vs slower speeds reduces total lower extremity loads when summed across all steps taken to run a standard distance. The purpose of the study was to compare total ground reaction forces (GRF), achilles tendon, patellofemoral, and tibiofemoral joint forces when summed across all steps taken to run 1 km at 3 running speeds.

Methods: 3D kinematic and GRF data were collected on 16 runners (7 males; age 22 yrs; mass 65 kg) at 2.68, 3.35, and 4.47 m/s running speeds. Inverse dynamics and a lower limb musculoskeletal model (11) were used to compute per-step patellofemoral and tibiofemoral compressive forces and achilles tendon force. Step length was assessed and used to compute total steps per kilometer per limb at each speed. Total peak values for these force variables and for resultant GRF were computed as the product of their per step value and number of steps per km at each speed. 1-way ANOVA was used to identify differences in total loads followed by t-tests between sample means in the case of significant F-ratio, all $p<0.05$.

Results: Slow, medium & fast runing speeds had 486±62, 418±63, and 363±81 steps per limb per km. Total loads per kilometer and limb were significantly lower at faster compared to slower running speeds (Table 1). Total GRF and tibiofemoral force were significantly lower at each speed from slow to fast and patellofemoral and achilles tendon forces were significantly reduced from slow to both faster speeds. All significant differences were ~10% lower from each slower to faster speed.

Figure:

Table 1. Maximum Values (mean, sd)	Per Stride			Per Kilometer		
	Slow	Medium	Fast	Slow	Medium	Fast
GRF max resultant (N), 1, 2	1,520	1,588	1,677	745,946	673,428	630,768
(sd)	228	226	230	124,010	122,756	164,087
Tibio-femoral max compression (N), 1, 2	6,828	7,123	7,600	3,339,455	2,966,631	2,800,082
(sd)	1,171	1,572	1,431	521,402	463,901	528,781
Patello-femoral max compression (N), 1, 3	3,094	3,310	3,461	1,512,160	1,366,838	1,266,047
(sd)	920	1,263	1,195	423,138	467,379	439,431
Achilles tendon max force (N), 1, 3	3,390	3,602	3,871	1,652,414	1,489,334	1,458,746
(sd)	840	804	815	363,099	324,510	453,193
For Per Kilometer Data Only: 1: sig ANOVA, 2: All speeds significantly different, 3: Slow > medium & fast						

Conclusion: Present data supported the hypothesis that total loads summed across all steps taken to run a standard distance are lower at faster vs slower speeds. Within the range of speeds tested, increased step length and not rate was the dominant mechanism to increase speed leading to fewer steps per unit distance. It remains to be seen whether total, summed loads are related to over-use running injuries and if reducing these loads reduces injury rates.

THE RELATIONSHIP BETWEEN MUSCLE MATERIAL PROPERTIES AND BODY MASS INDEX

Ann Marie Tullock [1] Jamie Hibbert [1] Paul Devita [1] Zachary J. Domire [1,*]

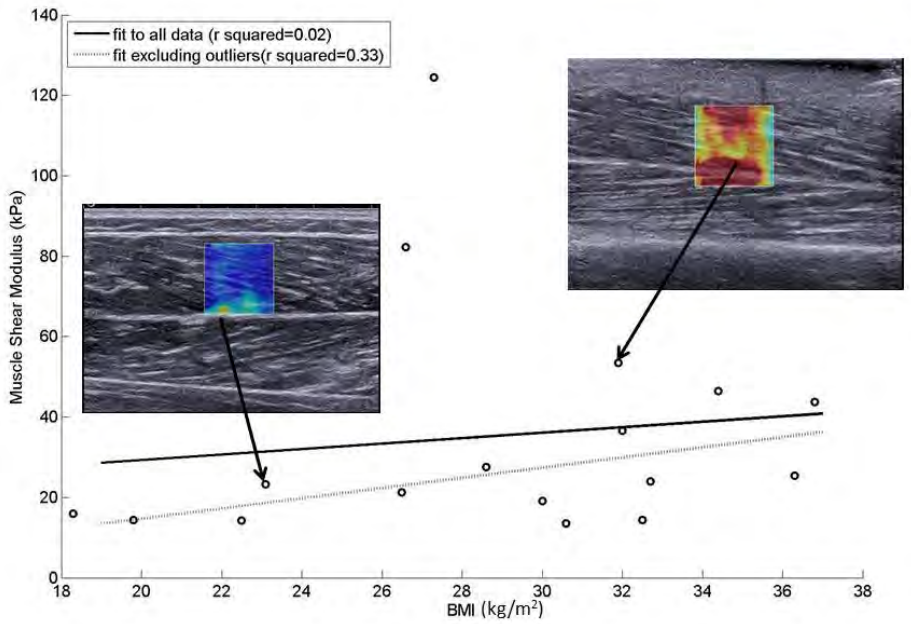
[1] Department of Kinesiology, East Carolina University, Greenville, United States

Introduction and Objectives: Obesity rates in the United States have been growing steadily over the last three decades [1]. It is well documented that obesity can lead to a wide range of other health problems [2]. One possible complication of obesity that has not been fully explored is increased accumulation of Advanced Glycation End-products (AGEs). Glycation is a non-enzymatic reaction between reducing sugars and proteins, and typically leads to the formation of covalent cross-links [3]. Tissues with greater AGE accumulation in the have been shown to have increased modulus [4]. Data collected by our lab group in aged animals has indicated that there is an inverse relationship between muscle size and modulus [5]. This indicates that increased muscle modulus may be implicated in decreased response to exercise. The purpose of this study was to identify the relationship between muscle modulus of the tibialis anterior and body mass index using elastography in a group of people with BMIs ranging from 18-44 kg/m^2. It was hypothesized that obesity may increase the rate of glycation in connective tissue and in turn result in an increase in muscle modulus.

Methods: Twenty-one participants were recruited for this study utilizing newspaper ads, flyers, and the East Carolina University listserve to reach university faculty and staff. Individuals were recruited based on BMI with the intention of testing one participant per BMI unit 18-50 kg/m^2. Inclusion criteria specified that subjects must be between the ages of 18 and 60 years old with a 18 $kg/m^2 \leq$ BMI $\leq$ 50 kg/m^2. In order to participate in this study, participants were required to be apparently healthy with the exception of high BMI. Individuals were excluded if they had any neurological, musculoskeletal, neuromuscular, or physiological disabilities. Previous surgeries to the lower limbs were also considered as exclusion criteria. This study was approved by the East Carolina University Institutional Review Board.
Elastography data was collected using a SuperSonic Imagine ultrasound unit (Axe-en-Provence, France). Each participant was positioned in a HUMAC isokinetic dynamometer chair with their knees flexed at 90° and ankles in anatomical position. Participants were asked to relax and remain as still as possible during measurements. Two five-second clips were collected for the right tibialis anterior. Tibialis anterior was chosen for measurements due to its accessibility. Additionally, the tibaialis anterior typically displays a lower level of adipose tissue than other lower limb muscles despite body mass index. Modulus was established by selecting a region of interest in the middle of the muscle belly. A Q-Box 3.0mm in diameter was placed in the area determined to contain adequate wave propagation at the frame in the middle of the clip. Statistical analysis included correlations of body mass index with mean muscle modulus and body mass index with the standard deviation of muscle modulus.

Results: The primary hypothesis of this study was that an increase in body mass index might lead to an increase in glycation of connective tissues and, in turn, result in an increase in muscle modulus of the tibialis anterior. Our results showed a low correlation between BMI and muscle modulus. The lack of a relationship was a largely a result of two participants who displayed extreme levels of muscle modulus.

Figure:



Caption: Figure 1. Relationship between BMI and shear modulus. Inset: Representative elastograms for a healthy weight and an obese participant

Conclusion: Based on the data collected during this experiment there appears to be a slight relationship between BMI and muscle modulus with higher BMI being related to increased muscle modulus. However, as mentioned above the weakness of this relationship was predominantly due to two participants who were outliers. These participants were not obese, but they were overweight. If these data points are excluded from the analysis the data show a clear relationship between increased BMI and increased muscle modulus. All participants were screened for diabetes in a pre-test questionnaire, but it is possible that the participants who were outliers are pre-diabetic or have undiagnosed type II diabetes. Increased muscle modulus may have serious implications including attenuated response to resistance exercise. Attenuated response to resistance exercise in obese individuals could be especially detrimental if it is found to interfere with exercise mediated glucose uptake. If this mechanism of glucose uptake is disrupted in individuals who have high BMIs it puts them at even greater risk of developing type II diabetes.

AS-0320

A FEEDBACK CONTROLLER TO PREDICT THE POSTURAL CONTROL IN RESPONSE TO A PERTURBATION

Maarten Afschrift [1,*] Friedl De Groote [2] Ilse Jonkers [2]

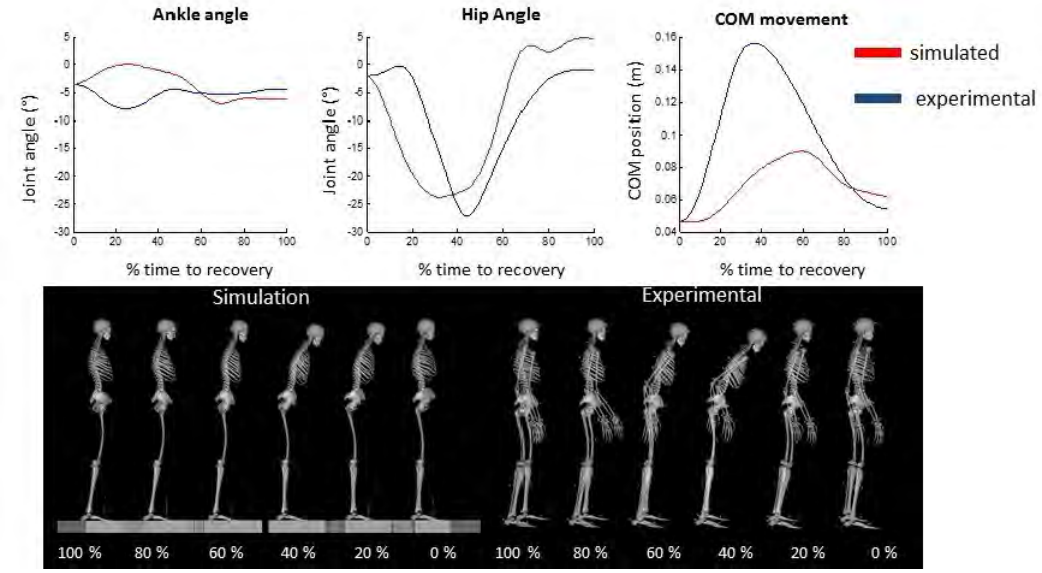
[1]Human movement biomechancis, [2]Production Engineering, Machine Design and Automation (PMA) Section, Ku Leuven, Leuven, Belgium

Introduction and Objectives: Postural control is a highly relevant topic, given the high incidence of falls in the elderly. The high location of the center of mass (COM) in combination with the small base of support (BOS) necessitates continuous postural control [1]. Postural control is often divided into feed-forward control (i.e. the control that anticipates a perturbation by adjusting the intrinsic stability) and feedback control (i.e. the control that generates stabilizing forces in response to a perturbation). The three major sensory systems that provide these feedback signals are the vestibular system, the somatosensory system and the visual system [1]. However, it is still unclear how humans modulate these feedback signals to excite their muscle for postural control. We hypothesize that human modulate their feedback signals to optimize their stability state and minimize the work needed for postural control. We will combine forward simulations with experiments of perturbed posture to define and evaluate the performance of the postural controller.

Methods: During the experiments, the posture of the subjects was perturbed by a backward translation of a motion base (range 0.16m, peak acceleration 1.5 m/s^2). The kinematics, kinetics and muscle activity in response to the perturbation were measured using integrated motion capture and processed using a scaled musculoskeletal model in Opensim. The forward simulations were performed with a simplified model: the models motion is limited to the sagittal plane and has only two degrees of freedom, one at the hip joint and one at the ankle joint representing the two main postural control strategies. The maximal moment generating capacities around the joints were constrained based on the moment-angle relationship of the muscles. The initial state (i.e. the joint angles and angular velocity) was modeled by imposing the experimental state before the perturbation. During the forward simulation, the posture of this model is perturbed by imposing a similar translation of the motion base. Secondly, we have implemented a feedback controller that uses feedback of the center of mass (COM) [position,velocity,acceleration] with respect to the BOS (somatosensory system) and the orientation [angle, angular velocity] of the torso with respect to gravity (visual and vestibular system). These feedback signals were scaled by gains to control the ideal moment actuators of the hip and ankle joint. The final gains were determined in an optimization routine with a cost function that combines the margin of stability (reflecting the stability state) and the joint work needed to restore balance.

Results: In general, the forward simulation with the optimized feedback gains results in a similar response to the perturbation as in the experiments (figure 1). More specific, there is only a small difference in the hip joint angle pattern, hip joint range of motion (ROM) and maximal hip extension moment (table 1). However, there are larger differences in the ankle angle pattern, ROM and peak plantarflexion. Furthermore, the center of mass range of motion and the time needed to bring the COM velocity below 0.02 m/s are larger in the experiment compared to the simulation.

Figure:



Conclusion: In conclusion, we are able to simulate the postural control in response to a perturbation using a simple feedback controller. This supports previous findings that suggest that humans use feedback of the orientation of the torso with respect to gravity and the location of the COM in relation to the BOS. Furthermore, the simulated kinematics and kinetics approximate the experimental kinematics and kinematics when we optimize the feedback gains to minimize the work needed for postural control and maximize the margin of stability. This suggests that the subject is using a similar strategy to modulate his muscle activity. However, there are still some important differences between the simulations and the experiments. Firstly, the simplifications in the simulation model will also influence the joint kinematics and kinetics. Secondly, the shorter time to stabilization and the decreased COM excursion in the simulation can be explained by the absence of a time delay on the feedback signals. In future research, we will implement a neural delay based on the first increase in muscle activity. Nevertheless, these results suggest that non-stepping postural control strategies can be approximated by a feedback controller with optimized gains. This controller could be highly relevant to predict the outcome of an intervention such as muscle strength training or the use of an assistive device on postural control. In other words, this framework allows, within the current limitation, to optimize interventions that maximize the subject's postural control capabilities.

Table:

	Time (s).	Ankle ROM (°)	Hip ROM (°)	Peak ankle moment (Nm)	Peak hip moment (Nm)	COM ROM
Experiment	1.9	4.6	26	85	50.3	0.11
Simulated	0.9	7.0	28	64.6	45.5	0.05

AS-0321

ASSESSMENT OF POSTURAL STABILITY IN MINIATURE DACHSHUNDS USING PLANTAR PRESSURE SYSTEMS AND FORCE PLATES

Aliah F. Shaheen [1,*] Thais de Mello Toledo [2] Daniela Macedo Lins de Araujo [2] Constanza Gómez Álvarez [2]

[1]University of Surrey, Guildford, United Kingdom, [2]School of Veterinary Medicine, University of Surrey, Guildford, United Kingdom

Introduction and Objectives: Miniature Dachshunds are a breed of dogs at a high-risk of developing intervertebral disc disease. This might result in spinal cord compression making them prone to developing neurological problems including paresis and paraplegia. Dogs that undergo spinal surgery will still have difficulties in walking and standing during the post-surgical recovery period, this is addressed using various rehabilitation techniques including physiotherapeutic exercises and other modalities. However, the efficacy of these rehabilitation techniques on their recovery time and musculoskeletal function is yet to be objectively assessed.

Postural stability is an important aspect of motor control which can be used as an indicator of musculoskeletal function. Objective measures of postural stability have been used in humans to assess rehabilitation programmes for patients with musculoskeletal disorders, to assess exercises used to reduce the risk of falling in older people and in stroke rehabilitation. Similarly, these measures can be used to assess the outcome of rehabilitation in dogs in the clinic, but it has not been reported in the literature.

The aim of this study was firstly to obtain measures of postural stability during quiet standing in healthy Miniature Dachshunds. Secondly, the study also aimed to assess the validity of postural stability measures obtained using plantar pressure data compared to data obtained from force plates.

Methods: 43 healthy Miniature Dachshunds of different body conditions (mean and standard deviation=5.8 ±1.7 on a scale from 1-9), gender (31 females and 12 males), hair type (smooth, long or wired) and age (6 months to 13.8 years) were recruited. The dogs' Body Condition Score were assessed by a veterinary surgeon using an established scoring system (Bartges et al. 2010). The dogs stood still on a plantar pressure mat (TekScan MatScan) placed on top of a force plate (AMTI). The two systems were synchronised and data were collected using the two systems simultaneously. Trials of 10 seconds long were collected, trials were the dog was seen to move, moved its tail or attempt to sit were discarded. A minimum of 5 valid trials were used for analysis.

Measures of Centre-of-Pressure (CoP) displacement and velocity as well as anterior-posterior and medial-lateral ranges were computed from force plate data. These were used to define normative values for healthy Dachshunds postural stability in quiet standing. Statistical analysis included t-tests, one-way ANOVA tests and Pearson correlation tests to examine the differences between gender, hair type, BCS and age. In addition, CoP measures were compared to those obtained using the plantar pressure system to assess the validity of computing postural stability measures using CoP data obtained from plantar pressure systems in the clinic.

Results: Table 1 describes the normative values for CoP measures for males and females and different hair types. There were no statistical differences between gender and hair type for any of the CoP measures. However, there was a

significant ($p<0.05$) negative correlation between the medial-lateral range and age (normalised to body weight). The CoP velocity was significantly ($p<0.05$) higher in dogs considered to be overweight (>6 from a scale 1-9) using the BCS. Finally, there were significant differences between measures obtained using the plantar pressure system and the force plate. The plantar pressure system underestimated the CoP velocity, anterior-posterior and medial-lateral ranges. However, the measures between trials and dogs were comparatively similar.

Conclusion: The study defined normative ranges of postural stability measures in healthy miniature Dachshunds. The results have shown no differences between males and females and between the different hair types. Some of the measures were different for older and overweight dogs, thus suggesting that postural stability measures are appropriate in measuring subtle differences in postural stability and may be an effective tool for rehabilitation monitoring. Future studies will focus on obtaining measurements of dogs at various stages of rehabilitation to assess the usefulness of these measures in evaluating functional improvement.

Data obtained from plantar pressure systems can be used to compute postural stability measures and are appropriate for clinical use; however, future studies using this system should note differences in the computed measures when comparisons with previous studies are carried out.

Table:

Category		AP Range (mm)	ML Range (mm)	Velocity (mm/s)
Gender	Female	22.6 ± 0.9	31.9 ± 1.4	259 ± 23
	Male	25.0 ± 2.7	37.4 ± 4.5	230 ± 36
Hair Type	Smooth	25.8 ± 1.6	36.0± 3.0	264 ± 30
	Long	20.3 ± 1.2	30.1 ± 2.0	249 ± 35
	Wire	23.8 ± 2.2	34.6 ± 3.4	236 ± 37

EFFECTS OF 45-MINUTE SOCCER MATCH SIMULATION ON BALANCE MECHANISMS FOR SINGLE-LEG HOP LANDING IN HEALTHY AND ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTED FEMALES

Sean Sankey [1 2,*]Raja Mohammed Firhad Raja Azidin [3]Holly Bradburn [1]Olalla Garcia Taibo [1]Ruth Cabeza-Ruiz [1]Mark Robinson [1]Jos Vanrenterghem [1]

[1]School of Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, [2]Engineering, Sport and Sciences, University of Bolton, Bolton, [3]Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, United Kingdom

Introduction and Objectives: The prevalence of Anterior Cruciate Ligament (ACL) injury in sport remains a major financial and rehabilitative burden. This is particularly true for female athletes in competitive team sports such as soccer. It is widely accepted that improper mechanics during dynamic tasks can lead to the loading at the knee joint sufficient to cause ACL injury (Dempsey et al., 2009). Hof (2007) has previously proposed the use of three balance mechanisms, including, Margin of Stability (MoS), which was quantified as the difference between the base of support and the extrapolated centre of mass. Recently Oberländer et al., (2012) investigated the differences between ACL ruptured and healthy physically active participants, observing balance mechanisms suggested by Hof (2007) in a single-leg landing task. Oberländer et al., (2012) suggested that ACL injuries cause participants to present a more anterior position of the centre of mass, and therefore reduced MoS. However, limb dominance and response to a specific soccer exercise bout has not yet been observed. The present study aims to investigate, firstly, how ACL reconstructed and healthy females present MoS in their dominant and non-dominant limbs, performing a single-leg landing task; and secondly, how a soccer specific match-simulation may challenge this MoS mechanism.

Methods: Twenty-nine females, who were active in competitive team sports such as soccer, took part in the study (age 23 ± 2.7 years; height 1.67 ± 0.06 m; mass 63 ± 7 years). These participants included females who had been involved in ACL reconstructive surgery (n=11) on average 25 months post-operative, and otherwise healthy females with no reported lower limb injuries (n=16). All participants took part in a modified 45-minute soccer match simulation, which included 3D motion capture of the single-leg landing task at times ‘00’ - preceeding the simulation; ‘45’ after one half match simulation; and ‘60’ following a 15-minute ‘half-time’ active rest. Each participant had 44 spherical reflective markers attached according to the LJMU-model - a 6-degrees-of-freedom, eight segment model including feet, upper and lower legs, pelvis and trunk. All single-leg landing trials were performed on the dominant and non-dominant sides using a force platform sampling at 1500 Hz, kinematic data were synchronously recorded using 10 optoelectronic cameras sampling at 250 Hz. It was noted that all ACL reconstructed participants had suffered injuries to their non-dominant lower limbs.

Results: No significant differences were found between ACL and healthy females for MoS in medio-lateral (X) and anterio-posterior (Y) directions, considering both limb-dominance and assessment time through the match simulation.

Conclusion: The fact that no significant differences were found between injured and healthy females, and irrespective of assessment time in the simulation, may indicate that other balance mechanisms were involved. Hof (2007) suggests the inverted pendulum and acceleration/counter-rotation of segments, may be considered, but further research is required here. Although, no significant differences were found there were some potentially important observations. MoS in the

anterio-posterior direction (Y) was noted to be higher in the ACL injured leg, and increased in response to the match-simulation to 45-minutes, and thereafter almost returned fully by time 60. This suggests ACL injured participants may try to extend their MoS, potentially as a protective mechanism on the injured side. Further to this, MoS presented in medio-lateral direction seemed to be more restricted in the injured limb of ACL participants, which is potentially a mechanism that may reduce the shear load at the injured knee joint.

AS-0323

THE ABILITY TO RECOGNIZE A SLIP

Sharon Ravindran [1 2] Yue Li [2] Tilak Dutta [2] Vicki Komisar [2 3,*] Geoff Fernie [2 3 4]

[1]Engineering Science, University of Toronto, [2]Toronto Rehabilitation Institute , University Health Network, [3]Institute of Biomaterials and Biomedical Engineering, [4]Surgery, University of Toronto, Toronto, Canada

Introduction and Objectives: Falls are a leading cause of injury in Canada [1], of which many result from slipping on snow or ice [2]. The ability to detect a slip is important for inducing proactive and reactive balance responses; however, the ability of a person to assess walkway slipperiness is unclear. With high variability in previous evaluations of slipperiness, no significant relationship exists between subjective evaluations with coefficient of friction or slip distance [3,4]. Further, no studies have explored the point at which people know if they have experienced a simultaneous slip of both feet (bilateral slip). The purpose of this pilot study is to quantify the range of slip distances that can be perceived, and to examine changes in gait resulting from perceived and non-perceived bilateral foot slips.

Methods: Data was collected in 'WinterLab' in the Challenging Environment Assessment Laboratory at Toronto Rehab (Figure 1). Six young women participated (age 23.7$\pm$2.1y; height 162.4$\pm$2.8cm; mass 58.7$\pm$8.0kg).

Harnessed subjects walked back and forth along a 2m-long wet-ice walkway. All wore the same type of winter boot and walked at a self-selected pace. After each walk, subjects reported whether they perceived a slip. The walkway angle was increased by 1^0 until the researcher saw a bilateral slip.

Reflective markers on the feet and pelvis were used to quantify key gait and slipping metrics (Table 1). Bilateral slip in this study was defined as:

1) If both feet on the ground move in the anterior-posterior (AP) direction but not in the vertical (z) direction (*vel-AP* > 0.10 m/s; *vel-z*<0.10m/s); or

2) If one foot is in the air and grounded foot has *vel-AP*>0.10 m/s and *vel-z*<0.10m/s

Slip distance was defined as the difference between the heel position at slip termination and heel contact (HC) in the AP direction.

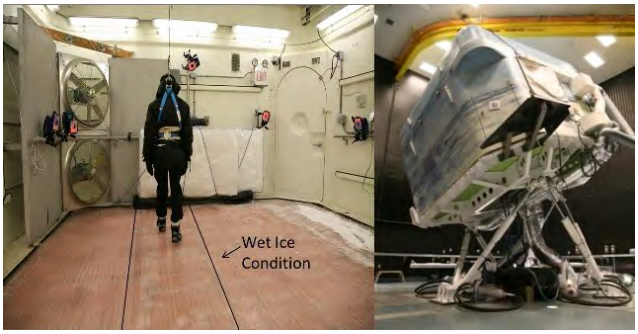
Slips were categorized into two groups: Perceived slips (where the subject correctly identifies a slip) and non-perceived slips (where slips were only detected from kinematic data). All variables were analyzed with a mixed model repeated measures ANOVA, with significance defined as p<0.05.

Results: *Seventy- eight* slips were recorded, of which 40 slips were successfully identified by participants, giving a success rate of 51% for the identification of a slip on a sloped icy surface. The main effect of direction (p= 0.43) was not significant and as a result the values from uphill and downhill were grouped together. A slip distance over 0.10 m can lead to a dangerous fall [5] and can lower a person's ability to recover should a slip occur [6]. Of the 78 slips, 17 slips had slip distances between 0.10 and 0.24m; where 13 (77%) of those slips were perceived.

Most gait parameters did not vary significantly between perceived vs non-perceived slips, except for slip distance (p= 0.004) and sliding heel velocity (p= 0.005). Perceived slips occurred with walkway inclines on average 1^o higher than

non-perceived slips. Higher slopes create surfaces that are more challenging and slipperier to walk on for the participant, which may explain the increase in slip distance and sliding velocity for perceived slips.

Figure:



Caption: Figure 1: Subjects walked uphill or downhill along a wet ice condition inside Winterlab (left). Picture on the right shows the exterior of Winterlab.

Conclusion: Subjective assessment of perceiving a bilateral slip should be cautiously used as a method to identify potentially- dangerous slips, as only 77% of bilateral foot slips were identified by the subject when the slip distance was greater than 0.10m. Higher slip distance and sliding heel velocity may be contributors in the identification of a bilateral foot slip, thereby making it easier for subjects to perceive that they have experienced a slip [7]. Further studies with a bigger sample size are needed to examine these subjective assessments in older adults, and EMG on key leg and trunk muscles should be incorporated to quantify muscular responses. In addition, more research needs to be done to investigate the feasibility of educating or designing interventions that can help people to recognize high slip distances that could lead to dangerous falls.

Table:

	Non-perceived slip	Perceived slip	*p* value
Slope Angle (°)	4.0 ± 0.7	4.9 ± 0.8	0.004
Slip Distance (m)	0.05± 0.02	0.09 ±0.04	0.017
Sliding Heel Velocity (m/s)	0.12± 0.04	0.18± 0.05	0.005
Floor Foot Angle(°)	18.0±6.8	15.5±6.2	0.21
Step Width (m)	0.11± 0.04	0.11± 0.04	0.74

THE ROLE OF SOMATOSENSORY PROPRIOCEPTION IN STANDING AND HANDSTAND BALANCE

Glen M. Blenkinsop [1,*] Matthew T. G. Pain [1] Michael J. Hiley [1]

[1]School of Sport, Exercise and Health Sciences, Loughborough University, Leicestershire, United Kingdom

Introduction and Objectives: The sensory organisation test was developed by Nashner [1] and is a computerised system that consists of a moveable force plate that can rotate about an axis level with the patient's ankle joint and track their sway during quiet stance. This sway referenced platform motion is intended to reduce the amount of ankle motion during normal sway to reduce sensory feedback from the surrounding somatosensory proprioceptors during quiet stance. The sway referenced platform has only been used to assess quiet stance in double leg stance as the rotation of the support surface is about a fixed point that cannot be moved. Past research has only examined the general effect of a sway referenced platform via analysis of the range and standard deviation of the centre of pressure (COP). The purpose of this study was to create a sway referenced platform on the CAREN system so that the role of visual and somatosensory proprioception could be assessed in both standing and handstand postures via a range of traditional and nonlinear analyses.

Methods: A sway referenced platform was achieved by creating a script program in the motek medical D-Flow software to control the CAREN system's Stewart platform. The platform was rotated about a virtual axis aligned with the subjects' ankle or wrist joints using the method from Barton et al. [2]. Body sway was tracked via a nine camera vicon system (200 Hz) and inputted into the D-Flow script program so that the platform could be rotated to track the subjects' body sway. Ten experienced handstanders performed balance trials with eyes open and eyes closed conditions in double leg stance and handstand on a static and sway referenced platform. Three trials of each of the eight conditions were completed for a maximum of 30 seconds duration.

Kinematic data were collected via 53 markers to divide the body into 18 segments and filtered with a fourth order zero lag, low-pass Butterworth filter with a cutoff frequency of 10 Hz, before quaternion algebra was used to calculate: segment centre of mass linear displacements, velocities, and accelerations; and segment angular velocities and accelerations. Kinetic data were collected via two Bertec strain gauge force plates (200 Hz), and raw COP data were used to assess balance via: traditional measures (trial duration, sway area, sway length, standard deviation, range, sway velocity), nonlinear dynamics (sample entropy, Lyapunov exponent), and recurrence quantification analysis (recurrence rate, determinism, Shannon entropy, divergence, trend). Kinetic and kinematic data were used to calculate 3D joint moments and forces via wrench notation, to assess balance via: estimates of neurological delay (delay, R^2, joint torque from proportional and derivative gains), and movement corrections (number of small, medium, and large corrections per second, mean torque, torque impulse, burst duration).

Results: The sway referenced platform resulted in increased sway in standing as measured by the traditional balance metrics of range, sway length, and sway velocity for eyes open, and even more so for eyes closed. Balance on a sway referenced platform resulted in reduced Lyapunov exponents, indicating trajectories became more organised with lower localised divergence. Balance on a sway referenced platform resulted in fewer corrections per second with reduced burst duration and higher mean joint torques. No significant changes were found in estimates of neurological delay.

Experienced handstanders balancing on a sway referenced platform had a loss of balance within a few seconds due to the reduced sensory information from wrist somatosensory proprioception. Handstand trials of short duration resulted in large variations in balance measures calculated from traditional and nonlinear analysis methods. Handstand balance on a sway referenced platform typically resulted in COP trajectories that were significantly less stationary, with decreased entropy and increased divergence. No significant changes were found for estimates of neurological delay, however, a significant increase in estimates of passive wrist stiffness was found for handstand balance on a sway referenced platform.

A residual effect from the sway referenced platform resulted in increased sway during static balance in standing and handstand on a stable platform compared to a previous session without any sway reference component.

Conclusion: When balancing in standing on a sway referenced platform balance becomes more regular with fewer corrections; whereas when balancing in handstand subjects tended to drift, or fall, with few corrections, leading to nonstationary signals with large divergence in local trajectories. The relationship between somatosensory and visual cue utilisation, and how this is affected by recent environmental experiences, is similar in both standing and handstand postures.

AS-0325

IS THERE A CORRELATION BETWEEN WOBBLE BOARD PERFORMANCE AND STATIC BALANCE PERFORMANCE?

Jamie Parkinson [1,*] Daniel West [1] Carol Clark [1] Jonathan Williams [1]

[1]School of Health and Social Care, Bournemouth University, Bournemouth, United Kingdom

Introduction and Objectives: Wobble boards (WB) are commonly used in clinical practice to rehabilitate and enhance proprioception and balance. However the relationship between wobble board performance and balance function has yet to be determined.

The aim of this study was to explore the relationship between wobble board performance and balance performance.

Methods: Ethics approval was granted from Bournemouth University. Thirty healthy participants completed a series of WB tasks (double leg stance and single leg stance) and a series of static balance tasks (double leg stance, tandem stance and single leg stance). WB performance was measured using the SMARTwobble instrumented wobble board (which produces 5 performance metrics) and balance performance was measured using a commercially available balance sensor (produces 3 performance metrics) based on the acceleration of the sacrum. The relationship between the performance on the WB and balance performance were explored using spearman's correlation coefficients.

Results: A possible 360 correlations were explored and 45 significant correlations were identified. Of these, 7 were deemed modest correlations ($r>0.50$). Greatest correlations were observed for time with WB in outer tilt banding during SLS and tandem stance eyes closed ($r_s = 0.60$) and WB time in inner banding during SLS and tandem stance eyes closed ($r_s = -0.56$). Despite these specific correlations, overall, the results show little correlation between WB performance and balance performance. These results imply that WB performance and balance performance are not interchangeable. This suggests the two elements challenge different balance constructs, perhaps with the WB targeting the ability to deal with continuous balance perturbation and the balance tasks exploring the ability to maintain static balance equilibrium.

Conclusion: There was little overall correlation between WB performance and balance performance. This seems to suggest that they assess different underlying balance constructs.

Table:

Wobble board task and metric	Balance task and metric	r_s	P
SLS time in outer tilt banding	Tandem EC JERK	0.60	0.001
SLS time in inner tilt banding	Tandem EC JERK	-0.56	0.002
SLS time in inner tilt banding	Tandem EC NPL	-0.54	0.002
SLS time in outer tilt banding	Tandem EC NPL	0.50	0.005

VARIABILITY OF TRUNK MUSCLE SYNERGIES DURING TARGET MATCHING TASKS

Ehsan Sedaghat-Nejad [1] Seyed Javad Mousavi [2] Mohamad Parnianpour [1] Malihe Hadizadeh [3] Bahman Nasseroleslami [4,*]

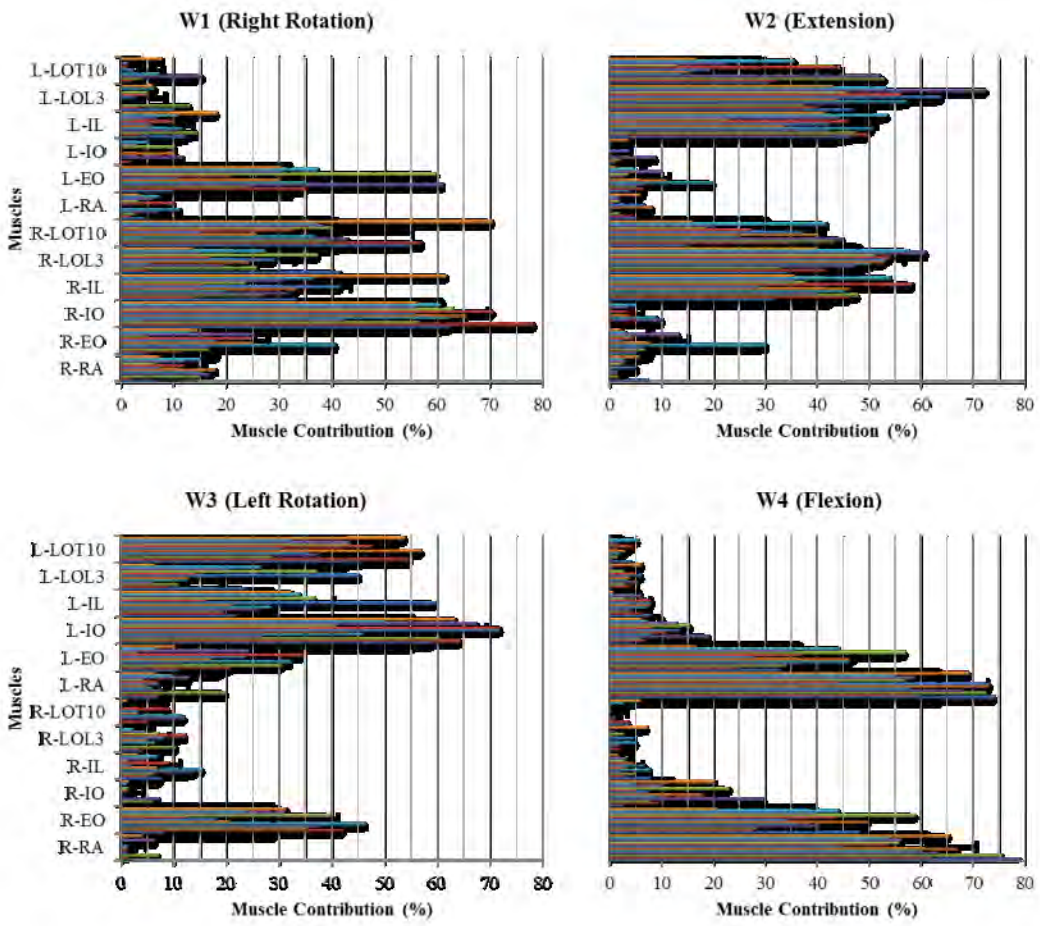
[1] Sharif University of Technology, Tehran, Iran, Islamic Republic Of, [2] University of Sydney, Sydney, Australia, [3] Tehran University of Medical Sciences, Tehran, Iran, Islamic Republic Of, [4] Academic Unit of Neurology, Trinity College Dublin, Dublin, Ireland

Introduction and Objectives: It has been suggested that the central nervous system simplifies muscle control through basic units, called synergies, to activate muscles in groups. Several authors evaluated consistency of muscle synergies during different tasks and found similar synergies across their populations. Since, trunk neuromuscular system is a complicated system with high degree of redundancy, assessing control strategies in this system will be crucial to advancing our understanding of neural control mechanisms for muscle exertions. The objectives of the present study were: (1) to examine the existence of muscle synergies - as a trunk neuromuscular system strategy - during multidirectional target matching tasks, (2) to investigate the consistency and inter-individual variability of extracted synergies in terms of their number and composition, and (3) to interpret the functional role of muscle synergies regarding their activation patterns and respective torque synergies.

Methods: We investigate the existence and inter-subject variability of trunk muscle synergies as well as torque synergies during a novel target matching task. In this regard, a population of twelve healthy participants (five female) with no history of back pain and other musculoskeletal and neuromuscular disease were studied. Generated isometric torque data at L5/S1 level and electromyographic (EMG) patterns of twelve abdominal and back muscles were recorded. Each participant performed a total number of 24 isometric target matching task in 12 different angles (0, 30... 330 degree) and 2 levels of uniaxial and biaxial exertions (45% and 70% of the Maximum Voluntary Exertion). Muscle and torque synergies were extracted using non-negative matrix factorization (NMF). Three different criteria including multivariate R^2, variance accounted for (VAF), and residual mean square error (MSE) were calculated to determine the proper number of muscle synergies. Further, a cross-validation (VAF_{cross} and R_{corr}) and reliability (ICC) procedure was assessed to verify the robustness of the extracted muscle synergies across different conditions. Also, the similarity of muscle synergies across participants was evaluated by a calculation procedure similar to VAF_{cross} and R_{corr}. Finally, torque synergies were calculated using muscle synergy activation coefficients and acquired torque data.

Results: Choosing four number of muscle synergies, the results showed mean VAF of 97.9±0.53% and mean R^2 of 94.5±1.1% which shows the efficiency of those synergies. Moreover, concerning between-subject variability of the muscle synergies, VAF_{cross} was 90.0±4.1%, and R_{corr} were 0.77±0.12, 0.86±0.08, 0.78±0.12, and 0.93±0.04 for synergy #1, #2, #3, and #4, respectively, which highlights their consistency across participants. For each set of muscle synergies, a set of four corresponding torque synergies were evaluated which had VAF_{torque} of 92.2±3.03%. Based on the torque synergies and the activation pattern of muscle synergies, functional role of muscle synergies was interpreted. As a result, synergy #1, #2, #3, and #4 were labelled as right rotation, extension, left rotation, and flexion, respectively. Each synergy was predominated in a specific direction and collaborated in other directions as well.

Figure:



Caption: Muscle synergy compositions

Conclusion: The results showed that there is a set of four muscle and four corresponding torque synergies for a healthy person, which could efficiently break the sagittal and transverse torque planes into its main directions. Overall, our results suggested that by taking advantage of muscle synergies we could overcome the redundancy faced in control strategies of trunk neuromuscular system. In future studies, the synergies identified in patients with LBP can be compared with this set of synergies extracted from asymptomatic participants. We are now planning larger studies to identify muscle synergies in people with LBP and evaluate the effect of training to address possible altered muscle synergies.

EFFECTS OF VOLITIONAL SPINE STABILIZATION ON LIFTING TASK IN RECURRENT LOW BACK PAIN POPULATION

Ram Haddas [1,*] James Yang [2] Isador H Lieberman [3]

[1]Reseach , Texas Back Institute Research Foundation, Plano, [2]Mechanical Engineering , Texas Tech University, Lubbock, [3] Scoliosis & Spine Tumor Center , Texas Back Institute, Plano, United States

Introduction and Objectives: Low back pain is reported in 75-80% of the population and can significantly influence an individual's quality of life [1]. Low back pain can result from mechanical irritations of selected anatomical structures, such as the intervertebral disc, the facet joints and the associated lumbar spine nerve roots [2,3]. Lifting is a ubiquitous activity, where individuals are required to manually manage materials and loads throughout occupational tasks and activities of daily living [4]. Such lifting behaviors are used in a repeated fashion during various occupational engagements, such as healthcare, farm animal management, labor employment, and performing arts [5, 6]. A volitional preemptive abdominal contraction (VPAC) is commonly used to improve lumbar spine stabilization and reduce pelvic motion in individuals with spine dysfunction [7]. A commonly used VPAC strategy is the abdominal bracing maneuver, which produces a global trunk muscle contraction [8]. The purpose of this study was to examine the influence of VPAC and recurrent low back pain (rLBP) on pelvic and trunk mechanics, as well as neuromuscular control, during a symmetric lift task.

Methods: Thirty-seven healthy individuals and 31 rLBP individuals performed symmetric weighted box lifting trials with and without VPAC to a 1 meter height table. The VPAC condition was presented in random order. Electromyography (EMG) data from the right external oblique (EO), erector spinae (ES), multifidus (Mf), semitendinosus (ST), and gluteus maximus (GM) were measured. Three-dimensional kinematics of the lower extremity and trunk were collected. Kinematics and EMG were analyzed at two times at initial position-0.05s after lifting was initiated and again at final position -0.05s before the subject placed the box on the table. A 2 (group) × 2 (abdominal contraction) crossover mixed design was used to examine the effects of VPAC and group on biomechanical and neuromuscular control variables in lifting.

Results: The VPAC altered joint kinematic and muscle activity in rLBP and healthy individuals during symmetric lifting. A significant two-way interaction effect was observed for the ST activity in final position. The VPAC increased EO muscle activity, reduced ES, reduced Mf muscles activity at initial position, reduced Mf muscle activity at final position, greater trunk flexion angle, greater trunk side flexion angle, decrease pelvis obliquity angle at final position, and greater hip flexion angle at initial position. Recurrent LBP subjects presented reduced EO, GM, and greater Mf muscles activity at initial position, reduced EO, greater ES muscle activity and greater pelvis posterior tilt angle at final position.

Conclusion: Our results provide evidence that a VPAC strategy that is initiated during symmetric lifting decreases exposure to biomechanical factors that can contribute to lumbar spine injury. This apparent protective response is present in both healthy and rLBP individuals when lifting to a 1 meter height. Incorporating VPAC during dynamic stressful activities appears to help improve sensorimotor control and facilitate positioning of the lower extremity and the pelvis, while protecting the lumbar spine. Clinicians can use this information when designing neuromuscular control training

programs for people who have rLBP to improve lower extremity and spine control and spine stability thus potentially decreasing injury risk.

CAN WE OFFER BIOMECHANICAL SUPPORT FOR LARGER BREASTED WOMEN WITH BACK PAIN?

Ambreen Chohan [1,*] Lauren Haworth [1] Jessie Janssen [1] James Selfe [1]

[1] Allied Health Research Unit, University of Central Lancashire, Preston, United Kingdom

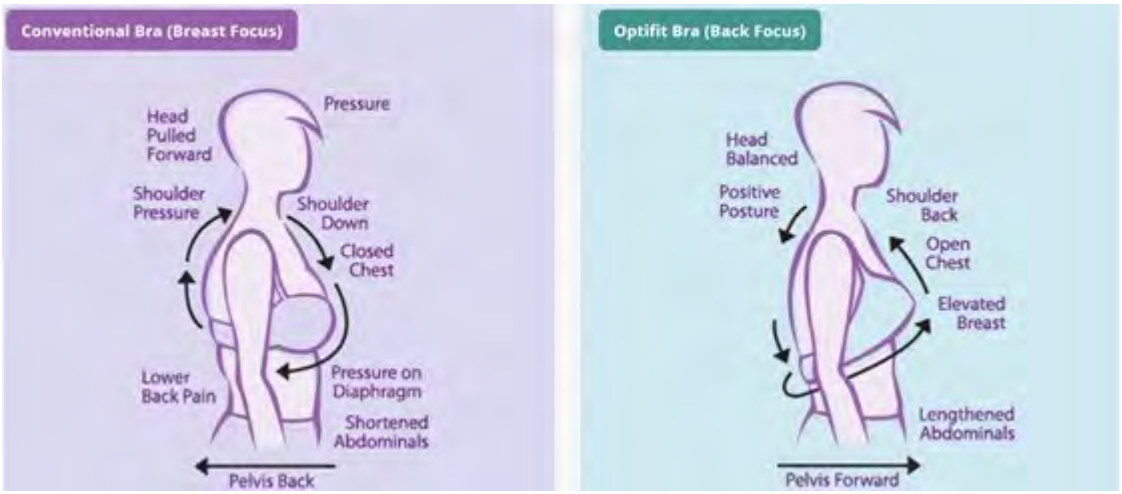
Introduction and Objectives: It is argued that larger breasted women (D+ cup) may not receive adequate levels of support or quality of fit when measured using the traditional Warner® Alphabet system as it was initially only established for cup sizes A-C [1]. With 40% of UK females now measuring a D cup or above, many British females are at greater risk of wearing ill-fitting bras. Most bra designs take a symmetrical approach and fail to consider the high prevalence of breast asymmetry (62-82%)[2]. With a large breast exceeding 1000g in mass and no evidence to confirm that the tensile strength of the Cooper's ligaments increases in proportion with breast mass [3], failure to effectively support both breasts during dynamic activity can cause breast pain and many upper body physiological symptoms, including neck, shoulder and back pain [4]. A new innovative bra solution claims to eradicate breast-bounce and lift the breast through altered weight-distribution from the shoulders to the lower back, promoting a positive posture and lengthened abdominals (Figure). This study investigates immediate changes in pelvis, spine and breasts kinematics under three breast support conditions. In addition the quality of fit and changes in back pain, discomfort and stiffness as a result of change in breast support over a 4-week period were investigated.

Methods: Following a modified Red Flags screening process, eight females with non-specific neck/back pain (mean $\pm$ SD: age 36$\pm$9.92 years;BMI 30.60$\pm$3.91kg/m^2) were recruited. Participants with multiple red flags, those who with a history of spinal or breast surgery (such as Mammaplasty or mastectomy) Pregnant women, those that had ceased breastfeeding in the last year or were menopausal/post-menopausal were not eligible for this study. All appropriate ethical approval was gained. Body charts and Patient Reported Outcome Measures (PROMs) were used to assess pain location, pain severity, discomfort and stiffness. Participants performed 5 drop jumps off a 20cm high step and performed a computer typing task in three breast support garments (usual bra, professionally fitted bra, Optifit bra). Kinematics of the pelvis, spine and breasts were recorded using a 10-camera Oqus Qualisys motion capture system. The calibrated anatomical system technique (CAST) was used together with a multi-segment spine model and ten additional breast markers to allow analysis in the sagittal, coronal and transverse planes. All data were analysed using Visual3D (C-Motion Inc.) and SPSS. Statistical significance was set to $P \leq 0.05$. Bra fit assessments were completed based on established guidelines for each of the three bras. Nipple to sternal-notch distance, multiplanar breast deflection relative to the thorax during dynamic activity and the thoracic spinal posture relative to the pelvis in a seated and standing position was calculated.

Results: Bra-fit assessments showed that both the professional and usual bras were equally poor (0% pass rate), compared to the Optifit™ bra (100%). Common fitting issues for the usual and professional bras included a tight band and straps and incorrect cup sizes. Over the 4-week period significant improvements were seen in back stiffness in the Optifit™ bra ($p<0.05$). Body chart analysis for pain location showed a significant reduction in reported pain in the thoracic region ($p<0.04$) with the Optifit bra. Near significant reductions of over 55% were also noted for reported pain in the lumbosacral region with both the Optifit and Professional bras, compared to the Usual bra.

Nipple-sternum distances showed the Optifit™ bra provided the greatest uplift. In a standing posture, there was a trend towards significance when comparing the usual bra with the professional and Optifit™ bras, indicating both bras may open the chest, reduce slouch and bring wearers into a more upright standing position. Seated thoracic posture during the typing task showed greatest improvement with the professional bra. The dynamic task revealed a significant difference in mediolateral deflection between breasts, suggesting the need to consider breast asymmetry. Superior-inferior breast deflection showed a trend towards significance between bras with the Optifit™ bra showing the greatest level of support.

Figure:



Caption: The proposed differences between a Professional bra, and the new innovative Optifit bra.

Conclusion: Overall, findings from this study support the increasing importance of bra fitting for larger breasted individuals with back pain; suggesting the need for alternative bra design and fitting guidance for these women. Further biomechanical research on alternative support solutions such as the Optifit™ bra may help to provide an alternative conservative management solution to those considering breast reduction surgery.

THE GEOMETRIC CURVATURE OF THE SPINE DURING THE SIRSHASANA, THE YOGA'S HEADSTAND

Nayane Giraldi [1]Mario H. Campos [1,*]

[1]faculdade de educação física, universidade federal de goiás, Goiânia, Brazil

Introduction and Objectives: The sirshasana is one of the complex postures of yoga. Some yoga students reported that they feel a decrease of loads in the lumbar spine during this headstand position. However, the yoga postures that were most often associated with adverse events were headstand [1].

It is established that a moderate curvature minimizes the loads generated on the spine in situations where it is subjected to compressive forces [2]. The posture presented during walking may be inside the Neutral Zone [3], and appears to be a good parameter for defining this moderate curvature, ideal on sagittal plane. In the frontal plane, yet it is reasonable to assume that a rectified spine is ideal and that lateral deviations in the spinal alignment are associated with asymmetric load applications on the spinal structure. The measurement of the curvature of the spine during sirshasana is an unexplored approach that can help understand the human posture.

This study sought to analyse the behavior of the spinal posture in the sirshasana.

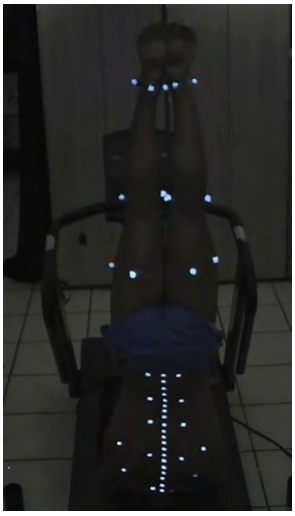
Methods: The study included 6 men and 5 women (63,0±11,4 kg; 166,4±8,0 cm; 29,4±8,8 years) that were able to execute the sirshasana (Figura 1). Adhesive retro-reflective markers (plane, square [8x12 mm]) were placed to mark and identify the spinous process of several vertebrae (from S2 to T1) and some another anatomical points on the back (Figure 1). Each volunteer was registered (60Hz) by 3 pre-calibrated camcorders (Mini-DV Panasonic) during: walking in a treadmill (5.0 km/h), orthostatic position and sirshasana. With Dynamic Posture system [4], the markers were identified and tracked in the movies. With DTL the 3D positions of all markers were computed in all activities.

The positions of the spinal markers were projected onto the sagittal and frontal planes. At each plane, the geometric two-dimensional curvature was computed [5]. The posture of the sirshasana was compared to the posture in the orthostatic position and with the average posture presented in all gait cycles happened between 700 frames. Kolmogorov-Smirnov (showed normally distributed data [$p>0,05$]), one way Anova ($p<0,05$) and post-hoc Tukey-Kramer tests were conducted in Matlab®.

Results: The absolute peaks of the spinal curvature of all volunteers were computed for each spinal region, in the frontal and sagittal planes, during gait, orthostatic position and sirshasana (Table 1). The frontal lumbar curvature ($p=0.87$) and the sagittal thoracic curvature ($p=0.51$) did not showed significant differences between activities. However, the sagittal lumbar curvature decreased ($p=0.01$) and the frontal thoracic curvature increased ($p=0.04$) in the sirshasana when compared to neutral postures of the gait and of the orthostatic position.

Probably, the data found at this work are associated with the position of the center of mass of the body in the erect position (near L2). During sirshasana, the mass supported by lumbar vertebrae is smaller than in the erect positions; and it is bigger for the thoracic region.

Figure:



Caption: Illustration of dorsal demarcation at sirshasana.

Conclusion: Although the number of participants in this study represents a limit to the work, the collected data are unpublished and may suggest recommendations for the practice of yoga. The findings suggest that the lumbar spine is less stressed during the execution of sirshasana. However, the sirshasana should be practiced very carefully by beginners and people who have problems in the thoracic region.

REPEATABILITY OF THE QUICK-RELEASE METHOD FOR ESTIMATING ACTIVE STIFFNESS OF THE TRUNK

Tara Diesbourg [1,*] Steven Fischer [2] Geneviève Dumas [3]

[1]School of Kinesiology and Health Studies, [2]School of Kinesology and Health Studies, [3]Department of Mechanical and Materials Engineering, Queen's University, Kingston, Canada

Introduction and Objectives:

The use of quick-release perturbations has been suggested as a method for estimating trunk stiffness. It appears to be effective for differentiating active trunk stiffness among individuals from special populations; however evidence supporting the validity of the method is limited [1]. The purpose of the current study was to examine the between-day repeatability of this process to see whether it can track changes in trunk stiffness over time.

Methods: Twenty subjects (10 male, 10 female: mean height – 174cm, mean weight – 72kg) were recruited from a university population. Trunk stiffness was estimated using a quick-release method [2]. Subjects were asked to adopt a semi-seated position with their arms crossed over their chest. Using electromagnets on cables affixed to the anterior and posterior aspects of a chest harness, weights (15% body weight) were suspended from the subject. At a random time (0-5s) and in random order either the front or the back weight was dropped (10 repetitions each), perturbing the subject in the opposite direction. A uniaxial load cell between the subject and the attached load was used to measure force. Acceleration was obtained from the force and was double-integrated to obtain displacement. It is assumed that vertical displacement of the load represents horizontal displacement of the trunk.

Trunk stiffness was estimated using least-squares optimization which used time-varying force, acceleration, velocity and displacement to estimate the system's effective mass (M), damping (B), and stiffness (K) coefficients [2]. The maximum vertical displacement (D) of the load and the time (T) required to achieve this maximum displacement were also calculated. This protocol was completed prior to and immediately following a seated 60 minute typing task (sessions = pre and post). These collections took place on 4 separate days.

For all statistical tests, coefficients obtained for forward and backward perturbations were analyzed separately. A Within-session (WS) analysis was conducted using Intraclass Correlation Coefficients (ICC(3,1)) for the 10 perturbations in each direction. The between-day (BD) analysis was completed using the mean of all perturbations in each direction and ICC(3,k) calculated across all 4 days.

Additionally, Standard Error of the Mean (SEM) were calculated for each of the WS and BD comparisons according to the method described by Weir [4] in order to better understand the test's inherent trial-to-trial noise.

Results: Due to load cell malfunctions, 46 backward sessions (23 pre and post) and 54 forward sessions (27 pre and post) were discarded prior to analysis. The ICC for all comparisons are provided in Table 1.

Repeatability within subject for stiffness in both WS was good [4] (overall mean ICC = 0.66 (Backward), 0.47 (Forward)). Repeatability for BD was moderate to good [4] (mean ICC = 0.46 and 0.38 for Backward and Forward respectively).

SEM estimates for K were 51.2% and 42.1% higher in the forward perturbation for WS and BD respectively, suggesting a larger variability exists in the data obtained from forward perturbations. Additionally, SEM estimates were 0.1 to 8 and 0.1 to 3 times greater than K for forward and backward perturbations respectively.

Conclusion: The overall results for this method indicate that it is repeatable for all types of analyses, more so for backward perturbations than forward. Therefore, this method is suitable for the desired within-subject over time comparisons, however due to the large SEM (especially for K), it may not be sensitive enough to detect minor changes in trunk stiffness over time. The SEM provides a threshold when assessing BD differences. In order to determine whether a difference should be considered real, it must surpass 2.75 times the SEM [4]. For forward perturbations, this is less likely to occur as the SEM was up to 8 times larger than the K estimate.

Table: Summary of all repeatability tests for all coefficients. WS = Within-session (pre), BD = Between-Day. M = Mass (kg), B = Coefficient of Damping (Ns/m), K = Stiffness coefficient (N/m), D = Max Displacement (mm), T = Time to Max D (ms).

THE GEOMETRIC CURVATURE OF THE LUMBAR SPINE DURING SQUAT EXERCISES WITH AND WITHOUT KNEE MOVEMENT RESTRICTIONS

Laizi Alaman [1] Marcelo Paula [2] Claudio Lira [1] Mario H. Campos [1,*]

[1]faculdade de educação física, universidade federal de goiás, [2]Unidade Goiânia, Instituto Federal de Educação, Ciência e Tecnologia de Goiás, Goiânia, Brazil

Introduction and Objectives: The squat is a exercise for strength training, widely used in physical conditioning programs, at rehabilitation processes and to improve sports performance.

The squat technique used can affect the distribution of forces between the knees and hips and on the kinematic properties of the exercise. The stress on the knees are minimized when the knees do not move anteriorly past the toes (restricted), but it is likely that load increases on the hips and the anterior tilt of the trunk increases [1] what could affect the lumbar posture. This study sought to analyse the behavior of the lumbar posture in the squat with and without knee movement restrictions.

Methods: The study included nine volunteers (21.7±4.1 years; 64.6±22.7 kg; 1.6±0.2 m), from both sex. All declared that were practicing strength training for one year or more than that and declared to use squat at their week training. Every one declared that had no back pain or other musculoskeletal problems. Each one indicated for the researchers the maximum (100%) load that was using at the squat training.

The volunteers wore shorts, running shoes, and for women, bikini or top with narrow straps on the back. Adhesive retro-reflective markers (plane, square [8x12 mm]) were placed to mark and identify the spinous process of several vertebrae (from S2 to T1) and some another anatomical points on the back (Figure 1).

Each volunteer was registered (60Hz) by 3 pre-calibrated camcorders (Mini-DV Panasonic) during four activities: orthostatic position; restricted squat with 100%; restricted squat with 50%; and unrestricted squat with 50%. For each squat condition, performed in a randon ordination, it was identified the most deeper position for analysis.

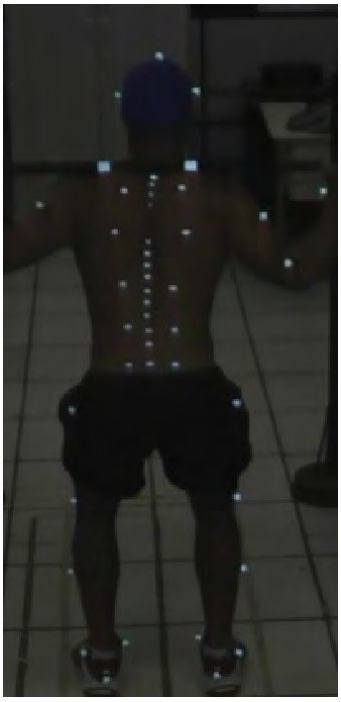
With Dynamic Posture system [2], the markers were identified and tracked in the movies. With DTL the 3D positions of all markers were computed in all activities.

The positions of the spinal markers were projected onto the sagittal plane and the geometric two-dimensional curvature was computed [3], in the lumbar region. The average lower lumbar posture presented in each situation was computed for analysis. Positive values indicated posterior concavities (lordosis), and negative values indicated anterior concavities (kyphosis). Kolmogorov-Smirnov (showed normally distributed data [$p>0,05$]), one way Anova ($p<0,01$) and post-hoc Tukey-Kramer tests were conducted in Matlab®.

Results: The results showed that the volunteers presented lordosis at the orthostatic position (5.1±2.1 m^{-1}) that was higher than all squat postures ($p<0.01$). The unrestricted squat with 50% of the load, was associated with a moderate lumbar lordosis (0.7±1.6 m^{-1}) that was higher than the restricted squat postures ($p<0.01$). The restricted squat postures were similar to each other and were associated with a moderate kyphosis at the lumbar spine (50% = -0.5±1.5 m^{-1}; 100% =-0.3±1.8 m^{-1}).

The data showed that happens an intense decrease of the lumbar lordosis during the squat exercise, independently of the technic adopted. However, when the knees were allowed to past ahead the toes, a posture with moderate lordosis is adopted. Differently, when the movement of the knees were restricted, the lumbar flexion was higher, and the lumbar spine presented a kyphotic posture.

Figure:



Caption: Illustration of dorsal demarcation

Conclusion: The data found at the present work shows a clear relationship between the squat technic and the spine posture. One should take into account the characteristics of each person, to choose the squat technique. To avoid kyphotic postures, one should choose a squat technique that does not restrict the forward movement of the knee.

COMPARISON OF FATIGUED AND NON-FATIGUED SQUATTING TRIALS USING MUSCLE SYNERGIES

Kenneth Smale [1,*] Mohammad Shourijeh [1] Daniel Benoit [1]

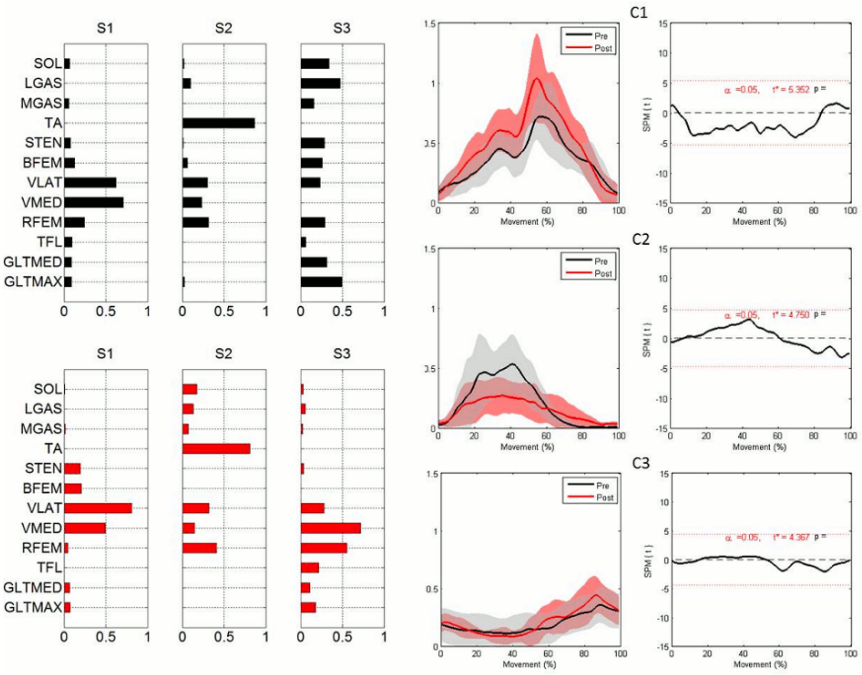
[1]Health Sciences, University of Ottawa, Ottawa, Canada

Introduction and Objectives: Humans have the ability to squat and jump with little to no conscious effort; however due to the high dimensionality of the neuromuscular system, the underlying mechanisms to perform such tasks are highly complex. Non-negative matrix factorization (NNMF) can be used to perform muscle synergy analyses, which decompose large quantities of high-dimensional EMG data into simpler components that can be used to describe the muscles' role in a certain task [1]. This procedure could be very beneficial as the shift of electrodes in relation to the underlying muscle fibres during dynamic contractions has rendered the use of traditional amplitude and frequency analyses in detecting fatigue inappropriate [2]. The **objective** of this study was to determine if muscle synergies are sensitive to detect fatigue-related changes during one and two-legged squats.

Methods: Eight healthy participants (23.8 ± 1.5y; 5 male) completed three one-leg squats on their dominant limb. To fatigue the participants, two-leg squats were completed at a pace of 35 squats/min with a standard 20.4 kg Olympic bar on their shoulders until exhaustion, which is the max value on the Borg Scale of Perceived Exertion [3]. The first three squats were used for the non-fatigued state, while the last three squats were used for the fatigued state. Once exhausted, participants completed three more one-legged squats.

Results: To account for 90% of variance in the original EMG signals, three muscle synergies (S) were needed in two-leg squats while four synergies were needed in one-leg squats. All synergy vectors had moderate to very strong correlations between fatigue states (r = 0.6 – 0.89+) except S4 of the one-legged squats. For both squat types, the coefficient (C) vectors showed no significant differences between the fatigue states (Figure). Interestingly, S3of the two-legged squats shifted from a general co-activation of all lower limb muscles pre-fatigue to a heavy weighting of rectus femoris and tensor fascia latae post-fatigue. This was reflected with a greater knee extensor moment throughout the entire cycle after as well as greater hip flexion moment at 35-65% of the squat after fatigue. Interestingly, the shift from a general co-activation of all lower limb muscles to knee extensor muscles (specifically the vastii) was also observed in S4 of one-legged squats, again suggested to correspond with an increase in knee extensor moment throughout the squat with significance occurring between 70-80% of the squat.

Figure:



Caption: Muscle synergies (S1-S3) and coefficients (C1-C3) for two-legged squats during non-fatigued (black) and fatigued (red) states. For each coefficient, the figure on the left displays the mean and standard deviation clouds for pre and post fatigue. The figure on the right displays the t-statistic continuum determined through statistical parametric mapping. The red dotted line indicates the critical threshold and when the t-value exceeds this threshold, it is statistically significant at the α = 0.05 level. SOL: soleus; LGAS: lateral gastrocnemius; MGAS: medial gastrocnemius; TA: tibialis anterior; STEN: semitendinosus; BFEM: biceps femoris; VLAT: vastus lateralis; VMED: vastus medialis; RFEM: rectus femoris; TFL: tensor fascia latta; GLTMED: gluteus medius; GLTMAX: gluteus maximus.

Conclusion: Synergy analysis revealed the last module of both types of squatting moved from a general co-activation of muscles in the pre-fatigue state to a knee extensor dominant weighting post-fatigue, which we believe is needed when the body works against gravity during the ascending phase. It was of particular interest that the more demanding one-leg squat task elucidated a more apparent shift to knee extensors than what was seen in two-leg squats. Synergy analyses have the potential to play a critical role in a clinical setting as they have the ability to elucidate reorganization of muscle activations when their efficacy has been compromised. In particular, synergies were sensitive to detect fatigue-related differences in EMG during dynamic tasks, which were supported by differences in joint moments. This is extremely beneficial as synergy analyses focus on the holistic activation of the muscle rather than individual muscle fibres like traditional amplitude and frequency analyses. In conclusion, muscle synergy analysis can be an effective technique in decomposing complex EMG signals into rudimentary modules that can identify differences in muscle activations between fatigue states.

ON THE METHODOLOGICAL IMPLICATIONS OF USING THE MUSCLE SYNERGIES CONCEPT

Alessandro Santuz [1,*] Lars Janshen [1] Antonis Ekizos [1] Adamantios Arampatzis [1]

[1] Training and Movement Sciences, Humboldt-Universität zu Berlin, Berlin, Germany

Introduction and Objectives: It has been generally accepted that the nervous system can simplify the production of movements by reducing the degrees of freedom through the creation of specific muscle activation patterns, called synergies[1]. It has been demonstrated that both human walking and running are likely to be controlled by shared synergies[2]. However, the methods used to process the EMG data, might influence the computation of muscle synergies. The purpose of this study was to investigate the outcomes and the reliability of two computational approaches ("classical" Gaussian[3] vs. Inverse-Gaussian[4] models) on muscle synergies using the non-negative matrix factorisation (NMF) approach. Furthermore, we examined the effects of the EMG processing procedures.

Methods: We recruited 20 healthy, young, adults (10 male, 10 female). The muscle activity of 24 ipsilateral muscles[5] was recorded with a wireless EMG system (myon AG, Switzerland). Ground reaction forces were recorded using a treadmill (H-p-cosmos GmbH, Germany) with an integrated pressure plate (zebris Medical GmbH, Germany). Out of the 24 recorded muscle activities, six were from the upper limb, four from the trunk and 14 from the lower limb.

The participants completed two tasks on the treadmill, in random order: shod running (2.8±0.4 m/s) and walking (1.4±0.2 m/s), both at their preferred speeds. We recorded the EMG signals during around 50 gait cycles (49±4)[6] and repeated the protocol after 15 minutes of rest, without removing the electrodes. After at least 48 h (122±84 h), the routine was repeated.

Surface EMG

The gait cycles breakdown was obtained from the pressure plate's raw data. We applied to the sEMG signals a high-pass filter (1st, 2nd and 4th order, 20, 50 and 250 Hz cut-off frequencies), a full-wave rectification and a low-pass filter (1st, 2nd and 4th order, 5, 10 and 20 Hz), creating 27 filtered and one non-filtered data sets. Each cycle was normalised to 200 data points[7] and the 50 cycles available for each trial were combined into one through averaging[6].

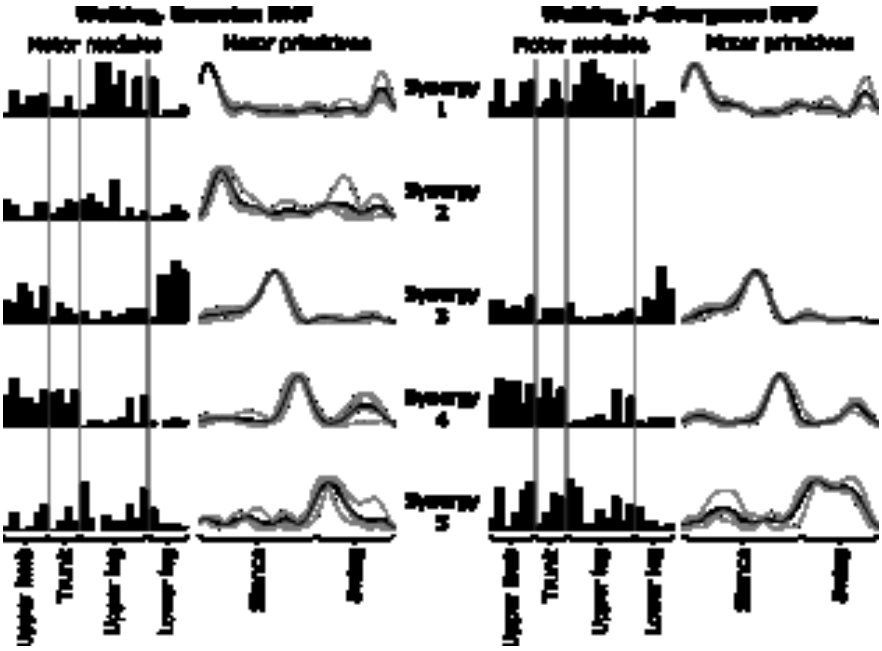
Motor modules extraction

We implemented (R Found. for Statistical Computing, Austria) two different NMF update rules for extracting motor modules. The first (GNMF) is based on maximising the Gaussian likelihood of reconstructing the original EMG signal[3]. The second (IGNMF) uses a special case of the generalized Inverse-Gaussian distribution[4]. To choose the minimum number of synergies required to represent the original signals, we applied two distinct methods. One is based on the cross-validation of the R^2 values used for describing the reconstruction quality[8]. The other uses the Akaike Information Criterion (AIC)[4] as an objective metric aiming to avoid over-fitting[9].

Results: The GNMF approach, consistently with previous findings[2], returns a similar number of synergies in both walking and running (5±1). The IGNMF approach, instead, can describe the original signal with only 3±1 synergies for walking and 4±1 synergies for running. The reconstruction quality, measured with R^2, is better after IGNMF (0.97±0.02 for walking and 0.98±0.01 for running) than after GNMF computation (0.86±0.04 and 0.85±0.04). Using the Pearson product-moment

correlation coefficient (r) for assessing the intra- and inter-day repeatability indicates a higher reliability of the IGNMF algorithm. As an example, the r-values for the inter-day repeatability of the motor primitives obtained using the non-filtered data set are the following (p<0.05): 0.48±0.34 (walking, GNMF), 0.63±0.29 (walking, IGNMF), 0.53±0.31 (Running, GNMF), 0.58±0.32 (Running, IGNMF).

Figure:



Caption: Motor modules (histograms) and motor primitives (curves) extracted with two NMF approaches for one participant during walking. The values of the motor modules are the average across four trials (two on Day1 and two on Day2). Bold curves describe the average activation patterns. Thin curves represent each single trial.

Conclusion: The filtering protocol preceding the NMF can influence both the GNMF and the IGNMF approaches. The second method shows better inter- and intra-day repeatability both in the motor modules and in the motor primitives. This is maybe due to the lower dimensionality of the resulting factorisation and it surely calls for a deeper analysis. In the future, it will be crucial to understand if the altered results are a consequence of a different description of the neurophysiological mechanisms underlying motor coordination.

INSTRUMENTED MEASUREMENT OF NEUROMECHANICAL ANKLE PARAMETERS IN CHILDREN WITH CEREBRAL PALSY

Lizeth Sloot [1,*] Marjolein van der Krogt [1] Karin de Gooijer-van de Groep [2] Carel Meskers [1] Jurriaan de Groot [2] Annemieke Buizer [1] Jules Becher [1] Erwin de Vlugt [3] Jaap Harlaar [1]

[1]Rehabilitation Medicine, VU University Medical Center, Amsterdam, [2]Rehabilitation Medicine, Leiden University Medical Center, Leiden, [3]Biomechanical Engineering, Delft University of Technology, Delft, Netherlands

Introduction and Objectives: Spastic Cerebral Palsy (CP) is a central movement disorder and characterized by increased joint stiffness, caused by a mix of increased stretch reflex activity and muscle tone, as well as tissue stiffness. Since treatment depends on the specific cause, objective quantification of the ankle neuromechanical parameters would contribute to patient-specific treatment selection. Previously developed instrumented assessment combined with neuromechanical modeling [1,2] was extended to include background muscle tone and differentiate between the three major lower leg muscles. We examined the outcomes of the extended model and its repeatability and construct validity, i.e. the ability to discriminate between patients and controls and to measure the effect of treatment targeting abnormal muscle activation.

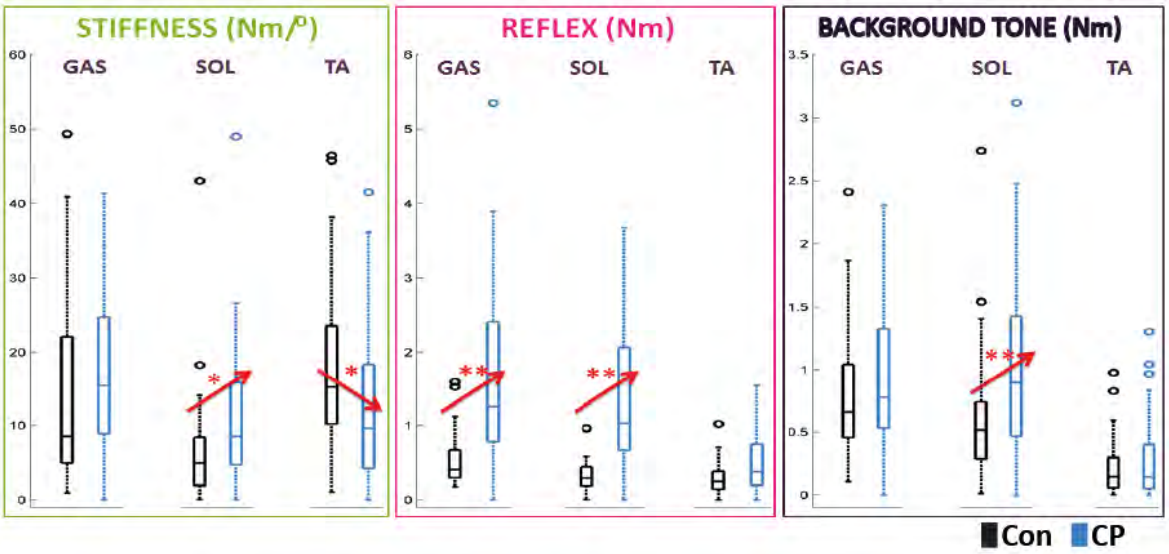
Methods: The most affected leg of 35 spastic CP patients (11.1±3.3 yr, GMFCS 1-3) and right leg of 35 controls (10.2±2.7 yr) was measured. Out of this population, 8 patients (10.3±3.5 yr, GMFCS 1-2) were measured again after 10±7 days to determine the inter-trial and between-day repeatability. Additionally, 6 patients (10.7±2.7 yr, GMFCS 1-3) were measured before and after treatment (4 received BTX-A in the calf muscles and 2 selective dorsal rhizotomy).

A motor driven footplate equipped with a force transducer and potentiometer applied 2 passive slow (5 °/s) and fast (100 °/s) ramp-and-hold rotations around the ankle joint. This was done at two different knee angles (20° and 70°) to discriminate between the triceps muscles, according to clinical conventions. Ankle angle and EMG of the gastrocnemius (GAS), soleus (SOL) and tibialis anterior (TA) muscles were used to optimize a nonlinear neuromuscular model to match the measured ankle torque. Tissue stiffness was based on the slow trials and taken at the highest plantar (40°) and dorsiflexion (5°) angle reached by all subjects. Root-mean-squares of baseline muscle activation and reflex torque were obtained from the fast trials. Repeatability was assessed using intraclass correlation coefficients (ICC), difference between patients and controls using non-parametric tests and treatment effect using t-tests.

Results: In CP, stiffness was increased by 70% in SOL (p=0.04), showed a trend of an increase by 80% in GAS (p=0.13) and was decreased by 37% in TA (p=0.03) compared to controls. Reflex activity was 3.5 and 3.1 times increased in CP for SOL and GAS (both p<0.01). Background muscle tone was increased by 70% in SOL (p<0.01). Variances were generally larger for CP and ratios between stiffness and reflex torque differed considerably between patients (Figure 1). Most parameters showed a good inter-trial repeatability with ICC ranging from 0.85-0.99, except for TA reflex and tonus (0.66 and 0.45) and GAS tonus (0.50). Between-day repeatability was lower, with ICC ranging between 0.54-0.96, except for SOL reflex and tonus (0.08 and 0.34) and GAS stiffness (0.32).

There was a trend of decreased reflex activity and a significant decrease in background muscle tone for the SOL (p=0.06, p=0.03) and GAS (p=0.10 and p=0.03) after treatment. Stiffness was not affected.

Figure:



Caption: Figure 1: Stiffness, reflex and background muscle tone for CP (blue) and controls (black) for GAS, SOL and TA. Significant differences are indicated with * (p<0.05) and ** (p<0.01).

Conclusion: We developed and evaluated an extended model to quantify neurmechanical parameters for the GAS, SOL and TA. Overall, the inter-trial repeatability of these parameters was good. Their repeatability decreased between days, likely caused by the introduced variability of electrode placement and the ability to relax of a subject. The method was suitable to discriminate between CP patients and controls. In CP, reflex torque and muscle tone were increased in the triceps surae muscles, and decreased after treatment targeting abnormal muscle activation. Stiffness showed an increase for SOL, although a difference also emerged for GAS when choosing a higher dorsiflexion angle for the analysis, and was not affected by treatment. The large variance in contribution of stiffness and involuntary muscle activation in CP indicates that instrumented assessments could contribute to patient-specific therapy selection.

The limitations of the study include a small sample size for the repeatability and treatment group, as well as the assumptions of a rigid foot, i.e. no foot deformations occurred during the movements, and a strict discrimination between SOL and GAS based on knee angle. To tackle the latter, we aim to further develop the neuromuscular model in order to optimize the model parameters simultaneously for the two different knee angles. Future research will focus on the validation of the neuromechanical parameters against current clinical and manual instrumented spasticity assessment, as well as dynamic spasticity modelled during gait.

THE EFFECT OF ANGULAR VELOCITY ON THE MUSCULAR ACTIVATION OF ELBOW FLEXORS BICEPS AND BRACHIORADIALIS

Sylvie Von Werder [1] Catherine Disselhorst-Klug [1,*]

[1] Department of Rehabilitation & Prevention Engineering, Institute of Applied Medical Engineering, RWTH Aachen University, Aachen, Germany

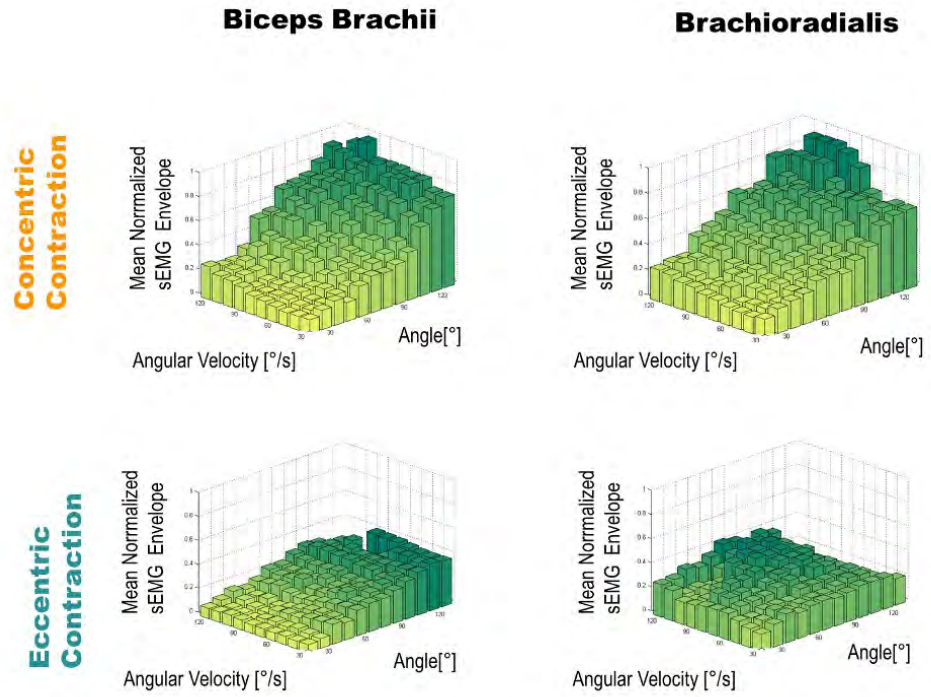
Introduction and Objectives: Elbow flexion and extension movements are incorporated into various daily living activities such as eating, dressing, using a telephone or opening a door. Thereby, daily activities involve a continuous change in movement speed. However, there is a lack of detailed observations regarding the impact of movement speed on muscular activation strategies. In that context antagonistic coordination of the biceps and triceps during isokinetic concentric exercises was evaluated and found to be not dependent on angular velocity [1]. Detailed investigations of the impact of angular velocity on the force sharing of elbow flexors are missing. Spinal pathways have been identified, describing inhibitory neural connections between biceps and brachioradialis at the spinal cord level [2], while inhibitory connections of biceps differ from those of the brachioradialis [3]. Therefore this study aims to systematically investigate the coordination patterns of two elbow flexors in different movement speeds.

Methods: Elbow flexion and extension in neutral forearm position was assessed in 12 healthy subjects (age 25.9 4.9). The measuring procedure consists of two parts: guidance of targeted movement and measurement of the performed movement. With the help of a real-time visual feedback the angular velocity was guided to be in the range of 30-120 °/s. In that context a feedback path was visualized, which included ten different categories of angular velocities with 10 °/s intervals sequenced in an arbitrary order. The measurement of the performed movement included the recording of surface Electromyography (sEMG) of biceps and brachioradialis, elbow flexion angles, as well as the corresponding angular velocities. The sEMG recordings were band pass-filtered (10-500 Hz), rectified and smoothed (moving average filter, window length 100ms) in order to compute the envelope of the sEMG signal. Normalization was conducted relative to the 75% percentile of maximal amplitude of the envelope of all measurements of each subject. With the help of a decision tree at each sampling point, the processed sEMG data was categorized into combinations of angular velocity, flexion angle and contraction type categories. Thereby the contraction type was derived from the sign of the angular velocity. Positive angular velocities represented concentric contractions, whereas negative angular velocities represented eccentric contractions. The correlation of the processed sEMG signal, the angular velocity and the flexion angle was visualized in form of a three dimensional representation, containing angular velocity on the x-, angle on the y- and mean normalized sEMG envelope on the z-axis (Figure1). Finally, changes of the categorized sEMG data of both muscles were correlated to the performed angular velocity.

Results: The three dimensional representation of the biceps and brachioradialis for concentric contractions showed an increase of muscular activity with increasing flexion angles and increasing angular velocities. A change of the relation of the muscular activation of both muscles due to the angular velocity was found for flexion angles between 60-90°, only.

For eccentric contraction the three dimensional representation of the biceps showed that with increasing flexion angles the muscular activation increased, but no impact of the angular velocity on the muscular activation of biceps was found. In contrast, for the eccentric contractions of the brachioradialis the muscular activation increased with increasing angular velocity but not with increasing flexion angles. Therefore, for eccentric contractions an impact of angular velocity on the change of the synergistic relation of both muscles was found for all angles between 0-120°.

Figure:



Caption: Mean three dimensional representations containing angular velocity on the x-, angle on the y- and normalized sEMG envelopes on the z-axis for biceps brachii (left column) and brachioradialis (right column) in concentric (upper row) and eccentric (lower row) contractions.

Conclusion: The present study showed that the movement speed correlates with a change in muscular activation of biceps and brachioradialis, however this effect is differently expressed for variant combinations of contraction type and flexion angle.

Due to the increased activation of brachioradialis in eccentric contractions with increasing velocities, the brachioradialis could be regarded as a controlling muscle, which helps to adapt the muscular coordination pattern of elbow flexors to the targeted angular velocity performance.

MUSCLE SYNERGIES AND MODULARITY IN THE RABBITS DURING NORMAL HOPPING AND JUMPING

Pavan Teja Devanaboyina [1,*] Massimo Sartori [2] Thor Besier [3] David Lloyd [1]

[1]Centre Musculoskeletal Research, Griffith University, Gold Coast, Australia, [2]Department of Neurorehabilitation Engineering, University Medical Center , Gottingen , Germany, [3]Auckland Bioengineering Institute, University of Auckland , Auckland, New Zealand

Introduction and Objectives: Musculotendon forces are needed to understand the strain distribution in human and animal tendons. In animals, implantable buckle transducers are used to measure tendon forces. However, this invasive procedure causes tendon damage and abnormal movement. Alternatively, forces can be estimated by less invasive methods using neuromusculoskeletal models driven by neural signals derived from muscle synergies extracted from electromyography (EMG) [1, 2]. Muscle synergies are a low-dimensional set of synergy excitation primitives (XPs) and muscle weightings [3] that are decomposed from high-dimensional, multi-muscle set of EMGs.

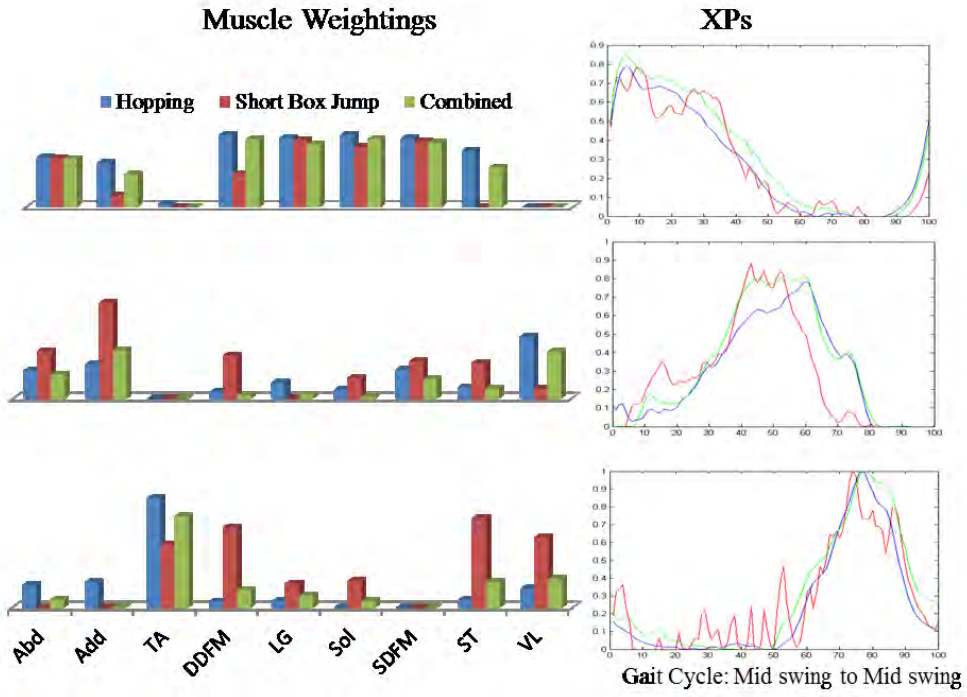
We aimed to see if muscle synergies could be used to characterise the muscle activation patterns used by rabbits across different locomotion tasks, the first step to enable subsequent estimation of musculotendon forces and Achilles tendon strain. In rabbits, *in-vivo* recordings from a large number of EMG channels is not feasible. So we created a comprehensive EMG dataset that characterizes the electrophysiological activity of a larger number of muscles by combining EMG recordings from various muscles and rabbits across different motor tasks. The comprehensive EMG datasets were decomposed into low-dimensional muscle synergies XP and weightings. We then examined if the same set of XPs could be used to recompose the muscle EMG patterns across the range of motor tasks.

Methods: Four healthy rabbits performed 2 locomotor tasks: 1) normal hopping, and 2) short box jump. A Noraxon system recorded EMGs at 1000 Hz from 5-to-7 bipolar fine wire electrodes inserted in each rabbit's left hindlimb muscles. This resulted in EMGs recorded from 9 muscles in total: abductor cruris cranialis (Abd), Adductor (Add), semitendinosus (ST), vastus lateralis (VL), superficial digital flexor (SDFM), deep digital flexor (DDFM), tibialis anterior (TA), lateral gastrocnemius (LG), and soleus (Sol). EMG data were band-pass filtered (30-400 Hz), full-wave rectified, and low-pass filtered (10 Hz) to create EMG linear envelopes. These were amplitude-normalised to the peak processed value on a trial-by-trial basis and time-normalised to 100 data points. Processed and normalised EMGs across all rabbits and trials were averaged and concatenated to create 3 EMG datasets: 1) normal hopping, 2) jumping, and 3) combination of normal hopping and jumping. For each EMG dataset, non-negative matrix factorisation (NNMF) [3] was applied to extract the XPs and weightings. The number of synergy modules were increased until the variation accounted for (VAF) was greater than 95%. For each EMG dataset the corresponding XPs and weightings were linearly recombined to reconstruct the each muscles EMG patterns and were compared to the measured EMG patterns using Pearson correlations for each task.

Results: NNMF extracted 3 XPs and weightings (Fig. 1), which had VAF more than 95% for all the EMG datasets. For the hopping motor task the averaged correlation between the measured and reconstructed EMG patterns was 0.78, 0.54 and 0.77 when using hopping, short box jump and combined EMG dataset respectively (Table 1). For the short box jump

motor task the correlation values were 0.47, 0.67 and 0.55 when using hopping, short box and combined EMG dataset respectively.

Figure:



Caption: Fig 1: Muscle synergies extracted from three EMG datasets

Conclusion: We derived synergies that explain neuromuscular control strategies across 9 muscles, 4 rabbits and 2 motor tasks. The combined EMG dataset synergies were not able to improve the prediction of the measured EMG patterns when compared to corresponding task specific synergies. Therefore for the future simulations the task specific synergies should be used for calculating musculoskeletal forces and tendon strain distribution.

Table:

Tasks	Hopping EMG dataset	Short box jump EMG dataset	Combined EMG dataset
Hopping	0.78±0.23	0.54±0.39	0.77±0.22
Short box jump	0.47±0.41	0.67±0.28	0.55±0.40

AS-0337

ANTICIPATED MUSCULAR SYNCHRONIZATION IN BAREFOOT CROSS-SLOPE WALKING

Anna S. Estermann [1 2,*] Lea Nösberger [1 2] Lukas Stammler [2] Vinzenz von Tscharner [3] Beat Göpfert [4 5]

[1]Health Division, Bern University of Applied Sciences, Bern, [2]BZG, Bildungszentrum Gesundheit Basel-Stadt, Münchenstein, Switzerland, [3]Human Performance Laboratory, University of Calgary, Calgary, Canada, [4]Center of Biomechanics, University of Basel, [5]Laboratory for Movement Analysis Basel, Children's University Hospital Basel (UKBB) Basel, Basel, Switzerland

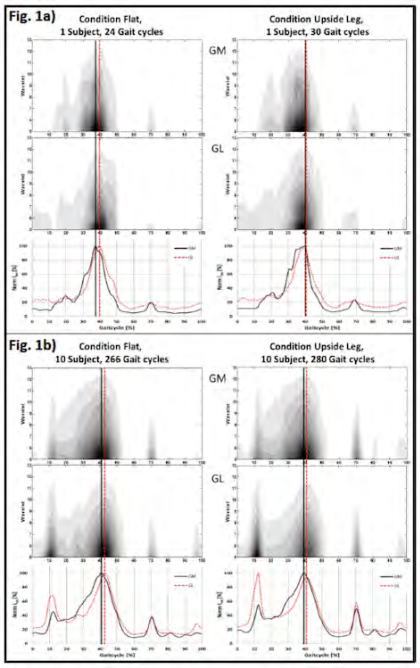
Introduction and Objectives: Movement adaptations are necessary to perform our daily activities. These adaptations are often done automatically, like varying the walking movement while passing a cross-sloped surface. Therefore we anticipate our muscular activation pattern with a slightly alternation to accomplish the movement task in an appropriated way, that may increase safety or performance.

The goal of this study was to analyze the anticipated muscular activity and the inter-muscular synchronization while walking barefoot on flat and cross-sloped surface within each and overall subjects.

Methods: A 3D-gait-analysis (Vicon, 12 Cameras T20) with a synchronous surface electromyogram (EMG) (Myon, 2400Hz) of the right leg muscles: Tibialis anterior (TA), Peroneus longus (PL), Gastrocnemius medialis (GM) and lateralis (GL), Vastus medialis (VM) and lateralis (VL), Rectus femoris (RF), Semitendinosus (ST) and Biceps femoris (BF) was done. 10 subjects (f, 22-25y) walked at a self-selected speed on flat and cross-sloped surface (6°). 10 trials of each condition and surface were measured: flat (F), cross-slope up-side-leg (US), cross-slope down-side-leg (DS). The time was normalised over a gait-cycle, the averaged kinematic data and the normalized Wavelet-Transformed-EMG Total-Intensity (I_{tot}) of the wavelets 5 to 8 with the center frequencies: 92; 128; 170 and 218 Hz were analyzed within a gait-cycle for each subject and overall subjects while walking on the different conditions.

Results: The results show a significant difference in the stance-phase for the knee flexion and ankle dorsi-flexion between the conditions flat and cross-slope down-side-leg as well as for cross-slope up-side-leg and down-side-leg for all 10 subjects. The overall mid-stance muscular adaption of one representative subject show e.g. on the flat surface is the GM-I_{totMAX} 2.4% before the GL-I_{totMAX} (Fig. 1a left), while for the cross-slope up-side-leg condition GM-I_{totMAX} is 0.3 % ahead of the GL-I_{totMAX} (Fig. 1a right). The results overall subjects show that GM-I_{totMAX} is significant earlier than GL-I_{totMAX}: 1.8 % (SD: 1.6% p: 0.016) on the flat surface (Fig. 1b left) and 3% (SD: 2.4%, p: 0.016) for the cross-slope down-side-leg, There is no significance for the cross-slope up-side-leg with 2% (SD: 2.5%, p: 0.081) (Fig. 1b right). The intra-muscular temporal shifts between the 3 conditions are for the GM-I_{totMAX} in the cross-slope up-side-leg 1.3% (SD: 2.5%, p: 0.26) and down-side-leg 1.7% (SD: 2.8%, p: 0.19) earlier than on flat surface, and the GL-I_{totMAX} is in the up-side-leg 1.1% (SD: 2.0%, p: 0.91) and the down-side-leg 0.5% (SD: 1.9% p: 0.41) earlier than on the flat surface.

Figure:



Conclusion: The results show that the movement, even with small changes in the surface condition lead to a delectable adaption in the kinematic and muscular activation pattern. The variation in the surface requires also a new synchronisation pattern of the muscular interplay similar as Wakeling [1] showed with the muscle tuning by varying the shoe elasticity. These optimising processes may be performed by a feed-forward controlling system and can therefore be seen as an anticipated muscular synchronization. This is necessary in adjusting our neuromuscular activity pattern in daily movement tasks. Further, the measured time shifts of the I_{totMAX} between the 3 conditions were small. A range of 1% corresponds to about 10 ms for the measured gait-cycle time of approximate 1s. Although it is known that small neuromuscular changes may lead e.g. to Patellofemoral Pain Syndrome due to a delayed onset of the VM vs. VL [2; 3], or increase the risk of ACL-Ruptures [4] due to a different muscular activation pattern of the ST. However neuromuscular training may increase the ability in anticipated muscular synchronization, which reduces the risk of injuries dramatically [5; 6] and increases the performance in sport [7].

Conclusion: The anticipated muscular synchronization adapts to the task and is an important aspect of neuromotor control required for performing the neuromuscular demands of everyday movements.

AS-0338

A MULTIDIMENSIONAL MODEL OF CHANGES IN KNEE JOINT MECHANICS DURING GAIT AFTER TOTAL KNEE ARTHROPLASTY

Janie Wilson [1] Jereme Outerleys [1,*] Cheryl Kozey [1] Michael Dunbar [1]

[1] Biomedical Engineering, Dalhousie University, Halifax, Canada

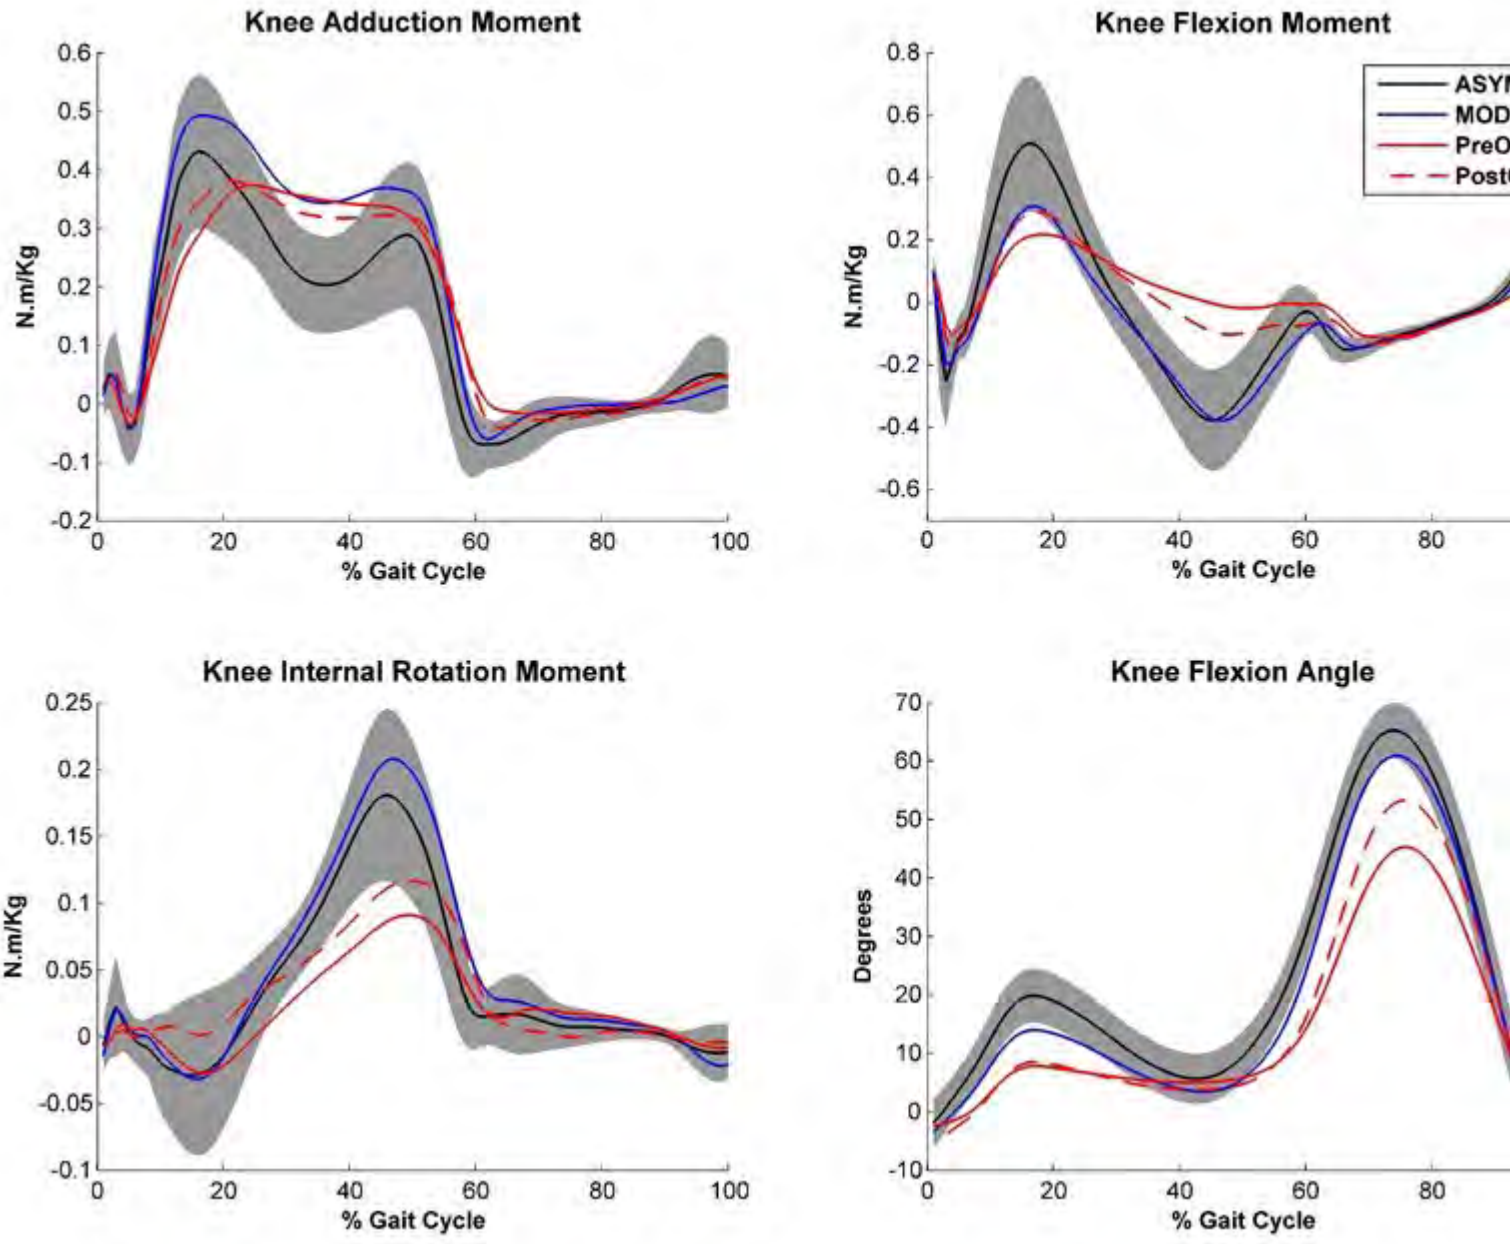
Introduction and Objectives: Total knee arthroplasty (TKA) surgery is the treatment of choice for those with severe knee osteoarthritis (OA). A primary aim of TKA is to improve knee joint function in daily activity. Surgery has been shown to improve knee joint kinematics and kinetics towards asymptomatic patterns, but variability and residual deficits remain post-operatively[4]. It is difficult to interpret multiple, often correlated, changes in gait mechanics simultaneously. The objective of this study was to use principal component analysis (PCA) on discrete knee kinematic and kinetic metrics to extract uncorrelated, multidimensional gait features, and to compare the gait mechanics pre-TKA to post-TKA, and relative to asymptomatic and early/moderate knee OA cohorts.

Methods: 46 patients (17M, 29F) diagnosed with severe knee OA and scheduled for primary TKA surgery underwent a 3D gait analysis 1 week prior to, and 1 year after, their TKA. Sixty asymptomatic adults and 60 with early/moderate knee OA also underwent gait analysis. Average 3D joint kinematics and kinetics were calculated at self-selected speeds and normalized to 100% of the gait cycle. TKA patients received 1 of 3 similar implant designs. Discrete gait knee mechanics metrics, reported in the literature[2], were extracted from all 166 subjects, and entered into a PCA (166 observations on 11 variables). Variables included average gait speed, stance and swing phase knee flexion angles, flexion angle range, peak flexion moment, peak extension moment (late stance), peak extension moment (early stance), peak rotation moment, first and second peak of the adduction moment, and the mid-stance adduction moment. PCscores were calculated for all subjects for the first three extracted PCs. Variables within each PC were interpreted if their coefficient was at least 50% of the maximum coefficient, and if their correlation with the PC was at least 50%[1]. ANOVA models with Tukey post hoc examined differences in PCs for the four groups ($\alpha = 0.05$).

Results: PC1, PC2, PC3 captured 43.8%, 25.5% and 9.6% respectively of the original data variability among subjects (cumulatively 79%). Gait speed, peak stance and swing flexion angle, range of flexion angle, peak early stance and late stance extension moment, and peak rotation moment in late stance had significant correlation and high, positive and equal weighing on PC1. Higher PC1 scores were associated with faster speed, more flexion, and higher peak extension and rotation moments. Thus PC1 was interpreted as a sagittal plane/speed metric, with higher scores related to higher function. Asymptomatic PC1 scores were significantly higher than all others ($P<0.03$), early/moderate OA were significantly higher than pre/post-TKA ($P<0.0001$), and post-TKA was significantly higher than pre-TKA ($P<0.0001$) (Table 1, Figure 1). PC2 had high correlation and high positive coefficients from the first and second peak adduction moments, and the mid-stance minimum of the adduction moment. PC2 was interpreted as capturing the overall magnitude of the knee adduction moment during stance, including not just peak values, but mid-stance as well. Asymptomatic PC2 scores were significantly lower than early/moderate OA and pre-TKA ($P<0.001$), meaning lower overall adduction moments throughout stance. Post-TKA PC2 scores were not significantly different than any other group ($P>0.05$). PC3 was

dominated by the peak flexion moment in stance, with high scores associated with higher peak flexion moments. Statistically significant differences in PC3 were observed between the asymptomatic and early/moderate OA group (P=0.017), with asymptomatic having higher peak moments.

Figure:



Caption: Mean gait waveforms

Conclusion: Summarizing pre to post-TKA gait mechanics changes in a few key, objectively extracted features, suggests that there is room for functional improvement post-TKA in terms of sagittal plane movement, loading and gait speed. PC1 captured significant differences among all groups, with a small, significant improvement in this metric post-TKA relative to pre-TKA. The post-TKA group was still lower than both asymptomatic and moderate OA, meaning that this aspect of gait

is not being restored. PC2 captured the overall magnitude of the adduction moment, similar to PCs from knee adduction moment waveforms[3]. The moderate and pre-TKA groups had higher adduction moments than asymptomatic, but the post-TKA group's distribution overlaps with the asymptomatic group, suggesting improvements in terms of lower adduction moments. These results also highlight that there are interrelationships among different combinations of discrete gait variables that may benefit interpretation by being combined by PCA.

NON-INVASIVE STIFFNESS ALTERATION DURING FRACTURE HEALING BY USE OF A NOVEL SHAPE MEMORY OSTEOSYNTHESIS.

Manuel Krämer [1,*] Christian Müller [2] Ronny Pfeifer [3] Sebastian Decker [2] Karen Meier [4] Christof Hurschler [1]

[1]Laboratory for Biomechanics and Biomaterials, [2]Department of Trauma Surgery, Hannover Medical School, [3]Laser Zentrum Hannover e.V., [4]Small Animals Clinic, University of Veterinary Medicine, Hannover, Germany

Introduction and Objectives: The fracture healing of bones is highly influenced by biological parameters and biomechanical stimuli. These mechanical conditions are determined by the stiffness of fixation and loading. Fixation in an optimal stiffness range stimulates bone healing by callus formation. Latest studies have shown that the progress of healing can be influenced by modulating the fixation stiffness during fracture healing [1]. In the literature concepts for the dynamization as well as for the inverse dynamization of the fracture fixation are lively discussed [1], [2]. However, alterating the stiffness of the fixation non-invasivly is so far only possible by use of a Fixateur externe. In the present study a novel Nickel-Titanium shape memory plate osteosynthesis is applied that allows contact-free stiffness modulation after fracture fixation [3]. The study was designed to test the following hypothesis: A novel shape memory plate stabilizes tibia osteotomies in rabbits and allows for fracture healing. After non-invasive electromagnetic induction heating three weeks post op. the plate changes its configuration towards a state of higher stiffness.

Methods: Prototype six-hole osteosynthesis plates were constructed and manufactured by laser based cutting and welding. The plates were manufactured from commercially available Nickel-Titanium alloy sheets. The design allows for change of shape and therewith bending stiffness. For the present study a plate which follows the concept of inverse-dynamization was realized. The modulation is triggered by warming the implant up to 50°C for a short period of time by use of electro-magnetic induction heating.

14 Rabbits were treated with prototypic plates after tibia osteotomies have been performed. Furthermore, four k-wires were implanted in each treated limb for in-vivo bending measurements.

Three weeks after procedure, animals were divided in two randomized groups. Stiffness alteration of the plate was performed only in one group by electromagnetic induction warming.

Repetitive in-vivo bending stiffness measurements were performed by use of an in-vivo bending stiffness test rig [4].

All Animals were sacrificed after six weeks. Tibiae were analysed morphologically by x-ray, µCT, and histology. The implants were explanted and bending tests of the tibiae were carried out.

Results: One rabbit died from anaesthesia during the induction warming procedure and one animal fractured its hind leg two days post op and was therefore sacrificed. The shape change of the implant in vivo could be observed radiographically during induction warming. There were no signs of implant loosening or displacement. Comparison between bending stiffness within minutes before and after induction warming confirmed a significant increase of mean bending stiffness of the tibiae ($p<0.05$). All osteotomies healed within six weeks. However, the ex-vivo bending tests showed not significant differences in stiffness between the two groups ($p>0.05$). The µCT showed successful bone

healing for both groups. The measured parameters such as bone volume, cortical wall thickness etc. showed no significant differences between both groups ($p>0.05$).

Conclusion: To the best of our knowledge, the present work is the first study applying the idea of inverse dynamization to an internal fracture fixation plate. We have demonstrated a successful application of a novel shape memory plate system for the stabilization of tibia osteotomies in rabbits. The contact-free triggering of the shape alteration of the plate could be approved and resulted in an expected increase of stiffness. Successful fracture healing was observed in all cases. These results contribute to the development of novel concepts for bone fixation that might lead to better fracture healing and less need for surgical interventions. Furthermore, in future this concept might be used for counteractions in cases of non-union.

THE INFLUENCE OF KINEMATIC CONDITIONS ON THE WEAR OF UHMWPE ARTICULATING AGAINST PEEK OPTIMA FEMORAL COMPONENTS

Raelene M. Cowie [1,*] Adam Briscoe [2] John Fisher [1] Louise Jennings [1]

[1]University of Leeds, Institute of Medical and Biological Engineering, Leeds, [2]Invibio Biomaterial Solutions, Thornton Cleveleys, United Kingdom

Introduction and Objectives: PEEK Optima has the potential for use as an alternative bearing material in joint replacement to give metal-free joints [1]. In this study, the novel bearing couple of PEEK articulating against polyethylene was investigated to ascertain whether PEEK would be a viable alternative for use as the hard bearing material in total knee replacements. The wear of all polyethylene tibial components articulating against PEEK femorals was assessed and compared to the wear against cobalt chrome femorals of similar surface topography and geometry in a knee simulator. To further investigate the appropriateness of this material, enhanced preclinical tests were carried out beyond the ISO standard.

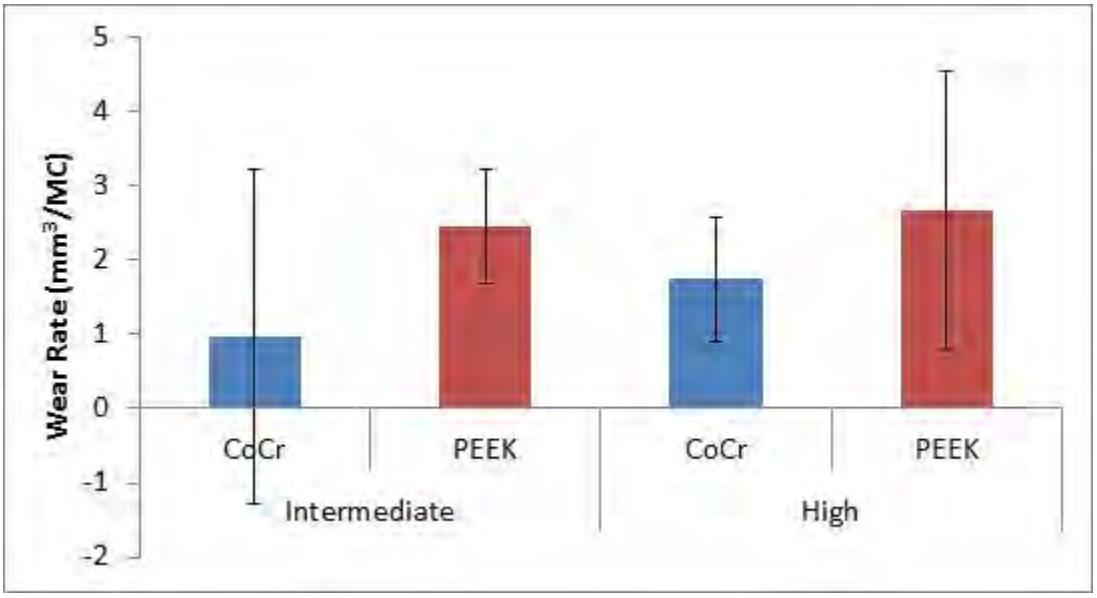
Methods: Three cobalt chrome (initial Ra ~0.02μm) and three moulded PEEK Optima (initial Ra ~0.02μm) femoral components (Invibio Biomaterial Solutions Ltd., UK) of similar surface topography and geometry were paired with GUR 1020 all polyethylene tibial components (conventional, unsterilised) in a 6 station ProSim knee simulator (Simulation Solutions, Manchester). Experimental knee simulation was carried out under displacement control with an anterior posterior translation of either 5mm (intermediate kinematics) or 10mm (high kinematics) [2] for 3 million cycles (MC) for each condition and using 25% serum as the lubricant. Wear of the UHMWPE tibial components was assessed by gravimetric analysis with unloaded soak controls used to compensate for the uptake of moisture by the samples. Changes in the surface topography of the bearing surfaces was measured using a contacting Form Talysurf (Taylor Hobson, UK) pre-test and at each measurement point; the temperature of the bulk lubricant was monitored close to the articulating surfaces. Statistical analysis was carried out using ANOVA, data was considered significant at $p<0.05$.

Results: Following 3MC of wear testing under intermediate kinematics, the wear rate of UHMWPE tibial components articulating against cobalt chrome femoral components was 0.97±2.26 mm^3/MC, which was similar ($p=0.06$) to that against PEEK femoral components 2.45±0.77 mm^3/MC (Figure 1). There was linear scratching on the surface of the femoral components in the principle direction of sliding, which was more evident on the PEEK components resulting in a mean surface roughness (Ra) of 0.03±0.04μm for cobalt chrome and a significantly ($p=0.009$) higher surface roughness of 0.23±0.18μm for PEEK; there was a polished region on the tibial components denoting the wear area. Following a further 3MC under high kinematics the wear rate was similar for both PEEK ($p=0.659$) and cobalt chrome ($p=0.240$) compared to intermediate kinematics (Figure 1), this may be due to the low conformity of the implant [3]. There was no significant change in the surface roughness of the femoral components following 3MC of high kinematics.

The mean temperature of the bulk lubricant under intermediate kinematics was 28.0±0.7°C for cobalt chrome and for PEEK was significantly higher at 29.5±0.1°C ($p<0.001$), changing from intermediate to high kinematics had no effect on

the lubricant temperature. The increased temperature may be a result of the higher friction of the PEEK bearing couple [4] but may also be an artefact caused by continuous running of the simulator.

Figure:



Caption: Figure 1: Wear rate per million cycles (± 95% confidence limits) of GUR 1020 UHMWPE tibial components articulating against either cobalt chrome or moulded PEEK femoral components in a knee simulator tested under intermediate and high kinematics (n=3).

Conclusion: The wear of UHMWPE tibial components was comparable when tested against PEEK and against a conventional material, cobalt chrome. This study shows that PEEK Optima has the potential for use as the femoral component in total knee arthroplasty.

WEAR ASSESSMENT OF TOTAL KNEE PROSTHESES USING HIGH DEMANDING DAILY ACTIVITY WAVEFORM

Saverio Affatato [1,*] Sami Abdel Jaber [1] Claudio Belvedere [2] Alberto Leardini [2]

[1]Medical Technology Lab, [2]Movement Analysis Laboratory, Istituto Ortopedico Rizzoli, Bologna, Italy

Introduction and Objectives: Total knee arthroplasty (TKA) is a consolidated orthopaedic procedure in case of severe knee arthropathies [1]. Unfortunately, as there is a good survival rate of primary TKA (92 to 100%), failures occur for factors concerning the polyethylene composition of the implants, secondary osteolysis, and ultimately loosening of the implants are the usual causes of failure after normal use [2].

Dynamic in vitro testing of the human knee continues to be an area of interest to the orthopaedic biomechanics community. A number of different styles of machines with varied capabilities have been designed to simulate the loads and motions of the knee. For the implementation of realistic loading scenarios during *in vitro* wear testing for human joint prostheses, typical frequency and duration of daily living activities are necessary. For this reason, wear analysis is moving towards the implementation of other daily living activities, in order to better describe and investigate prosthesis wear resistance, also with the goal to offer better versatility to include those patients that are expected to recover full mobility.

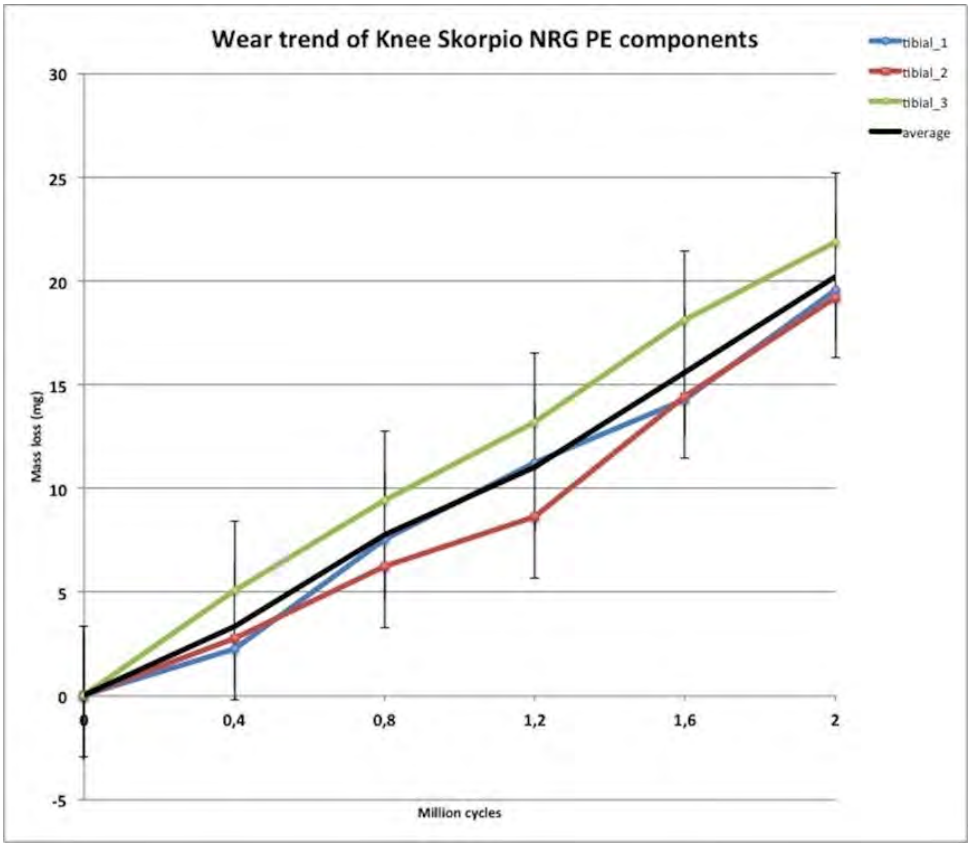
The objective of this study is to perform a knee wear test applying a previous validated protocol for *in vitro* wear simulation of stair climbing [3]. A collection of pertinent real human motion data obtained by fluoroscopy and gait analyses on 15 patients operated at our Institution, were elaborated and adapted to apply onto our knee simulator in order to simulate a highly demanding daily activity (HDDA).

Methods: Four commercial cruciate-retaining fixed-bearing component prosthesis for TKA were tested in this study (Stryker®-Orthopaedics, Mahwah, NJ-USA). These were new and delivered in sterilized packages. Particularly, corresponding UHMWPE tibial inserts (size #7) were made of conventional surgical grade polyethylene resin (GUR 1020), consolidated by compression moulding (accordingly to ISO 5834/1-2), and EtO sterilized. These were tested in conjunction with corresponding CoCrMo alloy femoral components. Following a standardized protocol the UHMWPE tibial components were pre-soaked for 4 weeks prior to the wear tests in order to achieve a steady level of fluid absorption as recommended by the international standard (ISO 14243-2).

The applied kinematics was derived from a study based on fluoroscopic analysis [4], where fifteen patients that underwent TKR were analyzed during stair climbing at 6 months' follow-up using standard 3D video-fluoroscopy technique. Axial input load data were derived from a previous study based on twenty healthy patients using standard gait analysis synchronized with two force plates during the same exercise [5].

Results: The components run under HDDA-Simulation completed the planned two million cycles under bovine calf serum as lubricant. The mass loss is showed in Figure 1.

Figure:



Caption: Figure 1 - Wear behaviour of the knee PE components run under HDDA motor task.

Conclusion: The knee simulator successfully executed the imposed physiological gait conditions under HDDA. To our knowledge, no previous studies have reported on a similar method. Essner et al. simulated Stair climbing activity on the Scorpio® PS tibial inserts design. However, in this study, simulation inputs were based on literature references [6]. Recently Schwiesau et al. [7] reviewed relevant published works and combined FE, AP and IE joint motion data from a number of different sources, which involved different motor tasks. The present experimental protocol and the relevant results, initially for stair climbing, may in fact open the way to understanding whether the present ISO 14243 standards, based on level walking alone, are a good representation of typical wear in TKR. Accordingly, the next step of this study might be using this new protocol to compare the results here reported with those obtained using traditional ISO 14243 applied on the same prosthesis design and size as in this study.

SURGICAL TRANSLATIONAL MALPOSITION AFFECTS THE LEVEL OF THE DYNAMIC MICROSEPARATION, THE SEVERITY OF EDGE LOADING AND THE WEAR IN TOTAL HIP REPLACEMENTS

Oscar O'Dwyer Lancaster-Jones [1,*]Mazen Al-Hajjar [1]Sophie Williams [1]Louise Jennings [1]Jonathan Thompson [2]Graham Isaac [2]John Fisher [1]

[1]Mechanical Engineering, Institute of Medical and Biological Engineering, [2]DePuy Synthes Joint Reconstruction, Leeds, United Kingdom

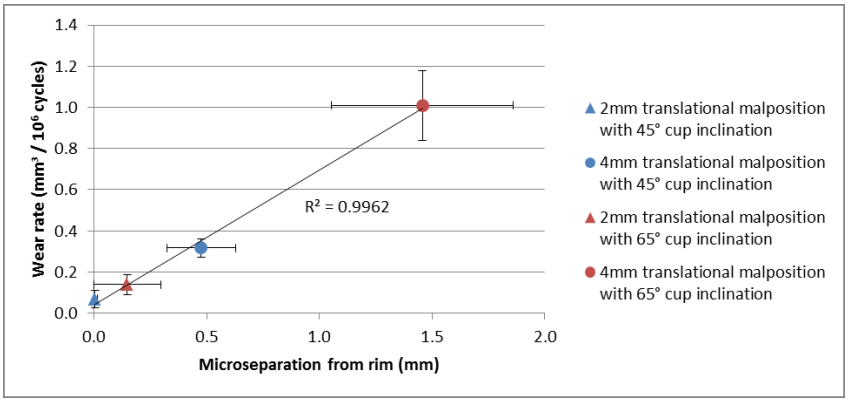
Introduction and Objectives: Hip joint replacement is a successful treatment for osteoarthritis and restores the mobility and function of the joint. However, the demands on these implants are increasing and patients want to continue with an active lifestyle. Pre-clinical testing standards assume optimal component position and do not account for the surgical and anatomical variations. Research has indicated that about 50% of acetabular cups are mal-orientated [1]. Cup malposition is a factor which has been shown to contribute to failure. Stripe wear has been observed on the surface of ceramic retrievals and has been associated with edge loading conditions [2]. It is well established that microseparation, where edge loading occurs due to translational malposition [3], increases the wear of hard-on-hard bearings [4, 5] and the possibility of failure. However, the influence of different levels of translational malposition, and the effect on wear has not been evaluated yet. Hence, it is important to understand the variables which affect the occurrence of edge loading. Many factors contribute to edge loading conditions; laxity of the joint, orientation of the cup and rim geometry of the cup. The aim of this study was to determine the effect of different surgical translational and rotational malposition on the level of dynamic microseparation, severity of edge loading and wear in total hip replacements.

Methods: Ceramic coupled bearings (36mm, BIOLOX® delta) were tested in a six-station Leeds Mark II Physiological Anatomical Hip Joint Simulator. The ceramic liners were inserted into titanium alloy shells (Pinnacle®, DePuy Synthes, UK). A standard twin peak load (3kN and a swing phase load of approximately 70N) walking cycle (flexion/extension +30˚/15° and internal/external ±10˚ rotation) was applied. New-born calf serum (25% v/v), supplemented with 0.03% sodium azide to retard bacterial growth, was used as lubricant. Two levels of translational malpositioning were used in this study where the level of mis-match between the reconstructed rotational centres of the head and the cup were set to 2mm and 4mm in the medial-lateral axis. Two cup inclination angles were assessed; an equivalent to 45° *in vivo*, representing an optimal anatomical position, and an equivalent to 65° *in vivo*. Four conditions were investigated in total (Table 1) with three million cycles completed under each condition. The wear was determined gravimetrically using a microbalance (XP205, Mettler Toledo, UK), and the depth of the wear stripe was measured geometrically using a Coordinate Measuring Machine (CMM, Legex 322, Mitutoyo, UK) every million cycles. The dynamic microseparation was checked routinely and measured by a Linear Variable Differential Transformer (LVDT). Mean wear rates and 95% Confidence Limits (CL) were determined and statistical analysis (one way ANOVA) completed with significance taken at $p<0.05$.

Results: A steep angle (65˚) resulted in a significantly higher level of dynamic microseparation and higher wear than the optimal cup angle for a given level of translational malposition (2mm ($p=0.02$) and 4mm ($p<0.01$)). The larger dynamic microseparation correlated with a higher wear rate for both cup inclination angles (Figure 1). The mean wear rates ±95%

CL for the 2mm translational malposition conditions for the cup inclination angle of 45° and 65° were 0.07±0.04mm³/10⁶ cycles and 0.14±0.05mm³/10⁶ cycles respectively. The final depth of the wear scar was 3±1μm and 8±3μm respectively. When a higher level of translational malposition (4mm) was applied the mean wear rate for the 45° and 65° increased to 0.32±0.04mm³/10⁶ cycles and 1.01±0.07mm³/10⁶ cycles respectively. The final depth of the scar also increased to 15±3μm and 33±6μm respectively.

Figure:



Caption: Mean wear rate of ceramic-on-ceramic bearings versus medial-lateral dynamic microseparation displacement under different testing conditions

Conclusion: This *in vitro* simulation showed the influence of cup inclination angle for a given translational malposition. The cups with a 45° inclination angle showed greater resistance to dynamic microseparation with the translational force applied medial-laterally. These results demonstrate that when a higher level of translational malposition is coupled with a rotational malposition, the damage caused due to edge loading conditions is greater than when tested with the cup in an optimal position. Future work will look into the factors which are considered to influence these results; the magnitude of the medial-lateral force, joint laxity and the magnitude of the joint reaction force during the swing phase.

Table:

	Translational malposition	
Cup inclination angle	2mm	4mm
45°	n=6	n=6
65°	n=6	n=6

EFFECT OF ANTIBIOTICS AUGMENTATION AND OPERATING TEMPERATURE ON IMPACT RESISTANCE OF ORTHOPEDIC BONE CEMENT

Maryam Kalantari [1,*]Ata Hashemi [1]

[1]biomedical engineering, Amirkabir University of Technology, Tehran, Iran, Islamic Republic Of

Introduction and Objectives: Bone cement has been used in joint replacement, and some surgeons advocate using antibiotic-impregnated PMMA bone cement prophylactically for all joint replacement surgeries. However, in the most cases, the mechanical strength of the bone cement is shown to be reduced by addition of antibiotic. Different mechanical tests have been utilized to characterize the mechanical properties of bone cements but there is few documents that focuses on the impact resistance of the bone cement. In the present study, the impact tests were carried out to investigate the different temperature and aging condition on the impact resistance of antibiotic loaded bone cements.

Methods: The C~ment® bone cement was used to prepare the test samples, in accordance with ASTM D256-06, the standard test methods for determining the pendulum Impact resistance of notched specimens of plastics. The bone cement components were mixed according to the medical guideline, used by surgeons. Except the control bone cement samples, bone cement samples were also mixed with gentamicin or vancomycin antibiotics. Then, the mixed bone cement was transferred to the mold. The solidified samples, i.e., the control, with gentamicin or with vancomicin groups were divided in 3 subgroups, the first were kept in ambient temperature (air) of 23°C, the second at 23°C saline, and the third one at 37°C saline. All test groups were maintained in their respective storage environments for two weeks before subsequent testing. To carry out the test, individual samples were first placed on the sample platform and centered. An impact tester with the capability of delivering energy of 3J is used to perform the tests. The specimens were carefully examined to ensure that the nominal values are in the allowable range. In addition, only samples with no surface defects were considered for testing. The tests were carried out on a bench-top impact testing machine (Ueshima IM-1100, Tokyo, Japan).

Results: The impact strength of control samples aged in air was obtained to be 3.28±0.26 while that of gentamicin and vancomycin loaded samples, respectively, was 2.13±0.09 and 2.13±0.35. The mean impact strength of all three group samples aged at 23°C saline was slightly higher than that found for samples aged in air. That of control samples was 3.64±0.31 while that of gentamicin and vancomycin augmented samples was 2.45±0.4 and 2.72±0.15, respectively. The mean impact strength of all samples aged at 37°C saline was found to be significantly lower for all three groups ($p<0.05$). According to the results, the control samples aged in saline at 23°C have the highest impact resistance and gentamicin loaded samples aged in saline at 37°C have the lowest resistance. Furthermore, reduction in the impact energy is minimum for vancomycin loaded samples aged in saline at 23°C.

Conclusion: Present study investigated the impact strength of antibiotic loaded bone cement at different storage conditions and temperatures. The results show that addition of 1.25 wt/wt % gentamicin/vancomycin significantly reduces the impact strength of the samples ($p<0.05$). Control samples aged in saline at 23°C have the highest impact energy and

gentamicine loaded samples aged in saline at 37°C have the lowest resistance. Reduction in the impact energy is minimum for vancomycin loaded samples aged in saline at 23°. Furthermore, it is observed that the samples aged in saline at 23ºC are more resistant than the samples aged in air at 23ºC. The effect of storage temperature was also studied showing that the impact strength decreases by increasing the aging storage temperature ($p<0.05$).

EXTRACTION OF PROTECTIVE REACTION IN CASES OF INDOOR FALL BEHAVIORS USING CHANGE POINT DETECTION METHODS

Masato Ito [1,*] Akira Mano [2] Yusuke Miyazaki [1] Ryoji Watanabe [3] Yoshifumi Nishida [4]

[1]Department of Mechanical and Environmental Informatics Graduate School of Information Science and Technology, [2]Mechanical and Environmental Informatics, Tokyo Institute of Technology, 2-12-1, Ookayama, Meguro-ku, Tokyo, [3]Analysis Center, Panasonic Corporation, 1048 Kadoma, Kadoma City, [4]National Institute of Advanced Industrial Science and Technology , 2-3-26, Aomi, Koto-ku, Tokyo, Japan

Introduction and Objectives: Human falls represent daily accidents. In fact, over half of all nonfatal childhood injuries result from falls, in accordance to a report issued by the World Health Organization [1]. In addition, the elderly often suffer from fall-related accidents and in many cases these lead to fatal injuries. Therefore, methods are necessary to evaluate risks of fall for minimizing injuries and reducing associated social costs.

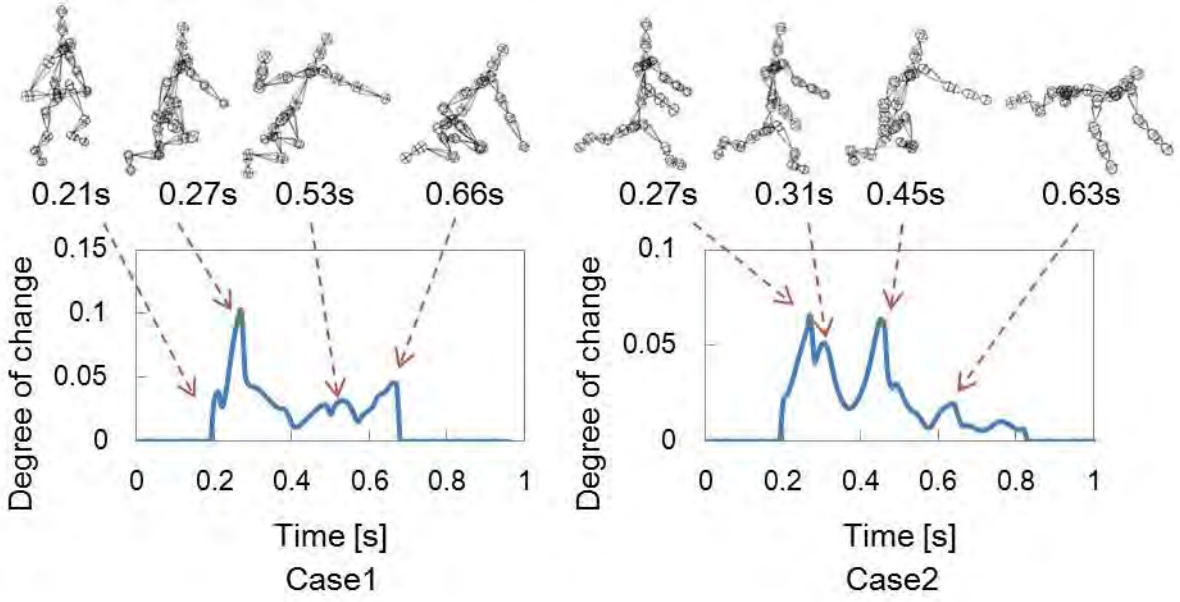
In earlier studies, many researchers have tried to estimate fall-related injuries, such as bone fractures, using human finite element models. However, avoidance or protective behaviors during the pre-injury phases have not been implemented in all human models that led to an overestimation of the risk probability. Therefore, for an accurate and comprehensive estimation of injury risks, the total number of fall-related injuries that involve both the pre-injury and injury phases are necessary. To clarify these mechanisms, it is important to employ methods that divide the fall-related action quantitatively into evasive, protective, and passive action phases. Therefore, the objective of our research is to develop the methods to appropriately divide the fall-related actions.

Methods: Three-dimensional motion data of child falls were captured from a fall-related motion database that focusses on unintentional daily falls occurring in a living environment [2]. The infants played freely in the room with their parents, and motions of falls naturally occurred. The latter were analyzed using a video-based motion capture system (Flame-Dias, DKH Inc.). The motion data were interpolated using cubic splines. The total number of degrees of freedom of the constructed model was fifty seven. To extract protective motions from captured data, we used the change point detection method calculated based on singular value decomposition (SVD), as proposed by Ide [3]. In this method, the degree of change of the time series data that indicates the distance between the two spaces that consisted of the backward feature motion and the current feature motion (both defined as right singular vectors) was calculated using SVD. When this value equals zero, no motion change is detected. On the other hand, when this value equals one, significant motion changes are detected. Furthermore, Ide [3] used only one-dimensional input data. In this work we improve the prior methodology extending its use to multidimensional input data.

Results: The fifty-seven multidimensional time series data, including rotation angles of whole body joints, and translational motion of hips in falling conditions were used to extract the early time periods of protective motion. Figure shows two examples of results. Both sets of results exhibit local peak values. We think that the posture may have changed drastically at the time the protective motion started. Therefore, one of the local peak values may show the early time period of the protective motion. To confirm this, we compared the results with captured motion data.

In Case 1, the maximum peak value occurs at 0.27s. Referring to the captured motion, the protective motion seems to start at approximately the same time. This indicates that the maximum peak value can be extracted from the early time period of the protective motion. On the other hand, in Case 2, similar local maximum values appear at 0.27s and 0.45s. Since protective motion also occurred at approximately 0.45s in the captured motion, the peak value at 0.27s may indicate the time when the subject lost his body balance. A total of thirteen fall datasets were investigated. We were able to extract the early data periods of the protective motion in ten cases. Furthermore, in five of the studied cases, the multilocal peak values appeared to exhibit similar patterns like that of Case 2. Because this method itself is not specialized for extracting protective motion, the input data should be selected a priori to extract protective motion. Moreover, a proper methodology is necessary to quantitatively determine which local peak value indicates protective motion. To achieve this, we need to clarify the feature motion of the fall behavior by analyzing additional motion data in the future.

Figure:



Caption: Two results of change point detection with captured motion data

Conclusion: Child falling behaviors were analyzed using the change point detection method that allowed the extraction of the early time periods of the protective action phase. The elicited results indicate that it is possible to extract these time periods of protective motion in falling conditions. On the other hand, methodologies are necessary to clarify which local peak value indicates the beginning time periods and which input data are appropriate for extracting protective motion.

ASSESSMENT OF A RIB-BASED TECHNIQUE TO DEFINE THE THORACIC COORDINATE SYSTEM FOR USE WITH BI-PLANE X-RAY IMAGING

Joshua W. Giles [1,*] Tim Baumer [2] Anne Drake [2] Michael Bey [2]

[1]Mechanical Engineering, Imperial College London, London, United Kingdom, [2]Motion Analysis Lab - Bone & Joint Center, Henry Ford Hospital, Detroit, United States

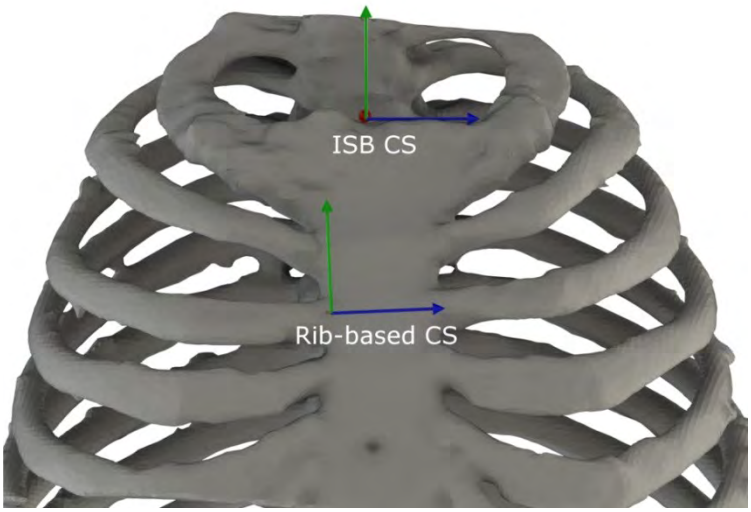
Introduction and Objectives: To describe the various contributions (e.g. glenohumeral, scapulothoracic, and thoracic) to humeral motion in a physiologically relevant manner and to achieve consistency within the literature, Wu et al. [1] described standard bone-fixed coordinate systems (CS) and rotation sequences for each contributing bone and joint, respectively. The thoracic bone-fixed CS is based on anatomical landmarks on the sternum, and two vertebrae. Recently, 3D model-based bi-plane x-ray systems have been developed which can accurately track joint kinematics and contact mechanics; however, this modality has not adopted the ISB thoracic CS as it would require the midline of the body to be CT'd, greatly increasing patient dose. As a result, scapular rotations have commonly been measured relative to the ground and thus incorporated thoracic rotations into descriptions of scapular motion. To overcome this difficulty, we have developed a method to measure the 3D pose of the thorax by tracking specific pairs of ribs which are visible in both CT and during bi-plane x-ray acquisition. Therefore, our objective was to assess the accuracy of various rib-based thoracic CS compared to the ISB standard.

Methods: A thoracic CT scan was acquired for each subject (n=5) and reconstructed into a 3D bone model which was then used to create the ISB recommended thoracic CS based on anatomical landmark digitizations (Fig 1). Additional rib-based CS were constructed for all combinations of ribs 1-6 as these are consistently visible in bi-plane x-ray images. The CS were created by identifying on each rib, the costovertebral joint and the sternocostal joint. For each rib pair, the CS origin was the superior rib's sternocostal joint. The superior/inferior axis was defined as the vector between the midpoints of the inferior and superior ribs' costovertebral and sternocostal joints. The medial/lateral axis was defined as a vector perpendicular to the plane created by the two ribs' costovertebral joints and the superior rib's sternocostal joint. Lastly, the anterior/posterior axis was defined as the cross-product of the superior/inferior and medial/lateral axes.

Accuracy of each rib-based CS was assessed by determining the three Cardan angles (flexion/extension(FE), lateral rotation (LR), axial rotation (AR)) that described its orientation relative to the ISB standard. Using these data, we calculated the Root Mean Squared Error (RMSE) and precision (standard deviation) across all five subjects.

Results: Misalignment to the ISB standard was highly dependent on the rib pair used. Averaging the RMSE of the three rotations produced average rotational errors ranging between 4.6 and 22.9° across the 15 rib combinations (RMSE range: 1.4≤FE≤8.5°, 1.5≤LR≤25.2°, 4.4≤AR≤38.1°) while for precision, the error ranged from 2.3 to 6.5° (precision range: 1.1≤FE≤6.0°, 1.5≤LR≤6.5°, 4.2≤AR≤8.2°) (Table 1). Filtering for rib pairs where no rotational error was >10° left 9 potential CS (Table 1 - Bold), while filtering these for pairs with a precision <5° left four candidates; namely, ribs 3&4, 3&5, 3&6, and 4&5.

Figure:



Caption: 3D reconstructed model of the thorax with ISB and one rib-based CS indicated.

Conclusion: The importance of the absolute errors is heavily influenced by the magnitude of the corresponding scapular rotation; whereby, errors that are large relative to the corresponding scapular rotation should have greater weight in selecting the best CS. Therefore, to understand their importance, the errors for the four remaining CS were calculated as percentages of published [2] scapular rotations (FE=35°, AR=25°, LR=65°) (Table 1 - % data). These data indicate that several rib-pairs yield an acceptable thoracic CS. In choosing the optimal CS, it is also critical to consider the importance of each rotation to the biomechanical question. If scapular tilting (FE) is most important, rib 3&4's CS produces the least meaningful error, while ribs 4&5 are preferable when scapular version (AR) is the critical motion. However, if both rotations are equally important, rib 3&6's CS produces an optimal compromise. Use of these new CS will greatly increase the physiologic accuracy of scapular rotations measured by bi-plane x-ray and allow thoracic rotations, which have previously been attributed to the scapula, to be independently described.

Table:

	RMSE&Precision(°)			RMSE&Precision(%)

VALIDITY OF THE NEW KINECT-SENSOR IN MEASURING UPPER BODY KINEMATICS

Eveline Graf [1,*] Roman Kuster [2] Markus Wirz [1] Bernd Heinlein [2]

[1]School of Health Professions, Institute of Physiotherapy, [2]School of Engineering, Institute of Mechanical Systems, Zurich University of Applied Sciences, Winterthur, Switzerland

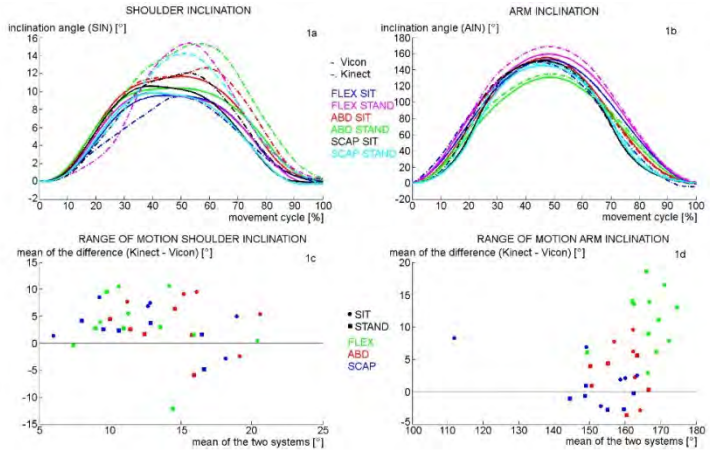
Introduction and Objectives: The quantitative description of human motion is used in various fields, e.g. in clinical settings to diagnose and assess progression of injuries or rehabilitation programs. This is mostly done using marker-based systems with accuracies of less than one millimeter [1]. However, such systems are very expensive and their usage is very time consuming, requires technical expertise and is bound to a laboratory, which severely limits their field of use. Recently, marker-less systems have been developed that are low cost and simple to use. Different studies have examined the accuracy of such systems as they, given sufficient accuracy, would provide a portable solution to quantify segmental kinematics in applied settings. While the validity and reliability of the first generation of Microsoft Kinect™ has been examined [2], there is no information about the validity of the new "Kinect for Xbox One" (Kinect) for tracking human motion. Therefore, the aim of this study was to determine validity of Kinect for measuring segment angles in upper extremity exercises.

Methods: Six subjects (31±5yrs, 1.75±0.09m, 70.0±7.77kg) provided written consent and wore tight fitting shorts and no shirt (sports bra for women). Reflective markers were placed on the skin according to the plug-in-gait model. Each subject performed unilaterally three repetitions of following tasks sitting (SIT) and standing (STAND): shoulder flexion (FLEX), shoulder abduction in frontal (ABD) and scapula (SCAP) plane. Frontal plane was defined by the vertical plane through the two shoulder centers, sagittal and scapula plane by rotating frontal by 90° and 45° around vertical axis, respectively. Inclination angle was calculated in the respective plane for the arm (AIN) and in the frontal plane for the shoulder girdle (SIN). The tasks were recorded simultaneously with a 7-camera Vicon® system and Kinect (placed according to manufacturer's recommendation). Kinect-skeleton was recorded using custom software based on "Kinect for Windows SDK 2.0", which directly provides trajectories of the joint centers. Vicon data was processed using standard pipeline from Vicon Nexus™ to calculate trajectories of the joint centers. Based on filtered data, segments were defined as the line between two joint centers (shoulder girdle: left to right shoulder, upper arm: shoulder to elbow). Data were synchronized between the systems. Resulting angles were compared between Vicon and Kinect using coefficient of multiple correlation (CMC) [3] and Bland-Altman plot.

Results: In general, there were strong correlations between the two systems. In SIT and STAND, AIN had higher CMCs compared to SIN (Table 1). For SIN, SIT resulted in higher CMCs than STAND except in FLEX.

Range of motion (RoM) was more than ten times smaller for SIN (Fig 1a) compared to AIN (Fig 1b). Figure 1 (c&d) shows differences in mean RoM between Kinect and Vicon relative to the average mean of both systems. SIN (Fig 1c) and AIN (Fig 1d) show a trend towards higher means for Kinect.

Figure:



Caption: Shoulder (a) and arm (b) inclination angle; Bland-Altman plot of ROM of shoulder (c) and arm inclination (d)

Conclusion: Figure 1 (c&d) displays that there is an error (larger RoM) associated with Kinect compared to Vicon. AIN of FLEX appears to have the largest error (Fig 1d), but is also associated with a slightly larger RoM (Fig 1b), so there may be a positive relationship between size of error and absolute RoM. Since RoM is calculated based on minimum and maximum positions that are very similar for all three tasks, the difference in motion direction may not explain this result. CMCs of AIN are excellent, indicating good agreement of the angle trajectories between Kinect and Vicon, independently of the direction of motion. For SIN, the values are constantly lower, showing that Kinect is better in tracking the extremity than the shoulder girdle. Unfortunately, the body-tracking algorithm of Kinect is unknown. Therefore, it is not possible to examine where this difference comes from. For SIN, CMCs for FLEX (SIT and STAND) are lower than for the other tasks. During FLEX, the arm is elevated in sagittal plane, temporarily occluding the view of the shoulder joint. It is likely that this results in a decreased accuracy of tracking the shoulder motion.

Kinect seems to track upper body motion fairly well. In order to determine if Kinect could be used as a low-cost tool to quantitatively record RoM, e.g. during physical therapy, the between-day repeatability needs to be determined.

Table:

	shoulder inclination (SIN)		arm inclination (AIN)	
	SIT	**STAND**	**SIT**	**STAND**
FLEX	0.74	0.80	0.99	0.99
ABD	0.92	0.84	0.99	1.00
SCAP	0.93	0.83	1.00	0.99

VELOCITY PROFILES OF SPATIO-TEMPORAL GAIT PARAMETERS IN LOW BACK PAIN PATIENTS: COMPARISON OF TWO REGRESSION METHODS

Clara Leyh [1,*] Véronique Feipel [1] Marcel Rooze [2]

[1]Laboratoire d'Anatomie Fonctionnelle [Laboratory for Functional Anatomy] , [2]Laboratoire d'Anatomie, Biomécanique et Organogénèse [Laboratory of Anatomy, Biomechanics and Organogenesis] , Université Libre de Bruxelles, Brussels, Belgium

Introduction and Objectives: Normalised gait velocity allows a better understanding of gait characteristics but this cannot clarify the implication of individual velocity variations on some gait parameters. Computed normalised gait velocity corridors (velocity profile) of spatio-temporal parameters (1,2) could help general practitioners to appreciate and evaluate specific locomotor disabilities and rehabilitation effects.

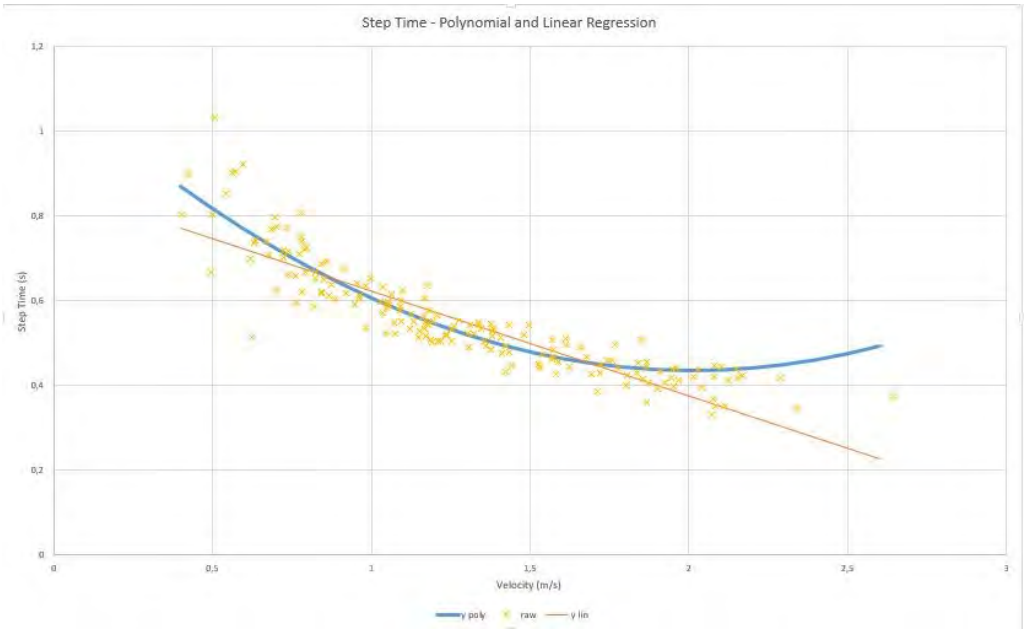
Low back pain patients exhibit among other a decrease of gait velocity, cadence, step length and an increase of support base, cycle time and single support time (3-7).

The aim of our study was to compute and analyse linear and polynomial velocity profiles distributions of spatio-temporal parameters of low back pain patients in gait. We also compared these profiles with those of healthy persons.

Methods: 59 low back pain patients (LBP) (females: n=30; age: 42 ± 17 years; males: n=29; age: 42 ± 15 years) and 34 healthy subjects (CG) (females: n=16; age: 45 ± 18 years; males: n=18; age: 45 ± 17 years) walked 3 times at 3 different speeds (slow, preferred and fast) over an electronic walkway (GAITRite Walkway system). The order of gait speeds was randomized and both groups were divided in 3 ages subclasses (“A”: 20-40 years; “B”: 41-60 years; “C”: 61-80 years). Spatial and temporal parameters were computed from contact data (i.e. velocity, cadence, step length, stride length, step time, cycle time, stance time, swing time, single and double support times, stride velocity). Each parameter was then analysed using both linear and polynomial regressions to estimate “velocity profiles” in both individual and normalised gait speeds within the range of speeds achieved by all subjects (0,90 – 1,25 – 1,90 m/s). A paired sample T-test analysed the influence of laterality on each spatio-temporal parameter. ANOVA for repeated measurements was used to investigate the influence of regression modality (within-subject factors) and pathology on parameters.

Results: Best fitting results were obtained using polynomial regression for almost all parameters (cadence, step time, step length, stride length, cycle time and single support phase). Both linear and polynomial regression may be used to analyse swing time, stance time, double support time and stride velocity. It appeared that age had a significant influence on two parameters (stance time and double support time). No significant differences were observed between control and LBP groups.

Figure:



Caption: Step Time (s) polynomial and Linear regression of LBP subjects

Conclusion: The use of polynomial regression seemed to match best the distribution of most spatio-temporal gait parameters. A significant influence of age on velocity profiles was demonstrated in both groups. Nevertheless, due to the heterogeneity of low back pain definition, further studies should be extended considering various larger subgroups selected from clinical specificities such as symptoms, clinical examinations or specific spine damages.

TURNING KINEMATICS IN THE ASSESSMENT OF GAIT FOR CHILDREN WITH CEREBRAL PALSY

Philippe C. Dixon [1,*] Julie Stebbins [2] Tim Theologis [2] Amy B. Zavatsky [1]

[1]Engineering Science, University of Oxford, [2]Nuffield Orthopaedic Centre, Oxford University Hospitals NHS Trust, Oxford, United Kingdom

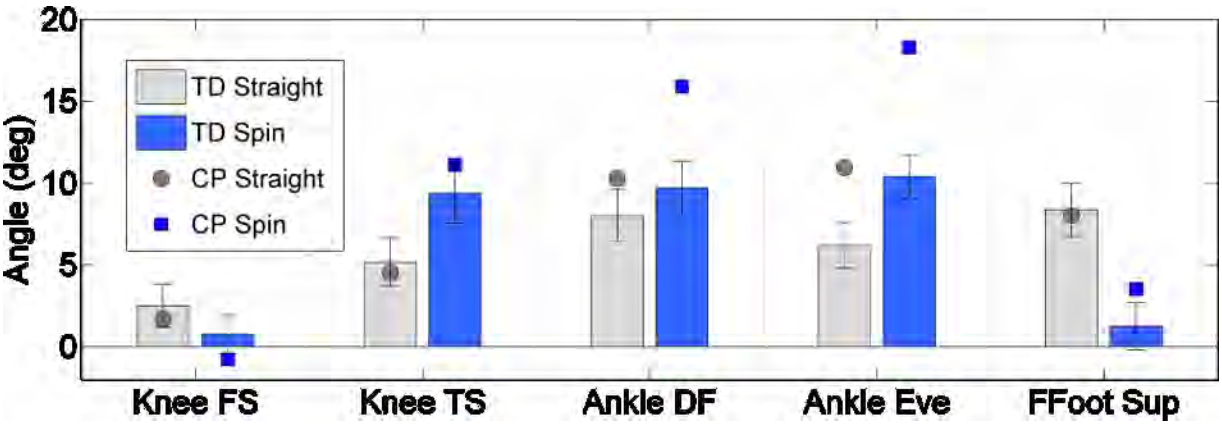
Introduction and Objectives: Turning is a crucial component of walking [1]. Kinematic changes required to successfully turn have been identified in typically developing (TD) children [2]; however, it remains unclear if children with cerebral palsy (CP) will adapt similarly to the turning condition [3]. The aim of this study was to investigate whether kinematic patterns exhibited by children with CP would be more atypical compared to their TD peers during turning gait than during straight walking given their existing neuromuscular pathologies. An understanding of turning kinematics in children with CP may be relevant in the clinical management of gait deviations.

Methods: Data from forty-four TD children (11.0 ± 2.6 years, 149.1 ± 15.5 cm) and twenty-two children with spastic diplegic CP (10 GMFCS 1 and 12 GMFCS 2) (12.4 ± 2.8 years, 149.7 ±17.7 cm) performing straight and 90° turning gait tasks were captured at 100 Hz using a Vicon system (Vicon, Oxford Metrics, Oxford, UK). For the CP group, limbs were found to have a mild (16), true equinus (9), apparent equinus (3), jump (6), crouch (2), or non-classified (8) kinematic pattern based on the algorithm of Sangeux *et al.* [4]. Kinematic data were extracted from the Plug-in Gait [5] and Oxford Foot Model [6] marker sets. Only turns about the inside limb (spin turns) are presented as both groups preferred this strategy. Left and right turns were pooled and a representative trial for each subject/condition was retained.

Inside limb kinematics were analyzed at discrete events starting at foot strike (FS) of the main turning stance phase: knee (Knee FS) and hindfoot with respect to tibia (Ankle FS) angles as well as minimum knee flexion in terminal stance (Knee TS) and maximum ankle dorsiflexion (Ankle DF) were identified as variables of interest based on clinical observation, while maximum hip adduction (Hip Add) and internal rotation (Hip IntRot), ankle maximum eversion (Ankle Eve), and forefoot with respect to hindfoot maximum supination (FFoot Sup) were extracted based on known turning gait adaptations in TD children [2]. Group differences were analyzed for each event using a 2 x 2 ANOVA (between-subject factor group and within-subject factor condition). A significant interaction would suggest that the two groups adapt differently to the turning condition ($\alpha = 0.05$, no correction for multiple comparisons). Analyses of individual subjects were conducted by counting the number of children with CP outside the 95% confidence interval (CI) range of the TD group for each event/condition. These children were considered to exhibit abnormal kinematic patterns. All analyses performed using Matlab (v2012b, The Mathworks, Inc. Natick. USA).

Results: No statistically significant group by condition interactions were found; however, subject level analyses revealed that a greater number of CP subjects exhibited abnormal kinematics during turning than straight walking for Knee FS, Knee TS, Ankle DF, Ankle Eve, and FFoot Sup (Table 1). Overall, 13 children with CP (9/12 classified as having a limb with a “mild” pattern) were assessed as having normal kinematics for at least one event using CIs based on straight walking data. Of these, only 2 exhibited normal turning kinematics. Data for one child with a mild gait deviation for whom kinematics deteriorated during turning are presented (Fig. 1).

Figure:



Caption: Normative range (mean ± CI) of events for straight walking and turning gait tasks derived from the TD group with data for one child with CP superimposed.

Conclusion:

This study investigated lower-limb joint kinematics during turning gait in children with CP. No significant overall group by condition differences were found, possibly due to the heterogeneity of the CP group; however, subject specific analyses showed that turning gait was a better discriminant of pathology than the standard straight walking protocol, especially for children with mild impairments. Although results are specific to the current cohort, this study outlines a simple methodology to assess individual children in a clinical setting. In practice, turning gait analysis may be conducted in cases where gait deviations exhibited during straight walking are minor, despite a child's reported difficulty in day-to-day gait activities. Future work could aim to develop a composite score for turning gait curves similar to the gait profile score [7] using these or other variables of interest such as joint kinetics.

Table:

	Hip Add	Hip IntRot	Knee FS	Knee TS	Ankle FS	Ankle DF	Ankle Eve	FFoot Sup
Straight	17	19	20	18	19	18	18	18

EFFECT OF A COMPRESSION GARMENT ON KINEMATICS OF JUMP-LANDING TASKS IN FEMALE RECREATIONAL ATHLETES AND PHYSICALLY ACTIVE WOMEN

Morgana A. de Britto [1,*] Andressa Lemos [2] Christielen dos Santos [2] Darren Stefanyshyn [3] Felipe Carpes [2]

[1]Center of Physical Education and Sport, Federal University of Santa Maria, Santa Maria, [2]Center of Health Sciences, Federal University of Pampa, Uruguaiana, Brazil, [3]Human Performance Laboratory, University of Calgary, Calgary, Canada

Introduction and Objectives: Previous research has shown that compressive garments can contribute to increase maximal height during vertical jumps and decrease hip flexion angles during dynamic tasks [1,2]. However, it is unknown whether movements in the frontal plane, such as hip adduction and knee valgus, can also be influenced. Knee valgus during landing is considered a major risk factor for knee ACL injury in sports [3]. Compressive garments could perhaps reduce maximum knee valgus angles during landing. Here we evaluated the effect of wearing a compressive garment on jump height and knee kinematics during a vertical jump-landing task performed by female recreational athletes and physically active women.

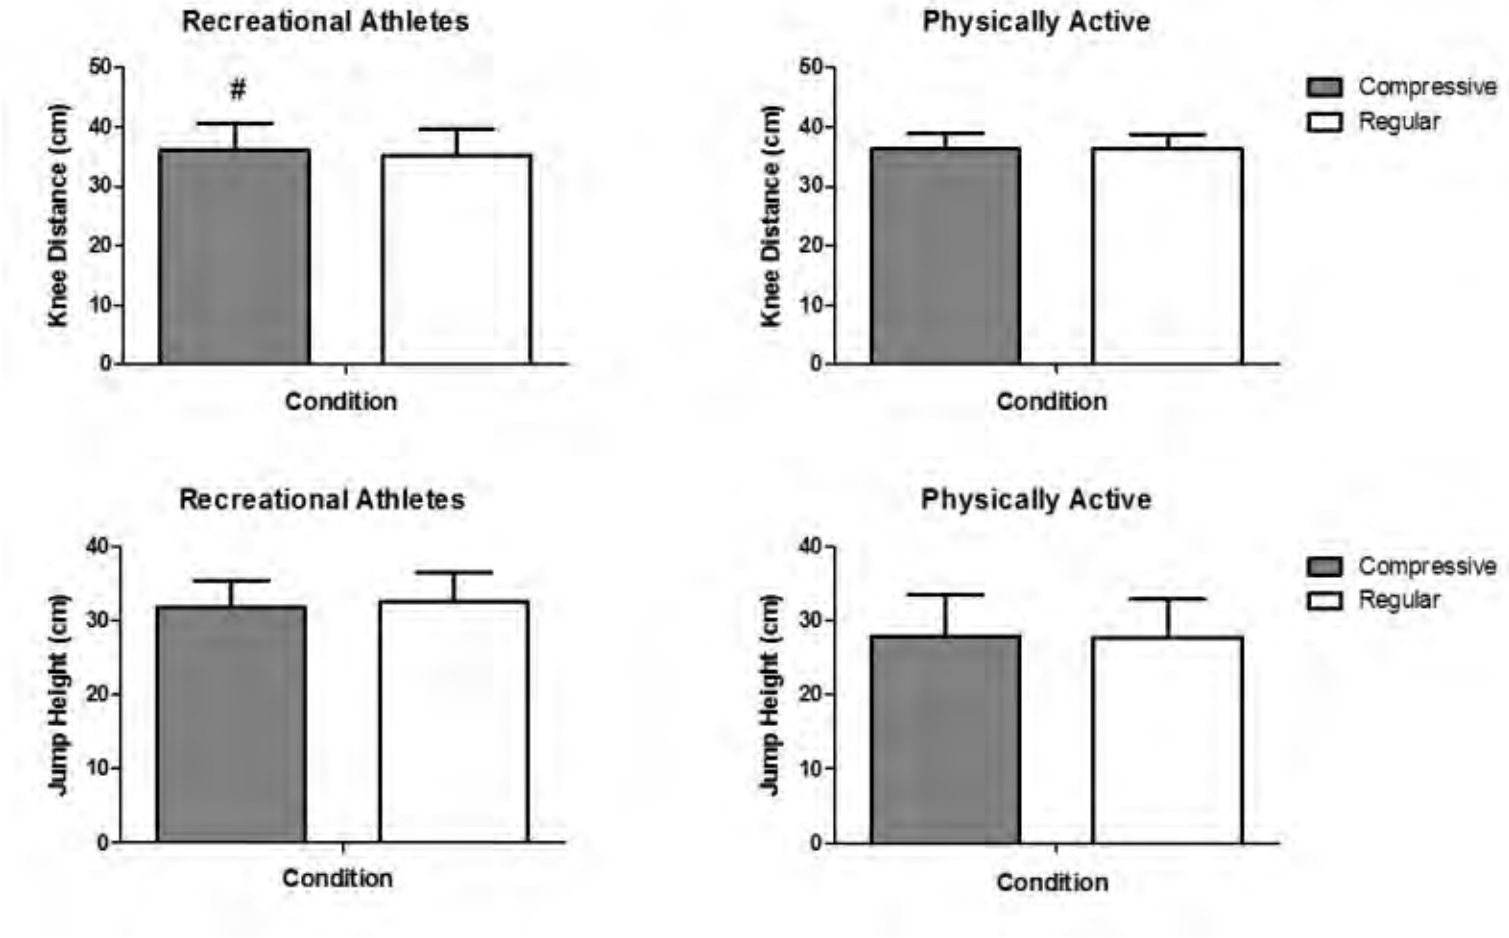
Methods: Eleven female recreational athletes and six physically active women participated in this study. To be in the recreational athletes group, participants had to train a team sport (with competitive goals) at least two times per week, for a minimum of 45 minutes per session. The physically active group included women that practiced walking, jogging or training at the gym. Kinematics of jump-landings were recorded using fifteen optical cameras (Vicon Motions Systems) and ground reaction forces were recorded using two force plates (OR6-2000, AMTI Inc.), one under each foot. The participants performed vertical jumps from a semi-squatted position, with the instruction to jump as high as possible and to land with one foot on each force plate. Trials were repeated if participants landed outside the force plates. Three vertical jumps were performed for each clothing condition (brand new compressive shorts or brand new regular sports shorts). Data were averaged for the three jumps in each condition. The frontal plane distance between markers on the left and right lateral femoral epicondyle at the peak of knee flexion during the landing phase was used as a measure of knee valgus angle. Also, the maximum jump height was verified through the change in vertical position of the center of mass determined based in plugin gait reference markers. A Shapiro-Wilk test was used to check whether the data were normally distributed. If they were, a paired t-test was used to test for an effect of the compressive garment and the regular sport shorts in each group.

Results: Among recreational athletes, there were no significant differences in the maximum height of jumps with and jumps without the compressive garment ($p=0.311$). Frontal plane knee distance was larger when recreational athletes used the compressive garment ($p=0.003$) compared to the regular garment. For the physically active women, there were no significant differences in maximum jump height between jumps with or without compressive garment ($p=0.822$). Knee distance was also not different between the conditions for the physically active women ($P=0.889$).

If jump height is considered as a performance marker, our data do not support the use of compressive garment as a strategy to improve performance of jumping. The increase of knee distance in the recreational athletes group calls for

explanation. It is possible that the compression above the knee (since the garments were shorts) lead to a more aligned position, helping the subjects keep their knees in less valgus positions. Our results concerning the use of compressive garments still requires a larger sample size to increase statistical power and properly address the implication for knee joint moments, frequently related to different knee injuries in sport.

Figure:



Caption: Figure 1. Means and SD values for knee distance and maximum jump height for the groups of female recreational athletes and physically active women, in two conditions (compressive or regular garment). # indicates significant difference between conditions.

Conclusion: The use of a compressive garment by female recreational athletes increased knee horizontal distance when performing vertical jump-landing tasks, in other words, decreased knee valgus.

A THREE-YEAR LONGITUDINAL STUDY OF BIOMECHANICAL ALTERATIONS IN KNEE OSTEOARTHRITIS AND ASYMPTOMATIC CONTROLS

Janie L Astephen Wilson [1] Dianne M. Ikeda [1,*] Scott C Landry [2] William D Stanish [3] Cheryl L Hubley-Kozey [4]

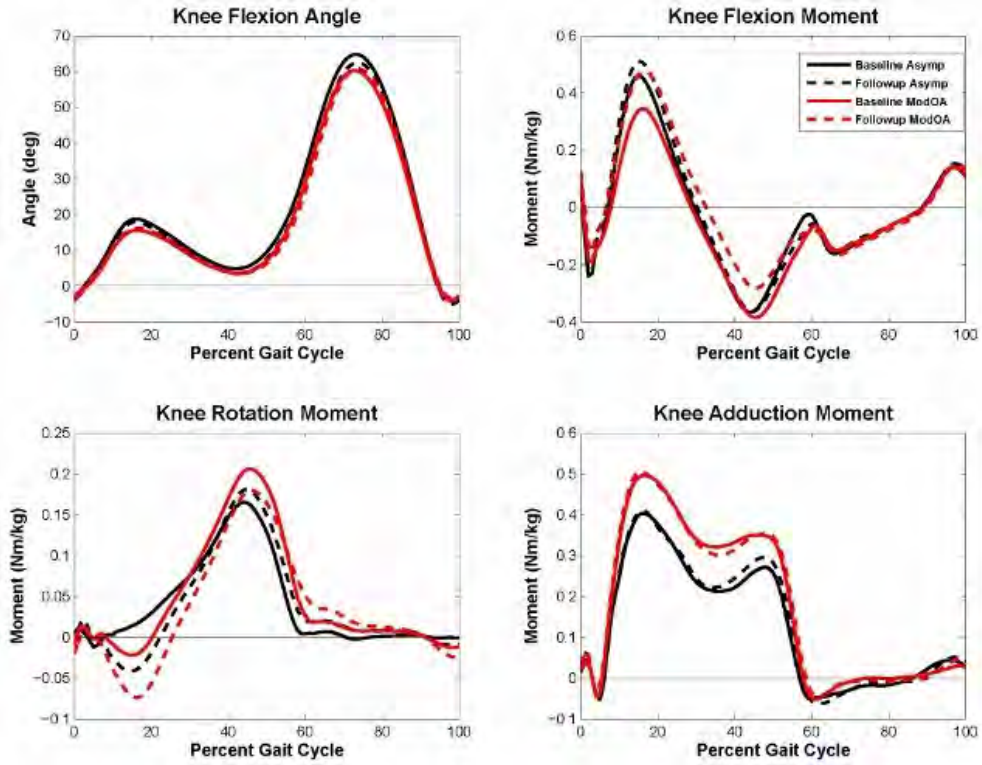
[1]Biomedical Engineering, Dalhousie University, Halifax, [2]Kinesiology, Acadia University, Wolfville, [3]Dalhousie University, Halifax, Canada, [4]Biomedical Engineering; Physiotherapy, Dalhousie University, Halifax, Canada

Introduction and Objectives: The literature linking joint-level gait biomechanics with structural knee osteoarthritis (OA) has focused on individual gait metrics, mainly knee adduction moment (KAM) [1,2]. This is limited in its ability to illustrate the change of joint level mechanics and limits the interpretation of simultaneous multiple, correlated changes in gait mechanics. The objective of this study was to use principal component analysis (PCA) on discrete metrics to extract uncorrelated, multidimensional features & to compare these after three years & between asymptomatic controls (ASYM) & those with baseline moderate knee OA (MOD).

Methods: Three-dimensional (3D) gait patterns of 23 MOD & 18 ASYM adults (n=41) were recorded at baseline & approximately 3 years later. Patterns of 3D knee angles & net resultant moments were calculated. Five self-selected speed gait trials were averaged & normalized to 100% of stance, except flexion angle (KFA) that was normalized to 100% of gait. Discrete metrics reported in the literature [3] were extracted from subjects including ASYM (n=188), MOD (n=240) & severe OA before (n=108) & after arthroplasty surgery (n=91) & entered into a PCA. Variables were average gait speed, stance & swing phase peak KFA, KFA range, peak flexion moment (KFM), peak extension moment (KEM; early & late stance), rotation moment (KRM) range, first & second KAM peak & the mid-stance KAM. PCscores were calculated for the 41 subjects for the first three PCs. Variables within each PC were interpreted if their coefficient was at least 50% of the maximum coefficient for that PC [4]. A 2-way mixed model ANOVA was run on PCscores with session as a within-subjects factor & group as a between-subjects factor (α=0.05).

Results: PC1, PC2, PC3 captured 35.8%, 23.6% & 15.5%, respectively, of the original data variability (cumulatively 75%). Gait speed, peak stance & swing KFA, KFA range, peak KFM, peak early & late stance KEM & KRM range had significant correlation & high, positive, equal weighing on PC1. PC1 was interpreted as a sagittal plane/speed metric, with higher scores related to higher function. There were no significant differences in PC1 scores between groups or time, meaning that this feature remained consistent over time, with no functional difference between groups (Table 1, Figure 1). PC2 represented the first & second peak KAM, & the mid-stance KAM minimum. PC2 was interpreted as capturing the overall KAM magnitude during stance. PC2 scores were significantly higher in the MOD than ASYM group (P=0.007), meaning higher overall KAM during stance with OA. There were no time-dependent changes in PC2. PC3 was dominated by peak KFM & KFA range, with high scores related to higher peak moments & range. There was a significant time-effect for PC3 (P=0.04), with higher peak moment & range at follow-up compared to baseline.

Figure:



Caption: ASYM &MOD baseline & follow-up waveforms of KFA, KFM, KRM, KAM

Conclusion: Summarizing gait mechanics in some key features did not show biomechanical change over 3-years. The only statistically significant change over time reflected an improvement in gait function, with higher peak KFM & KFA range at follow-up. PC2 captured the overall KAM magnitude, similar to PCs from KAM waveforms [5]. There was a significant group difference, but no worsening of this feature over time in either group. These results also highlight interrelationships among different combinations of discrete gait variables, so combining variables into PCA may improve interpretation.

Table:

	Baseline ASYM	Baseline MODOA	Follow-up ASYM	Follow-up MODOA
BMI (kg/m^2)	27.1 (4.4)	29.8 (4.9)	28.2 (4.7)	29.8 (4.4)
Age (years)	49.8 (6.5)	56.5 (6.1)	52.7 (6.6)	59.5 (6.1)

PROGRESS AND BENEFITS OF SUBJECT SPECIFIC MUSCULOSKELETAL MODELING OF THE HAND

Clint Hansen [1,*] Khalil Ben Mansour [1] Pierre Devos [1] Frédéric Marin [1]

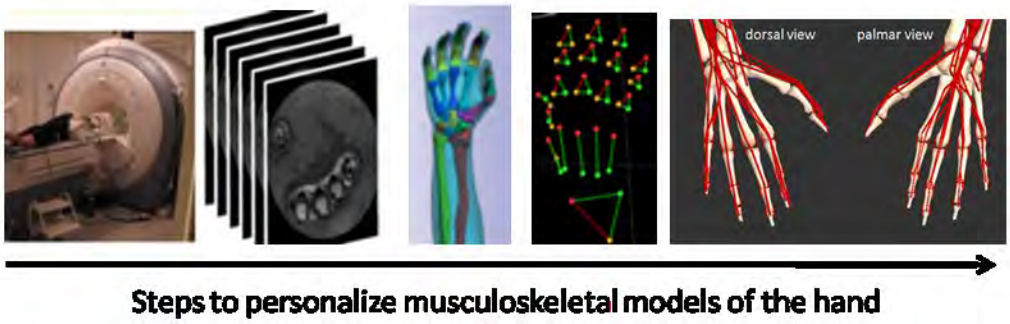
[1] Université de Technologie de Compiègne, UMR 7338 : BioMécanique et BioIngénierie (BMBI), Comipiègne, France

Introduction and Objectives: Hand movements such as reaching or grasping are performed on a daily basis, but the analysis of these movements may differ due to the joint model specifications [1]. The question arises as to how the results are affected by the model choice since previous research has highlighted differences, e.g. due to personalized model scaling and manual scaling using motion capture data [2]. In the case of musculoskeletal modeling of the hand, the definition of the model parameters becomes a critical issue due to the small size of the anatomical structures. The sensitivity of the geometrical parameters of the musculoskeletal modeling was already clearly demonstrated [2,3], and the results motivated the necessity of the subject specific procedure. The aim of this study was to evaluate the differences between generic and personalized musculoskeletal models during a functional movement task.

Methods: The musculoskeletal model consisting of 28 rigid segments, 36 joints and 14 muscles [4] was implemented in the interactive modeling software (SIMM, Motion Analysis Corporation, Santa Rosa, CA). Six subjects (age: 31.7±9.1, body mass: 72.3±13.7kg, height: 1.73±0.11m) voluntary participated in this study. The personalized models were scaled based on the internal geometry given by the MRI, while the generic models were scaled based on the positions of the 3D marker positions and the generic hand joint model. To analyze the specific features of the functional movement, both models were driven by 3D positions of 59 markers (1.5 mm) from a motion capture system (Vicon Motion Systems Ltd. UK). The internal geometry of the personalized joint model was obtained from a 3D image data visualization software (ScanIP, Simpleware©) using images from a 1.5 T MRI system (GE Signa HDx™) with a spatial resolution of 0.3x0.3x0.5 mm3. In this article, we present differences between the above-mentioned models and compare the kinematics and the force values from the personalized and generic musculoskeletal model focusing on eight hand flexor muscles (Figure 1) and four hand extensor muscles during a clinical opposition movement of the thumb.

Results: A Wilcoxon matched pairs test ($p<0.05$), Pearson correlations and nRMSE analyses were implemented in Matlab (MathWorks Inc.) to evaluate the differences between the twelve joints and the twelve muscle forces with respect to each model. While all joint kinematics differed statistically ($p<0.05$), the correlation between the models was consistently high ($r>0.7$), and the nRMSE was consistently small. The obtained muscle forces differed statistically ($p<0.05$); however, the correlation between the muscle activity pattern was consistently high ($r>0.7$). In contrast to the kinematics, the nRMSE for the forces was high. Personalizing the model demands additional material (e.g. medical imaging) and also time-consuming post processing. However, significant differences between the models have been demonstrated. Implementing in-vivo data from medical images is a first step for more detailed investigations in the field of musculoskeletal biomechanics. Personalizing musculoskeletal models using, for example, MRI or CT imaging to obtain the internal geometry can help to improve the outcome of the conducted study. This study itself provides evidence of the difficulty and delicacy of multi-body musculoskeletal modeling and, specifically, the comparability of the results.

Figure:



Caption: Subject specific musculoskeletal modeling of the using hand internal geometry given by the MRI and driven by 3D marker positions

Conclusion: Personalizing musculoskeletal models to obtain the internal geometry of the hand increases the complexity and the details of the musculoskeletal model. As the results show, differences in the scaling of the models led to small changes in the kinematic chain, as well as drastic changes in the computed muscle forces. Based on the aforementioned results, we emphasize the ideas of personalization of muscle-tendon paths and use of high resolution IRM. These analyses will increase the details and precision of hand modeling. However, musculoskeletal modeling of the hand remains very challenging due to the complex anatomical structures, which include 27 bones, 21 joints, 15 extrinsic and 11 intrinsic muscles. This study provides evidence of the difficulty and delicacy of multi-body musculoskeletal modeling and, specifically, the comparability of the results. In conclusion, musculoskeletal models of the hand are very valuable tools, but they must be used with caution. The outcome of this study is subject to further investigations and the necessity to improve and implement personalized models for clinical diagnoses.

SUBJECT-SPECIFIC MODELLING OF THE FOOT INTEGRATING FINITE ELEMENT MODELLING, GAIT ANALYSIS AND OPENSIM: PROOF OF CONCEPT IN DIABETIC NEUROPATHIC SUBJECTS

Annamaria Guiotto [1] Alessandra Scarton [1] Valentina Camporese [1] Claudio Cobelli [1] Zimi Sawacha [1,*]

[1] Dept of Information Engineering, University of Padova, Padova, Italy

Introduction and Objectives: Diabetes and in particular diabetic neuropathy have their main biomechanical effect on the lower limb and may lead to diabetic foot pathology and foot ulcerations.

While gait analysis allows the acquisition of the ground reaction forces (GRF) and kinematics in-vivo during gait, three-dimensional (3D) finite element analysis (FEA) allows characterizing the loads developed in the different internal structures of the foot [1]. State of art of foot FEA generally adopts both experimental kinematics and ground reaction forces as boundary conditions in order to predict plantar pressure and internal stresses distribution [2].

The aim of this study was to verify whether the inclusion of muscles forces as boundary conditions could improve foot FEA results. For this purpose subject specific muscle forces were extracted in Opensim [3] and FEA results obtained by including them or not within the boundary conditions were compared.

Methods: 3D foot gait analysis was carried out as in [4] on a diabetic neuropathic subject: age 71 years, BMI 37 kg/m^2, with type 2 diabetes, affected also by peripheral neuropathy and vasculopathy, HbA1c of 8.6%, with cavus foot, valgus heel, claw toes and callosities under the metatarsal heads. Experimental setup included a 6 cameras motion capture system (60-120 Hz, BTS S.r.l, Padova), 2 force plates (FP4060-10, Bertec, USA) and 2 plantar pressure (PP) systems (Imagortesi, Piacenza). The signals coming from all systems were synchronized. The hindfoot, midfoot and forefoot subsegments and tibia 3D kinematics, GRF and PP were calculated as in [4]. The protocol was approved by the local ethic committee. A right foot MRI (Siemens Avanto, 1.5 T, Spacing between slides: 0.7mm, Slice thickness: 1.5mm) was acquired and a FEA model was generated as in [2]: the MRI was segmented with Simpleware ScanIP (v.5.0), meshed with ScanFE module and imported into Abaqus. The muscles' insertions were identified in the MRI and then modelled as connectors in the FEA model. Material properties were obtained from the literature as in [2].

Subject-specific simulations were ran in Abaqus by conducting a quasi-static analysis on 4 gait cycle phases (initial contact, loading response, midstance, push off). Two different boundary conditions were considered: one including kinematics and both the GRF and the muscle forces (C1); one including only kinematics and GRF (C2).

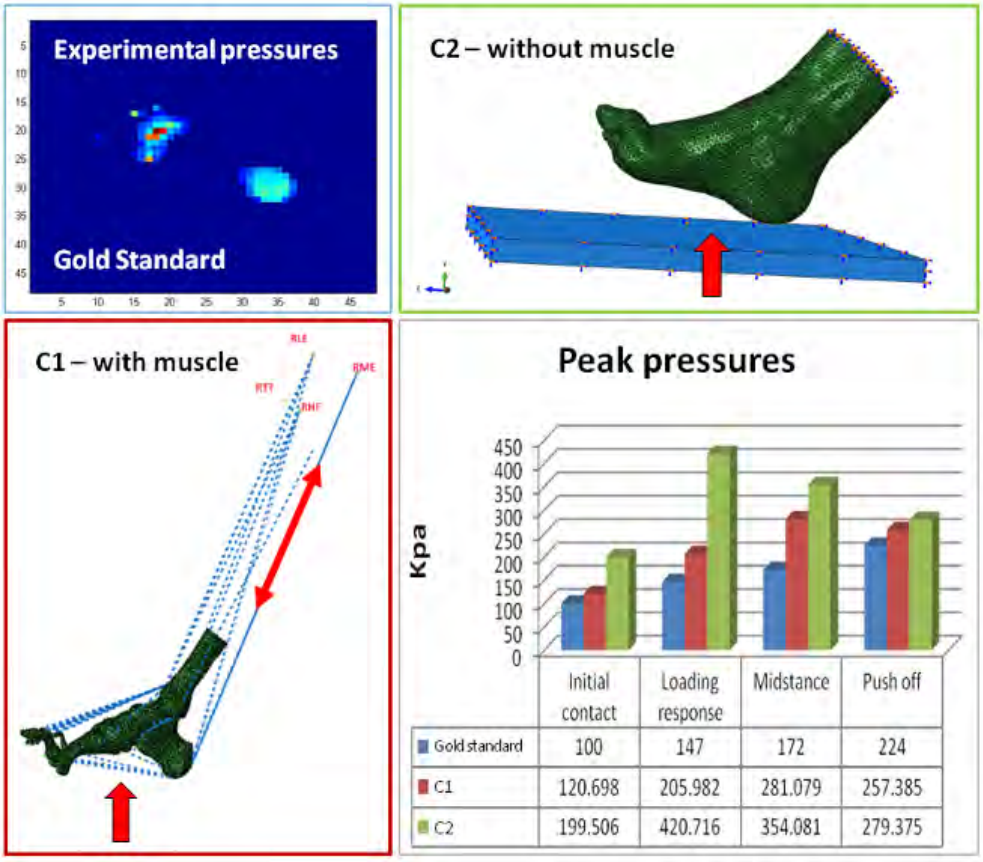
Simulated PPs were extracted from Abaqus, subdivided into 3 subareas as in [4] and peak pressures were respectively calculated in C1 and C2. Errors in percentage of the experimental peak and root mean square errors (RMSE) were computed in order to compare C1, C2 and the experimental PP.

Results: The comparison between simulated and experimental data showed a good agreement in all phases of the gait cycle. Better results were obtained in C1 including kinematics with both the GRF and the muscle forces, thus confirming the important role assumed by the muscles in the modelling stage (Figure 1).

A good correspondence was also found in the identification of the peak plantar pressure's site between experimental and simulated ones.

A slight overestimation of the simulated PP resulted in both conditions.

Figure:



Caption: Figure 1. Experimental pressures, modelling conditions and simulated peak pressures results.

Conclusion: The differences between experimental and simulated pressures were mainly due to the non-subject-specificity of the material properties of the soft tissues applied in the FEA.

Furthermore it should be considered that muscle forces were obtained in Opensim, which adds another model within the FEA modelling procedure.

An important limitation is represented by the fact that only one subject participated in the study. However the method proposed herein, once applied to a wider subjects' cohort, may help in the management of diabetic foot pathology and in understanding its aetiology.

3-D PRESSURE-TIME DISTRIBUTION DURING PELVIC FLOOR CONTRACTION AND VALSALVA MANEUVER IN CONTINENT WOMEN

Licia P. Cacciari [1,*]Anice Pássaro [1]Amanda Amorim [1]Juliana Burti [1]Simone Silveira [1]Isabel Sacco [1]

[1]Universidade de São Paulo, São Paulo, Brazil

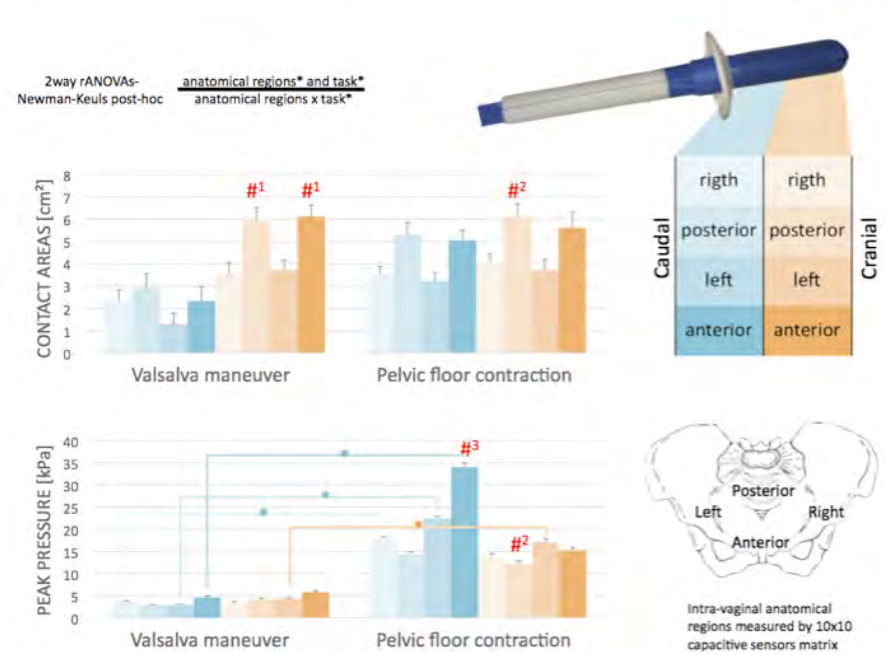
Introduction and Objectives: Pelvic floor (PF) muscles forces pull on the vaginal tissue is involved in bladder neck opening and closure guaranteeing urogynecological functions. PF dysfunctions affect the majority of women, for at least some time in their lives [1]. Clinicians usually evaluate PF function either subjectively by digital palpation or objectively by perineometers (intra-vaginal manometers) and dynamometers (strain gauges). Although objective evaluations assure better reliability and accuracy, the resultant force measured does not differentiate PF contraction (guaranteed by observed perineal cranial lift) from increases in abdominal pressure (leading to perineum downward movement - Valsalva maneuver). Our aim is to study the PF pressure distribution, taking into account its flexible surface with 3-dimensional deformations, objectively differentiating muscular force vectors from intra abdominal pressure raises in different regions of the vaginal cavity.

Methods: Twelve continent nulliparous woman (28.7± 5.6) were assessed in supine with knees flexed with an intra-vaginal probe (2.5cm diameter and 8cm length) introduced 7cm deep into their vaginal cavity. The probe involves 100 capacitive transducers (Pliance System - Novel, Munique, Germany) placed on a 10x10 matrix configuration. The pressure distribution map covering the whole vaginal cavity was divided into 8 sub regions (anterior, posterior, left and right; all of them cranial and caudally). Two trials of 2 different tasks were performed: (a) maximum voluntary PF muscles contraction (PFMC) and (b) maximum force in a valsalva maneuver. The data was subtracted from the passive force (acquired after one minute accommodation period inside the vaginal cavity). The maximum peak pressure and contact area were calculated and compared between tasks and regions by 2-way ANOVAs ($p<.05$).

Results: The interaction effect was significant between tasks and anatomical sub regions (figure). The highest peak pressure was achieved during PFMC in the anterior caudal region. The latero-lateral caudal peak pressures were smaller than the anterior caudal for PFMC, but still higher than in all regions during Valsalva. The Valsalva maneuver led to higher contact areas in the cranial anterior-posterior region than all other regions for this task, though it was similar to the contact areas during PFMC. The cranial anterior-posterior peak pressure were also not different between tasks. Considering the whole vaginal cavity area, 30% larger contact area and 4 times higher peak pressures were observed during PFMC (table). The PF muscles together with its passive structures must prevent incontinence and pelvic organ prolapse during abdominal pressure increases. The pressures observed during PFMC resulted in a pulling force up to cranial and anterior direction toward the hard surface of the pubic symphysis, what explains the higher peak pressures observed in the caudal anterior region during this task. It is interesting to note that PFMC resulted in increased pressures across the whole vaginal cavity, being more expressive in caudal regions, corresponding to its anatomical location [2]. During Valsalva, the observed increase in cranial contact area can be explained by increases in intra-abdominal pressure, pushing the pelvic organs towards the sensor probe, even though it did not result in higher peak pressures. It is also interesting to observe

that although the contact area was high in cranial regions during Valsalva, it was not higher than in any other regions during PFMC, making it easy to distinguish muscle force directions between tasks. Shifts in force-displacement-vectors of PF structures have been related to parity, mode of delivery and age [3]. This is an alternative protocol, which could help to elucidate the pathogenesis of PF dysfunctions.

Figure:



Caption: Intra-vaginal contact area and peak pressure during two tasks. Means ± standard errors. *significant differences between tasks within the same region. #differences between regions within the same task. #1- different from all caudal and cranial left/right regions. #2- different from caudal left region. #3- different from all the other regions. $p<0.05$.

Conclusion: Pressure-time distribution during pelvic floor contraction and valsalva maneuver showed different patterns of peak pressures and contact areas across the vaginal cavity and could be used as an objective evaluation of the pelvic floor muscle function, elucidating the role of muscular force vectors on urogynecological function.

RELATIONSHIP BETWEEN LOADING INTENSITY AND DOSE OF PHYSICAL ACTIVITY WITH AGE AND BMI WHEN RECORDED BY ACCELEROMETRY AND QUESTIONNAIRE: POTENTIAL IMPLICATIONS FOR BONE HEALTH

Tina Smith [1,*] Sue Reeves [2] Jorg Huber [3] Lewis Halsey [2] Jin Luo [2]

[1]Institute of Sport, University of Wolverhampton, Walsall, [2]University of Roehampton, London, [3]University of Brighton, Brighton, United Kingdom

Introduction and Objectives: Fractures of the hip are an increasingly prevalent problem in an ageing population. Exercise is considered an effective measure in maintaining bone health and preventing the development of osteoporosis and hence decrease the risk of such fractures [1]. However, further clarity is required regarding how the intensity of exercise translates to mechanical stimulus at the site of the proximal femur to promote osteogenesis. In addition there is a need to identify the level of physical activity (PA) undertaken by differing individuals to accurately assess whether adequate PA is being undertaken to help maintain bone health.

Convenient and non-invasive ways of measuring PA are through questionnaires. However there could be issues around the accuracy with which participants recall and self-report previous or regular PA. Bone loading in PA can be measured more accurately by using accelerometers. Our latest research has developed a method using accelerometers to assess both loading magnitude and frequency in PA [2], which are two important parameters related to the adaptation and remodelling response of bone to mechanical stimuli [3].

The objectives of this study were to examine the relationship between loading intensity and dose at the proximal femur with age and BMI. Also to explore the relationship between PA levels determined via questionnaire with age and BMI.

Methods: A total of fifteen male and female participants (30.4±7.6y (range 18-45y), 1.7±0.1m, 76.7±14.9kg) with a mean BMI of 25.9±4.2kg/m^2 wore a tri-axial accelerometer, sampling at 10Hz, for 12 hours in order to record typical daily PA. The accelerometer was mounted directly above the hip joint as this was close to the site of typical proximal femur fractures and would therefore more accurately reflect the accelerations experienced within that region.

The 12 hours accelerometer data were filtered and then divided into 5-second long segments. Loading intensity was calculated for each segment [2] and the duration of physical activity at the following loading intensities was calculated – loading intensity of <5 BW/s, >5 BW/s, >10 BW/s, >15 BW/s, and >20 BW/s. The loading dose (BW) of physical activity was calculated at four frequency bands (0-5, 0-2, 2-4, and 4-5Hz).

Participant's usual PA levels were also measured using the short form of the International Physical Activity Questionnaire (IPAQ-SF). Accelerometer and IPAQ-SF data were correlated with age and BMI.

Results: Accelerometer and questionnaire data are provided in Table 1. Significant correlations were reported between age and loading dose for PA with frequencies ranging from 0-5Hz (overall dose: $r = 0.531$, $p = 0.041$) and loading dose for PA with a frequency range of 2-4Hz ($r = 0.547$, $p = 0.035$). Greater loading dose being associated with older age. Although not significant similar trends were observed for loading dose with a frequency range of 0-2Hz ($r = 0.487$, $p = 0.066$) and 4-5Hz ($r = 0.495$, $p = 0.061$). Questionnaire data revealed significant correlations between age and moderate ($r = 0.827$, $p < 0.001$) and vigorous ($r = -0.555$, $p = 0.049$) PA. Whilst moderate PA was significantly associated with an

increase in age, decreasing amounts of vigorous PA were associated with older age. There were no significant correlations between BMI and any of the PA measurements.

Conclusion: Acceleration data showed that the dose of mechanical loading in everyday activity tended to increase with age in the range from 18 to 45 years. It was also shown that age in this range does not seem to influence the time spent in very light (<5 BW/s) to vigorous (>20 BW/s) activity. These results suggest that people can generally maintain or increase their bone loading in daily activities from the age of 18 to early 40s. This is beneficial for the accumulation and preservation of greater peak bone mass to prevent osteoporosis. However, these results were not totally matched by questionnaire data which indicated that moderate PA increased with age, but vigorous PA decreased with age. This discrepancy could be due to the accelerometer providing only a snapshot of PA in the current cohort. However it could also reveal evidence of inaccurate reporting of levels of PA by participants.

Table:

	Variable	**Mean ± SD**
Accelerometer Data	Overall Dose 0-5Hz (BW)	80315.5 ± 20772.6
	Dose 0-2Hz (BW)	14206.1 ± 4095.3
	Dose 2-4Hz (BW)	42232.3 ± 11012.2
	Dose 4-5Hz (BW)	24884.5 ± 6407.4
	Loading Intensity < 5 BW/s (s)	38767.4 ± 1847.3
	Loading Intensity > 5 BW/s (s)	4432.6 ± 1847.3
	Loading Intensity > 10 BW/s (s)	1509.7 ± 1339.3
	Loading Intensity > 15 BW/s (s)	378.1 ± 465.4
	Loading Intensity > 20 BW/s (s)	199.8 ± 330.2
IPAQ-SF Data	PA Walking (MET-mins/wk)	1223.5 ± 1346.4
	PA Moderate (MET-mins/wk)	430.8 ± 420.8
	PA Vigorous (MET-mins/wk)	1224.6 ± 980.5
	PA Total (MET-mins/wk)	2878.9 ± 1462.5
	Weekday Sitting (mins/day)	420 ± 160.6

PASSIVE ELASTIC PROPERTIES OF HIP EXTENSORS IN SUBJECTS WITH LOW BACK PAIN

Mark Hines [1 2,*] Neale Tillin [2] Raymond Lee [1]

[1]School of Applied Sciences, London South Bank University, [2]Life Sciences, University of Roehampton, London, United Kingdom

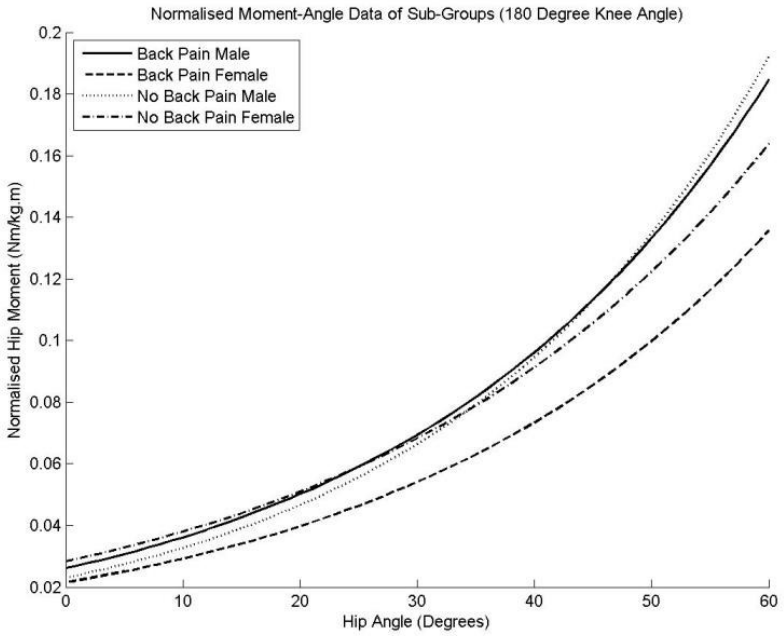
Introduction and Objectives: Due to observed alterations in hip function, during activities of daily living in low-back pain (LBP) patients, hip range of motion (ROM) is commonly assessed by clinicians and physical therapists (Tafazzoli and Lamontagne, 1996, Parks et al., 2003, Sjolie, 2004, Davis *et al.*, 2008, Ekedahl *et al.*, 2010, Ylinen *et al.*, 2010). However, it has been proposed that an assessment of hip extensor passive properties may be a more useful indication of mechanical limitations than ROM (Hamill *et al.*, 2009, Marshall *et al.*, 2009, Gombatto *et al.*, 2008). The purpose of the present study was to compare the passive properties of the hip extensors in individuals with and without chronic, non-specific LBP.

Methods: 61 participants (back pain n = 30 (male n = 15. female n = 16), no back pain n = 31 (male n = 15, female n = 15)) volunteered for this study and were allocated to groups according to gender and presence of back pain. Participants were positioned supine on a standard treatment couch, with the knee of the test leg supported into a straight or bent angle with 1 of 4 knee braces. 2 inclinometers were secured using straps to the thigh and shank, to measure hip angle and hip angular acceleration, and to monitor knee angle, respectively. Two surface electromyography (EMG) electrodes (SX230, Biometrics, UK), were placed over the biceps femoris and rectus femoris, in accordance with the SENIAM guidelines for electrode placement. A custom-built force transducer was inserted into an ankle brace, designed to house the transducer with minimal friction, whilst maintaining the ankle in plantigrade.

The tester performed 3 leg raises with a minimum of 1 minute rest between each with each of 4 knee braces. Data from the load cell and inclinometers was used in combination with anthropometric limb segment and mass data to calculate passive hip moments, stiffness and strain energy. The passive moment calculation was based upon the dynamic biomechanical model established by Lee and Munn (2000).

Results: Figure 1 shows normalised sub-group moment-angle curves at a knee angle of 180 degrees (knee straight). A MANOVA demonstrated no significant effects between groups at any hip angle for normalised moments, stiffness or strain energy, within any of the 4 knee angle conditions ($p > 0.05$).

Figure:



Conclusion: This study demonstrates that LBP does not significantly influence the hip extensors during passive leg raising. Observed differences during ADLs may potentially be due to alterations in active contributions to movements, such as motor control. Further research will be useful to better understand adaptations to long-term pain, and which tissues and components of movement should be targeted with clinical assessments and rehabilitation programmes.

WHOLE-BODY ENERGY TRANSMISSION EFFICIENCY IN KICKING A FOOTBALL

Shoma Kudo [1,*] Ryosuke Akaguma [1] Akinori Nagano [2]

[1]Department of Sport and Health Science, [2]Faculty of Sport and Health Science, Ritsumeikan University, Shiga, Japan

Introduction and Objectives: In football games, giving effective shots that are appropriate in individual situations is so important. Experienced players are able to control the ball skillfully. Moreover, kicking is the most important attacking option and most widely studied skill in football. There are many previous researches that analyzed the motion of kicking. Sinclair et al, (2014) [1] aimed to measure the technical aspects of kicking related to the generation of ball velocity using regression analyses. This study measured angular velocity and joint moment of the hip and knee joint. Zago et al, (2014) [2] used a total body center of mass based approach for the analysis of the kinematics of inside kick. Their study focused on the control of ball kicking. Kick motion consists of not only leg movements but also movements of the whole body. Therefore, it is important for football player to convey the energy efficiently from the whole body to the ball. The purpose of this study was to evaluate the energy transmission efficiency in kicking a football with respect to the whole body.

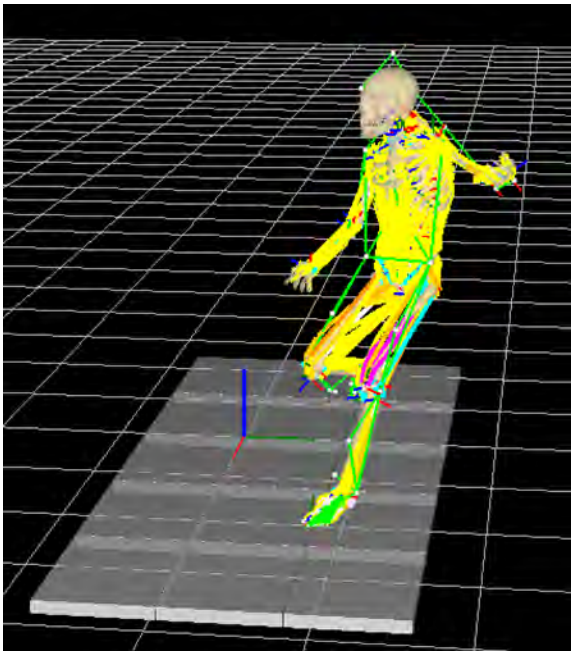
Methods: Participants: Six male subjects (age=21±1 years old) were examined while kicking a stationary football (size 5, mass= 410g). The subjects were divided into two groups (experienced or non-experienced). The experienced person had been playing football for at least three seasons. The participants were all free from musculoskeletal pathology at the time of data collection.

Procedures: We took 3-D kinematic data from the full body of the subjects performing three ways of kicks (inside, infront and instep) by a motion capture system (Motion Analysis, MAC3D system, USA). The ball was positioned such that the support foot land on a force platform (Tec Gihan, TF-4060-B, Japan). Force data were sampled at 1000 Hz. The ball speed was measured by a high speed camera (CASIO, EX-ZR1000, 480 frames/sec). Six subjects (3-experienced and 3-non experienced) wore underwear on which 29 reflective markers were attached. The markers were attached based on Helen Hayes marker set. They wore a pair of indoor shoes. After a warm up session, the subjects performed three kinds of kick at three strength variation.

Data processing: Three-dimensional kinematic and kinetics measures were calculated using nMotion musculous (nac Image Technology Inc, Japan) (Figure). We determined the impact as the instant at which the toe velocity decreased rapidly. The mechanical energy of the ball was calculated from the velocity and the height of the ball determined using a high speed camera. We evaluated the percentage of the energy transmission efficiency. We compared the mechanical energy change of the whole body and the ball.

Results: Energy transmission efficiency in kicking ranged between 13.1% ~ 29.1%. Transmission efficiency of experienced subjects ranged between 16.8% ~ 29.1%. Transmission efficiency of non-experienced subjects ranged between 13.1% ~ 21.7%. There were not large differences in energy transmission efficiency among the three kinds of kick form. Experienced subjects exhibited high energy transmission efficiency in kicking compared to non-experienced subjects. We consider that experienced subjects could kick the ball effectively because they have high skills.

Figure:



Caption: Snapshot of a kicking motion, processed with a musculoskeletal modeling software.

Conclusion: We evaluated the energy transmission efficiency of kicking a football. The experienced subjects exhibited high energy transmission efficiency in kicking compared to non-experienced subjects. The exact techniques to enhance the energy transmission efficiency need to be clarified in future studies.

Table:

		non experienced subjects		experienced subjects	
Kick	Strength	Average (%)	SD	Average (%)	SD
Inside	Weak	13.2	2.6	16.8	1.9
	Medium	18.2	4.9	29.1	2.5
	Max	21.7	5.6	25.4	1.5
Infront	Weak	16.4	7.5	26.3	2.6
	Medium	16.5	1.0	25.9	2.8
	Max	18.0	3.0	27.3	4.0
instep	Weak	18.7	3.5	25.8	4.7
	Medium	19.2	3.4	28.3	9.2
	Max	20.5	2.8	27.6	4.2

HOW DOES PLAYING SURFACE AFFECT TIBIAL ACCELERATION DURING FAST BOWLING IN CRICKET?

Billy Senington [1,*] Jonathan Williams [1] Raymond Lee [2]

[1]School of Health and Social Care, Bournemouth University, Bournemouth, [2]School of Applied Sciences, London South Bank University, London, United Kingdom

Introduction and Objectives: Previous studies have suggested that repetitive exposure to high levels of ground reaction force (GRF) may correlate with the abnormally high prevalence of lumbar stress fractures, knee and ankle injuries [1-3]. GRF is typically obtained using a force plate, introducing environmental constraints to data collection especially relating to the effect of different playing surfaces. Novel methods using accelerometer derived accelerations, have been shown to strongly correlate with GRF [4]. Therefore this study aims to classify different playing surfaces and quantify the effect of different playing surfaces on peak and time to peak acceleration experienced at the front tibia during fast bowling.

Methods: A custom built impact tester was used to measure vertical acceleration across four different surfaces: Grass wicket, outdoor astroturf wicket, indoor wood and rubber composite surfaces. Variables of peak and time to peak acceleration were used to classify individual surface firmness.

To determine the effect of surface on tibial impact five trained amateur fast bowlers completed 12 deliveries on the four different surfaces whilst tibial acceleration was measured. Bowlers were recruited from local cricket clubs and instrumented with a three-dimensional accelerometer (±200g) (THETAmetrix, ADXL377) sampling at 750Hz. This was attached to the medial aspect of the mid-tibia on the subjects' 'front' leg. Peak and time to peak tibial acceleration were identified for the front-foot impact phase of the bowling action.

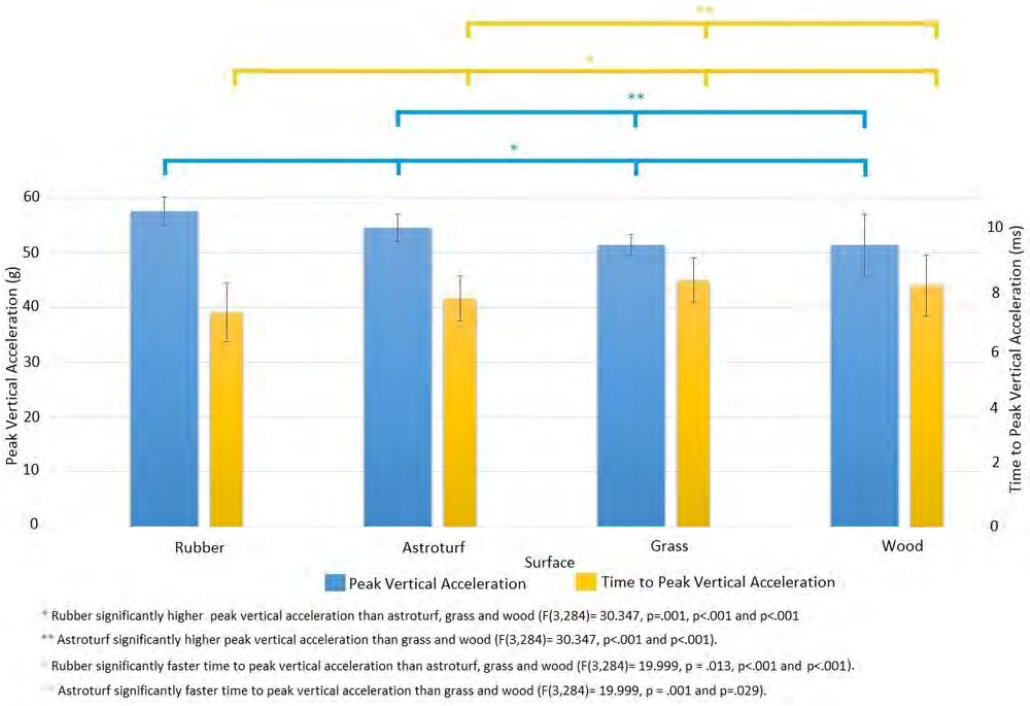
Intraclass correlation coefficients (ICC) were calculated from pooled data across all surfaces, standard error of measurement (SEM) and minimum detectable change (MDC) calculations for both the impact tester and tibial accelerations were calculated for all four surfaces. ANOVAs were used to analyse any differences between surfaces for both the impact tester and tibial accelerations.

Results: ICC, SEM and MDC results (seen in table 1) demonstrate high reliability between tests with ICC values between 0.716-0.932. SEM for all measures were low, consequently producing low MDC values of 2.92g and 4.21ms for tibial acceleration and time to peak acceleration and 3.52g and 1.92ms for the impact tester.

Peak and time to peak vertical acceleration results for the impact tester can be seen in figure 1.

Tibial acceleration during bowling on the wooden surface was significantly lower than grass, rubber and astroturf ($F(3,236)=33.972$, $p<.001$, $p=.001$ and $p<.001$). Peak tibial acceleration was significantly greater on the astroturf surface compared with grass, rubber and wood ($F(3,236)=33.972$, $p=.007$, $p<.001$ and $p<.001$). Time to peak tibial acceleration during bowling was longer on grass compared with astroturf ($F(3,236)=5.231$, $p=0.001$). No other significant differences were present (seen in table 1).

Figure:



Caption: Figure 1. Peak and time to peak vertical acceleration of a custom built impact tester on four cricket playing surfaces.

Conclusion: Novel methods were used to assess the effect of surface firmness on front tibial acceleration during fast bowling. Reliability testing demonstrates the results produced were highly reliable. This study has highlighted that there was no significant difference in the tibial impact characteristics of the two most commonly used surfaces in professional cricket (grass and rubber). However, peak tibial and impact tester accelerations agree that the wooden surface produced significantly lower peak accelerations. Time to peak tibial accelerations were significantly longer on grass compared with astroturf. No other significant differences in time to peak accelerations suggests that the wooden surface produced lower peak tibial acceleration, over a similar time when compared with the other surfaces. Therefore, wooden surfaces may be beneficial if impact reduction is desired. Conversely, it may be advisable to avoid high workloads on the 'harder' astroturf surface. As no studies have investigated the effect of bowling surface on kinematics, further work may be required to analyse how these results impact bowling kinematics.

Table:

	Peak Acceleration				Time to Peak Acceleration			
Surface	Peak Acceleration (g (SD))	ICC	SEM (g)	MDC (g)	Time to Peak Acceleration (ms (SD))	ICC	SEM (ms)	MDC (ms)
Astroturf	28.14 (5.79)	.932	1.17	2.95	26.93 (13.23)	.919	1.99	3.78
Grass	24.68 (6.64)	.93	1.54	3.39	36.36 (16.11)	.91	3.68	5.24

		2				9		
Rubber	21.97 (4.89)	.932	0.86	2.52	30.55 (13.42)	.919	1.67	3.45

HOW DOES THE SHOOTING MECHANICS CHANGE AFTER 3 MONTHS OF SHOOTING PRACTICES IN YOUNG BASKETBALL PLAYERS?

Yuki Inaba [1,*] Noriko Hakamada [1] Mitsuo Sasaki [2]

[1]Department of Sports Science, Japan Institute of Sports Sciences, Tokyo, [2]Keio University, Kanagawa, Japan

Introduction and Objectives: Improving the percentages of goals made among attempted shots during a basketball game is crucial for winning the game. Thus, optimal trajectory and spin rate of the ball that result in higher probability of shots made were investigated[1,2]. Also, shooting motion was investigated to examine intratrial variability of the shots, so kinematic analyses were conducted to investigate the variability of the joint motions [3,4]. However, since shooting mechanics how the ball is accelerated and how the back spin is applied is not investigated, the shooting motion that can improve the probability of shots made is not understood. Therefore, the first objective of this study was to investigate the mechanics of the shooting motion by conducting kinematic and kinetic analysis of upper body. In addition, in order to examine shooting motion with higher probability of shots made, the effects of shooting training that was attempted to improve ball trajectories and spin rate on shooting motion were assessed by pre- and post-training motion analysis tests, which was the second objective of this study.

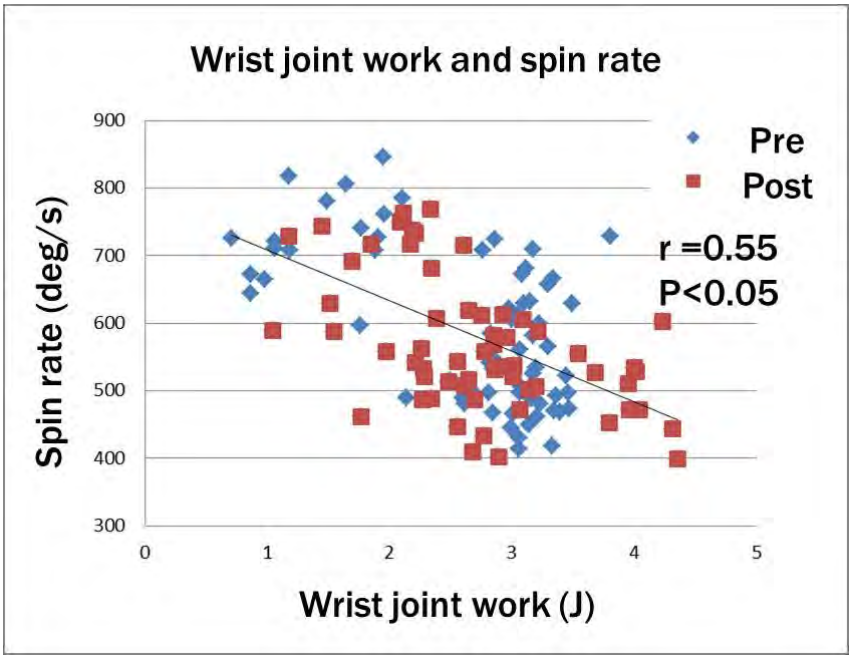
Methods: Eight young basketball players who were selected to national elite academy team (height: 184.1 ± 3.7 cm, weight: 76.6 ± 10.9 kg, age: 14.2 ± 1.2 years-old) participated in this study. All participants joined five times of basketball camps in 3 months (each camp consisted of 3-days with various basketball training) and their shooting motion were assessed before and after the training program (pre- and post-test). During the camps, players went through shooting drills and were instructed to increase the maximum height of the ball and increase the spin rate. In pre- and post-tests, each participant performed 10 shots from a line 5.5 m behind a backboard. The shooting motion and the trajectory of balls were captured with VICON motion analysis system with 18 cameras (MX-series) at 500 Hz. 45 markers were attached to the whole body of the participant and 5 markers to the ball surface.

Initial velocity and acceleration of the center of the ball, release angle in the saggital plane, and maximum height of the ball were analyzed. Spin rate was also calculated as the absolute value of the angular velocity vector of the ball [5]. Theoretical optimal projection angle of the ball in saggital plane was calculated as the minimum-speed angle defined by Brancazio in 1981 [6]. Also, force exerted on the ball from shooting finger was computed from the calculated acceleration of the ball. Then, joint moment at wrist, elbow, and shoulder were calculated using standard inverse dynamics methods. Joint work at each joint was calculated by integrating the joint power from the start of the elbow joint extension to ball release.

Results: Sum of joint works or total joint works from set position to release at shoulder, elbow, and wrist joint flexion/extension axis were 17.6 ± 3.2 J at pre-test and 15.7 ± 3.6 J at post-test. Among the total work, most of the joint work was done at the elbow joint flexion/extension axis (0.5 ± 2.7 J at shoulder, 13.7 ± 2.2 J at elbow, and 3.4 ± 0.6 J at wrist joint at the pre-test). Thus, it was suggested that elbow joint extension work contributed more to accelerate the ball compared to shoulder and wrist joint.Maximum height of the ball and the projection angle increased from the pre-test to

the post-test except one subject whose arch was relatively high at the pre-test. However, there were no significant changes in the spin rate from the pre-test (562.1±138.6 deg/s) to the post-test (539.9±118.1 deg/s). In order to increase the projection angle, the direction of the force exerted to the ball from finger should be directed more upward. This result in the force application line to pass through closer to the center of the ball and the moment exerted around the ball center would be smaller. Thus, it was speculated it is difficult to increase the spin rate at the same time as increasing the ball arch if appropriate skill for applying ball spin was not acquired.

Figure:



Caption: Figure: Spin rate decreased as the wrist joint work increased.

Conclusion: Firstly, it was found that joint work at elbow joint contributed more to accelerate the ball compared to shoulder and wrist joint work. After training session, even though the trajectory of the ball was improved, no improvement on spin rate was observed. It was considered that trying to increase the arch of the ball without having enough strength at elbow extension have the possibility to change the shooting mechanics and spin rate is not improved at the same time unless specific technique for increasing spin rate is learned.

BIOMECHANICAL AND GENDER DIFFERENCES BETWEEN SINGLE-LEGGED AND TWO-LEGGED RUNNING VERTICAL JUMPS

Masanori Sakaguchi [1,*] Ryan Madden [1] Nicole Schrier [1] Daniel Koska [1] John Wannop [1] Darren Stefanyshyn [1]

[1] Faculty of Kinesiology, University of Calgary, Calgary, Alberta, Canada

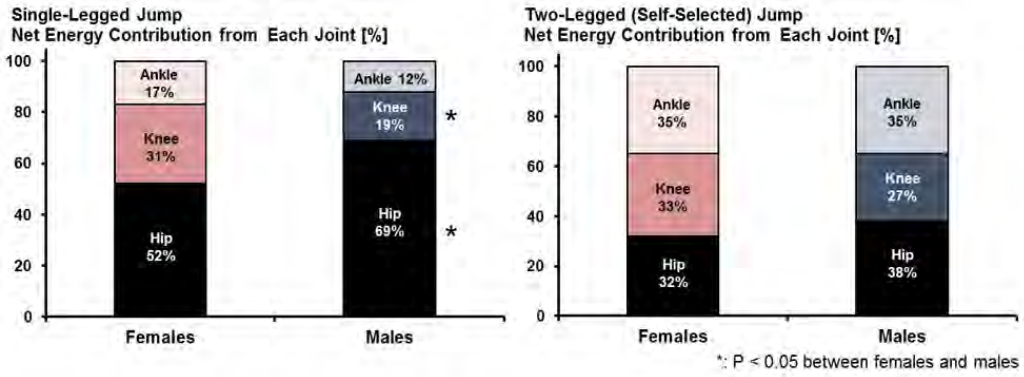
Introduction and Objectives: Vertical jump height is a crucial variable in many sports and depending on the situation, athletes may utilize either a single-legged running jump or a two-legged counter-movement jump. Interestingly, single-legged and two-legged running vertical jumps do not differ in maximum jump height despite the two-legged jump having twice the available leg musculature to produce vertical ground reaction impulse [1]. Vertical ground reaction impulse, therefore, is not sufficient to predict jump performance for a single-legged jump as it does not adequately capture the mechanical contributions of the swing leg. Furthermore, while gender differences have been studied during many athletic tasks, there is little information regarding differences for a running vertical jump. Therefore, the objectives of this study were to determine the biomechanical differences between single- and two-legged jumps, and to determine any differences in these jumps between males and females.

Methods: Twenty varsity athletes, 10 male and 10 female, were tested. Markers were attached to the athlete to determine segmental motions of the foot, shank and thigh for both legs as well as the pelvis and torso. Kinematic (240 Hz) and kinetic (2400 Hz) data were simultaneously recorded with an 8-camera motion capture system and 2 force plates. Jump heights were measured using a Vertec jump meter. To minimize the influence of footwear, all participants performed in a properly sized neutral training shoe (adipure 360, adidas). Athletes were asked to jump and reach as high as possible and contact the Vertec fins with their dominant hand using a single-legged running jump as well as a jump technique which they were free to choose with the only criteria being to reach as high on the Vertec as possible. All females and 6 of the 10 males selected a two-legged jump as the self-selected jump technique, while the remaining males selected a single-legged jump. Ten trials of each jump type were collected. Vertical ground reaction impulse and joint energetics were calculated. The net joint energy for the stance legs was calculated from the instant of the lowest position of the pelvis to takeoff. The energy from the swing leg was calculated from the same starting point to when the energy generated reached zero to account for any contributions during the flight phase. These time points were chosen as they are associated with the propulsive phase of the jump, where the energy generated is utilized to propel the athlete upwards. Paired t-tests were performed to compare between single- and two-legged (self-selected) jumps. Additionally, comparisons were made between the female and males using independent t-tests. Significance was set at $\alpha = 0.05$.

Results: A summary of the results is shown in Table 1, while joint energy contributions are shown in Figure 1. Comparing the single-legged and two-legged running jumps, results were the same regardless of gender with no significant difference in maximum jump height despite a greater vertical ground reaction impulse during the two-legged jump. The ankle and knee joint energetics were significantly greater during the two-legged jump, while the hip joint energetics were substantially greater during the single-legged jump with the influence of the swing leg becoming a significant factor, resulting in no difference in net energy of all joints combined compared to the two-legged jump. Comparing genders,

during the two-legged technique the ankle, knee and hip joints all contributed equally to the net energy between males and females ($P > 0.4$ for all). Conversely, during the single-legged jump males generated a greater amount of energy from their hip joint compared to the females ($P < 0.001$), while the females used a greater amount of energy from their knee ($P < 0.05$) with a trend toward significant difference at the ankle ($P = 0.067$).

Figure:



Caption: Joint Energy Contributions of Males and Females for Single- and Two-legged Jumps

Conclusion: While the maximum jump heights were similar between single-legged and two-legged running jumps, the jumping strategies employed to achieve the jumps were markedly different. Regardless of gender, the ankle, knee and hip joints all contributed equally to the net energy during the two-legged jump, whereas the hip joint energetics contributed the majority of the net energy during the single legged jump. In terms of the gender differences, males were able to generate significantly greater energy at the hip, resulting in greater net energy generation and increased jump height compared to the females.

Table:

		Female		Male	
		Single-legged	Two-legged	Single-legged	Two-legged
Maximum jump height [cm]		52	52	61	64
Vertical ground reaction impulse [Ns]		391	538 *	530	839 *
Net energy	Ankle [J]	51	110 *	45	142 *
	Knee [J]	95	103 *	83	121 *
	Hip [J]	160	101 *	269	157 *
	All joints [J]	306	314	384	407
*: P < 0.05, Single- vs. Two-legged jumps

THE DIFFERENCES OF THE KNEE JOINT KINEMATICS AND KINETICS BETWEEN VERTICAL AND ROTATIONAL JUMP LANDING

Daisuke Bai [1 2,*] Takahiko Fukumoto [2] Munehiro Ogawa [3] Yasuhito Tanaka [3]

[1]Heisei Memorial hospital, [2]Graduate School of Health Science, Kio University, [3]Department of Orthopaedic Surgery, Nara Medical University, Nara, Japan

Introduction and Objectives: Large knee valgus angles and moments during jump landing are considered as an important predictor of non-contact anterior cruciate ligament (ACL) injury risk, particularly in females. The vertical and rotational jump training was included for ACL injury prevention program. The drop vertical jump task was commonly used to assess biomechanical performance measures that are associated with ACL injury risk. However, there are no reports to analyze the biomechanics of rotational jump landing. The purpose of this study was to assess peak knee valgus angles and moments during vertical and rotational jump landing.

Methods: Ten healthy females participated in this study. The tasks were vertical jump, clockwise 180 and 360 degrees rotational jump. Peak knee valgus angles and moments of bilateral leg were investigated during 3 different jumps with a 3-dimensional motion analysis system (Vicon) and force plate (AMTI). 3D motion was collected with a 6-camera motion capture system that sampled at 120 Hz. Vertical ground reaction force was sampled at 120 Hz and the initial ground contact was defined as the time when the vertical ground reaction force exceeded 10N. A repeated-measures ANOVA with Bonferroni post hoc analysis was used to determine whether there were any significant differences between tasks for angles and moments. Written informed consent was attained from all participants, and approval for the study was provided by the university's ethical committee.

Results: No significant differences between vertical jump landing and 180 degrees rotational jump landing were found in peak valgus angles and moments. Peak valgus angles and moments during 360 degrees rotational jump were significantly increased than the other jump landings ($P < .05$).

Conclusion: Our findings showed that knee kinematics and kinetics changed with different jump landings. Modification of high-risk movement strategies such as dynamic knee valgus angles and moment is key to the reduction of ACL injury. The results of the present study implicated that it is necessary to take into account not only vertical jump landing but also rotational jump landing to develop ACL injury prevention programs.

EFFECT OF BRA STRAP STIFFNESS ON BREAST KINEMATICS AND PERCEIVED BRA PERFORMANCE DURING TREADMILL RUNNING

Steph Forrester [1,*] Laura Whittingham [1]

[1]Wolfson School oif Mechanical and Manufacturing Engineering, Loughborough University, Loughborough, United Kingdom

Introduction and Objectives: Sports bras aim to reduce breast motion during exercise and thereby eliminate pain or discomfort commonly present under lesser breast support conditions [1]. The ability of a specific sports bra to reduce breast kinematics is a function of the bra structure and the properties of the materials used. Therefore, understanding the relationship between breast kinematics and the mechanical properties of a bra can help in the development of more supportive bras, particularly for high impact sporting applications. Previous studies that have tried to link breast kinematics to bra mechanical properties have typically used commercial bras where many aspects of the bra structure and materials varied simultaneously making it difficult to isolate the individual effects, e.g. [2]. The objective of this study was to investigate the effect of strap stiffness on bra performance (breast kinematics and perceived performance) during treadmill running by manipulating the material properties of the strap whilst holding the remaining structural and material aspects of the bra constant.

Methods: Following institutional ethical approval, ten recreationally active female participants (age 25.9±5.5 years; height 1.65±0.09 m; body mass 67.0±9.6 kg) with large breasts (underband size range 32–36 and cup size range D–F) provided informed consent. Following a short warm up, each participant completed treadmill running trials at 10 kph for each of three different strap stiffness conditions in a randomised order. Breast kinematics (relative to the torso) was captured using a seven marker set torso model and a marker on the fullest part of each breast. A marker on the right heel allowed gait cycles to be identified. Following each trial the participants were asked to rate the comfort, fit and support of the bra on a 7-point Likert scale.

Strap stiffness was modified by adapting an existing popular sports bra (Shock Absorber High Exertion N109). A section of the existing strap was removed and replaced by either a single, double or triple layer of 20 mm wide elastic (woven polyester as typically used for waistbands). The straps were connected to the bra at either end by steel hooks allowing strap changeover without removal of the bra, while the stiffness properties of each strap condition was quantified through tensile testing (Instron 5569).

Statistically significant differences between the strap conditions in three-dimensional breast displacements and participant perceptions were tested using the Friedman test with Wilcoxon post-hoc ($p < 0.05$).

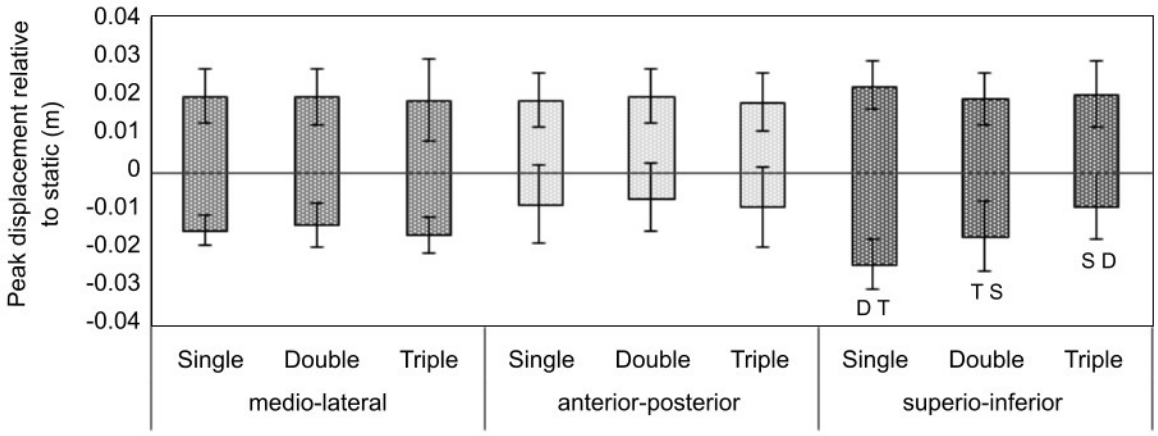
Results: The single, double and triple elastic layer straps had stiffness values of 200, 550 and 800 $N \cdot m^{-1}$ respectively.

The only significant difference in breast displacement between strap conditions was in the downward superio-inferior direction (Fig. 1). The double and triple straps reduced downward breast displacement by 7 and 15 mm respectively compared to the single strap, confirming that the principle role of the straps is in controlling downward motion of the

breasts. The lack of significant differences in medio-lateral and anterior-posterior breast displacements suggests that other aspects of bra design are more important for controlling movement in these directions.

Significant differences in perceived support were observed between the single and triple strap conditions. The values increased from 0.1±1.2 to 1.4±1.0 to 2.1±0.6 for the single, double and triple strap conditions respectively (-3 corresponded to extremely unsupportive, 0 to neutral and +3 to extremely supportive). Examining the support ratings across bra sizes, then negative ratings only occurred for the single strap and only for bra sizes of 36D and above suggesting that the single strap may still have provided adequate support for the smaller-breasted participants. Perceived comfort (overall 1.8±0.6 where 2 is very comfortable) and fit (overall 1.3±0.6 where 2 is very good fit) were high with no significant differences between strap conditions thereby supporting the method used to manipulate strap stiffness.

Figure:



Caption: Figure 1. Three dimensional relative breast displacements for the single, double and triple strap conditions. S, D, T indicates significant differences to the single, double and triple strap conditions respectively.

Conclusion: Increasing strap stiffness improved sports bra performance with respect to reducing breast motion and improving the perceived support. However, the displacement improvements were limited to the downward superior-inferior direction reinforcing the role of the straps in controlling only this aspect of breast motion.

AS-0362

A NOVEL DEVICE FOR PROTECTING AND RESTRAINING HEAD AND NECK IN TACKLE FOOTBALL PLAYERS

Paolo Caravaggi [1,*] Alberto Leardini [1] Giada Lullini [1] Sorin Siegler [2]

[1]Movement Analysis Laboratory, Istituto Ortopedico Rizzoli, Bologna, Italy, [2]Mechanical Engineering and Mechanics, Drexel University, Philadelphia, United States

Introduction and Objectives: In tackle football, large contact and inertial forces and moments act on the player's head [1] resulting in elevated risk for traumatic head, brain, and cervical spine injuries [2]. Mandatory helmets for head protection together with a variety of rules were designed in order to minimize helmet collisions [3,4]. However, brain and spinal cord injuries resulting from large hits still persist with devastating consequences to players [1,5]. The goal of this study is the development and the evaluation of a novel customizable, visco-hyper-elastic, multi-directional Head and Neck Protective Device (HNPD, Figure 1a) providing limits to head and neck motion in order to prevent injury without compromising the athletic performance.

Methods: The HNPD (Figure 1a) consists of adjustable composite bands having low modulus of elasticity combined with a rigid non-elastic band with high modulus of elasticity, inspired by the known visco-hyper-elastic properties of biological connective tissues such as tendons and ligaments. The area between the elastic and the non-elastic bands is filled with a viscous material; when the elastic band is un-stretched, the non-elastic band is crimped and folded.

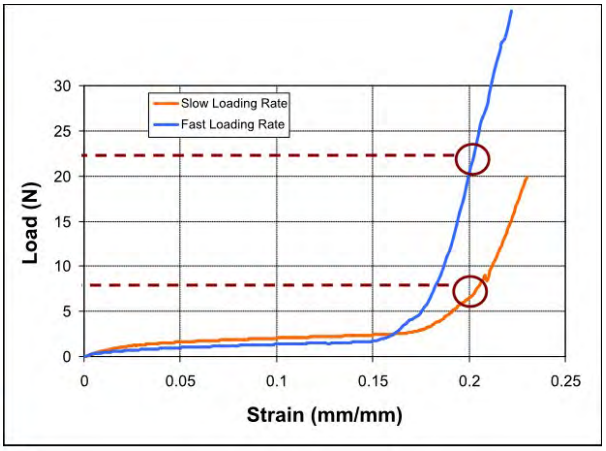
Tensile testing of the composite band was conducted at two different loading rates in order to measure its mechanical properties.

In addition, passive and active range of motion (ROM) of head and neck in all three anatomical planes was investigated using a C-ROM device in ten healthy male subjects (Figure 1a). Tests were conducted in each subject in four configurations: fully unrestrained (free motion); wearing a football gear (shoulder pads and helmet); wearing the HNPD, and wearing the HNPD under the football gear.

Results: As the composite band is initially stretched, the non-elastic band starts to unfold thus the net modulus of elasticity is very low (Figure 1b). Once the non-elastic band becomes fully unfolded, the composite band becomes stiffer and provides higher resistance to increased forces. Also, due to the presence of the viscous material, the resistance to external forces increases with increased loading rate.

The data on the effects of the HNPD on ROM of head and neck are shown in the table. All subjects experienced reduced ROM in all anatomical planes during active and passive neck motion wearing the HNPD. The decrease in head and neck motion was significantly larger ($p<0.05$) compared to the restraint provided by the gear alone.

Figure:



1a **1b**

Caption: 1a A subject wearing the HNPD during testing with the C-ROM device. 1b Load/strain behavior of one of the visco-hyper-elastic bands comprising the HNPD at slow and fast loading rates.

Conclusion: A novel device for restraining head and neck excursion within safe, injury free limits in tackle football has been developed and introduced in this study. The present HNPD prototype, worn under the football gear, incorporates five adjustable hybrid bands connecting between the player's head and his torso enabling adjustable desired resistance to external forces in all planes of motion.

Testing indicate that the HNPD is capable of protecting the head and cervical spine by limiting head and neck motion. Further investigations will be performed with inertial motion units in a variety of neck motion patterns, and in the field during typical football training movements.

Table:

	gear vs. free		HNPD vs. free		gear+HNPD vs. free	
	active	passive	active	passive	active	passive
flexion	2 (17)	10 (13)	-47 (20)*	-42 (23)*	-54 (26)*	-56 (18)*
extension	-23 (8)	-21 (9)	-57 (19)*	-47 (18)*	-64 (15)*	-55 (13)*

DOES SELECTION OF STAIR GAIT CYCLES AFFECT RESULTING LOWER LIMB BIOMECHANICS?

Daniel Watling [1] Paul R. Biggs [1,*] Cathy Holt [1] Gemma Whatling [1]

[1] Arthritis Research UK Biomechanics and Bioengineering Centre at Cardiff, Cardiff University, Cardiff, United Kingdom

Introduction and Objectives: Stair gait is a valuable activity for the assessment of lower limb function [1]. Stair ambulation is a functionally challenging activity of daily living which can eliminate variations in gait velocity within biomechanical analysis [1] [2]. A large amount of data can be generated at the different levels of the staircase. This has resulted in a variety of different stair gait cycles (SGCs) reported in the literature and little agreement as to which SGC should be selected for analysis [3]. In order to discern differences in biomechanical data between healthy and pathological subjects these differences must be greater than the inter subject variability within groups. This study quantifies the differences and variability in bilateral hip, knee and ankle joint rotations and moments during 2 different SGC's of stair ascent and descent in healthy subjects.

Methods: Motion capture and simultaneous force plate data was collected from 37 healthy volunteers (14 male, 23 female, BMI 71k±13kg) during stair ascent and descent on a previously reported validated 4 step staircase [4]. Simultaneous, synchronised bilateral lower limb kinematics were assessed with 8 Qualisys Pro Reflex cameras (Qualisys, Sweden) sampling at a frequency of 60Hz. A modified Helen Hayes marker protocol was adopted [5] using four rigid marker clusters and an additional 22 retro-reflective markers at specific anatomical landmarks. Kinematics and inverse dynamic calculations were performed for the hip, knee and ankle within Visual 3D (C-Motion, USA).

Four stair gait cycles (SGC's) are defined for analysis. SGC 1 (ascent) was defined between foot strikes on step 1 and step 3, SGC 2 between foot strikes on step 2 and step 4, SCG3 (descent) was defined between toe offs on step 3 and step 1, and SGC 4 between toe offs on step 4 and step 2. Mean three-dimensional hip, knee and ankle kinematics and joint moment waveforms were calculated for the six trials of each SGC for each participant. Discrete parameters including range of motion (ROM) and peak joint moments were calculated from each waveform for statistical analysis.

The coefficient of variation (COV) was used to investigate variability between subjects for each of the test parameters based upon the recommendation of [6] and expressed as a percentage.

COV=(Standard deviation/mean)*100%

Statistical analysis was carried out in SPSS using a one-way ANOVA test in SPSS using an alpha level of 0.05.

Results: Lower limb kinematics were not affected by the choice of SGC in ascent of descent. A statistical difference was identified for knee range of motion between the SGC's of stair ascent, though the difference of less than 2° falls within accepted errors associated with motion analysis techniques analysis [7, 8]. Peak ankle plantar-flexion, knee flexion and knee adduction moments were significantly different ($P < 0.05$) between SGC's in ascent. Peak knee flexion, knee adduction, hip flexion, extension and adduction moments were significantly different ($P < 0.05$) between SGC's in descent.

Conclusion: Lower limb kinematics are insensitive to SGC selection for a 4 step stair case. Hip, knee and ankle joint moments varied significantly between SGC's. The results suggest SGC's at gait initiation (SGC1 and SGC4) demand a

greater magnitude of peak sagittal plane moments than those close to gait termination. Measurements taken with force plate strikes on step1 in ascent (SGC1) and descent (SGC3) introduce less inter-subject variability and are therefore recommended for future group comparisons. While a larger staircase design might enable the subjects to reach a steady gait [9], practicalities such as cost, ceiling height, capture volume and subject fatigue have resulted in a number of researcher groups using small staircase designs [10]. These results will help ensure biomechanical, functional changes following joint pathology more are more easily distinguishable from individual variation.

ACHILLES TENDON MOMENT ARM GEOMETRY IN TYPICALLY DEVELOPING CHILDREN

I-Zack Lum [1] Cyril Donnelly [2,*] Siobhan Reid [2] Caroline Davis [2] Catherine Elliott [3] Jane Valentine [3] Amar El-Sallam [2]

[1]School of Sports Science, Exercise and Health, University of Western Australia, Singapore, Singapore, [2]School of Sports Science, Exercise and Health, University of Western Australia, [3]Deparment of Paediatric Research, Princess Margaret Hospital for Children, Perth, Australia

Introduction and Objectives: The ankle is one of the most important joints to absorb and generate forces and moments of force during gait. Surgeries are frequently used to correct observed differences in a patient's ankle mechanics during gait. To inform researchers and clinicians on specific mechanical characteristics of pathological gait pattern prior to surgeries, musculoskeletal models of the ankle are sometimes used. To accurately model muscle forces and joint moments about the ankle, reliable subject-specific *in vivo* moment arm estimations are required. Current 3D *in vivo* models use multiple magnetic resonance imaging (MRI) scans across the ankle's full range of motion, which is extremely time consuming with pragmatic limitations. Our aim was to develop a reliable MRI based, 3D, *in vivo* method to estimate Achilles tendon (AT) moment arms in typically developing children from a single scan sequence at a single joint posture. The secondary aim was to develop a regression equation to predict AT moment arm lengths using specific anthropometric variables.

Methods: A single time point cross-sectional design was used. Fifteen typically developing children, aged 4-12 years (mean 8.1 years, standard deviation (SD) 2.3 years), with no history of musculoskeletal conditions or injuries participated. A T1 spin echo MRI scan sequence of the lower limb was performed at Princess Margaret Hospital to obtain images of the AT and talocrural joint in the transverse and sagittal planes. Images were collected using a repetition time of 572ms, echo time of 13ms, slice thickness of 3mm, and mean inter-slice gap of 0.3mm. MR images were processed using MimicsÒ and six model combinations were used to estimate AT moment arms of participants. These include three definitions of the ankle's flexion-extension (F/E) axis of rotation (the Two-marker method (TMM), 2-point Talus method, and 3D Geometric model) (Fig. 1) each matched with two definitions of the AT line of action (the linear and polynomial methods). 3D coordinates of the talocrural joint's F/E axes and the AT were exported from MimicsÒ and processed using MATLAB to calculate the AT moment arms from each model combination.

To test the intra- and inter-rater reliability of all six AT moment arm model combinations, the first researcher processed the scans and calculated the AT moment arms twice (one week apart), and a second researcher did this once. Both researchers were blinded to the identities of participants. Intraclass correlations (ICC) and Bland-Altman plots were used to assess intra- and inter-rater reliability of all AT moment arm models. Bland-Altman plots were used to compare relative differences between methods and the limits of agreement (LoA) of their respective measurement errors (±2 SD). A stepwise regression analysis was used to formulate a regression equation to predict AT moment arm length using the anthropometric variables foot length, tibia length and ankle plantar-flexion angle calculated during the scan sequence.

Results: Irrespective of the modelling approach, all methods displayed high intra- and inter-rater reliability (ICC = 0.957-0.990), low mean errors (-1.97-0.98) and tight LoA (1.57-2.72). A difference of 9.8mm in AT moment arm measurement was observed between the 3D Geometric model and TMM. There were minimal differences between the AT moment arm

measured by the 3D Geometric model and 2-Point Talus method when calculated with the AT modeled as both a straight line and fifth order polynomial. Using the 3D Geometric model and polynomial method, foot length ($p = 0.002$) and tibia length ($p = 0.002$) were significant predictors of AT moment arms, accounting for 92% ($R^2 = 0.92$) of the variance in AT moment arm length.

Figure:

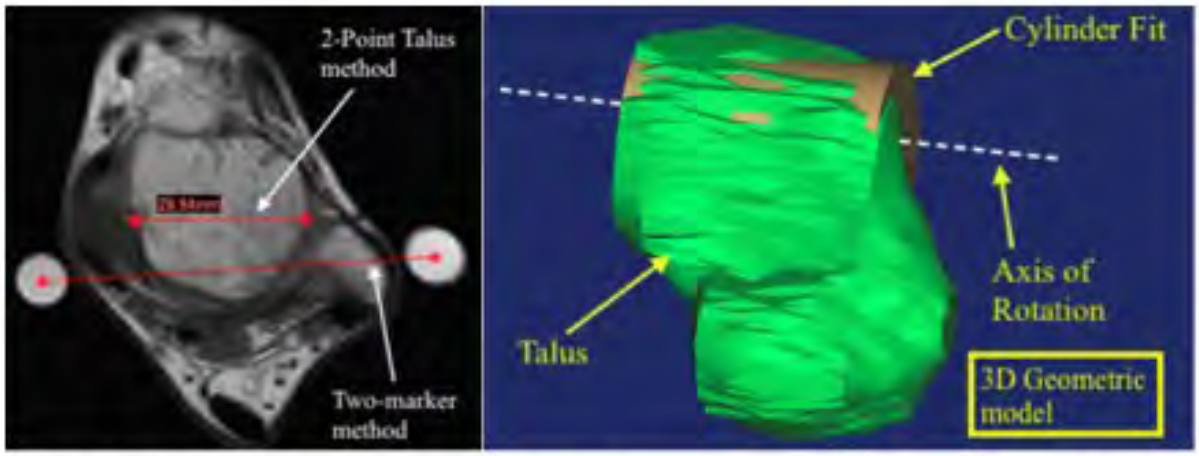

Fig. 1 The Two-marker-method, 2-point Talus method, and 3D Geometric model

Caption: The Two-marker method, 2-Point Talus method, and 3D Geometric model

Conclusion: All models for estimating 3D AT moment arms in typically developing children had high intra- and inter-rater reliability. The 3D Geometric/Polynomial model is recommended as the method of choice for three reasons; 1) it accounts for the geometry of the talus when defining the F/E axis of the talocrural joint; 2) a polynomial better represents the curved geometry of the AT, particularly during non-weight bearing tasks; and 3) a geometric cylinder to define the F/E axis of the talocrural joint may be more appropriate for populations with boney deformity where specific anatomical landmarks may be difficult to define. The current regression model predicted AT moment arm length across a wide range of foot and tibia lengths regardless of ankle position, potentially removing the need for MR images to estimate the AT moment arm in typically developing children. We recommend that the 3D Geometric/Polynomial model be tested for the measurement of AT moment arms among pathological paediatric populations with foot and ankle deformities. The current findings will have clinical relevance if used for the development of subject-specific musculoskeletal ankle models in a clinical paediatric population.

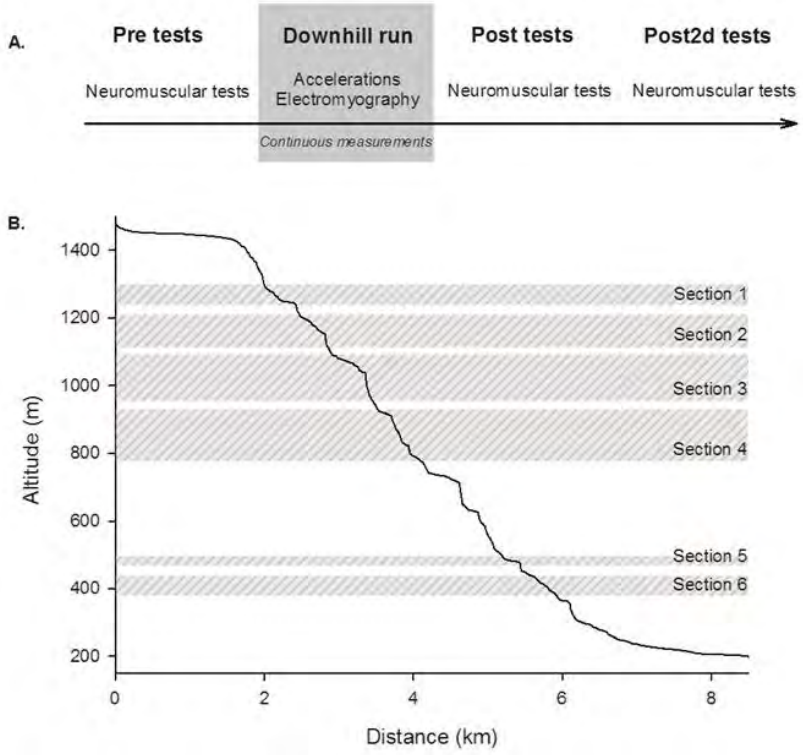
EFFECT OF THE FOOT STRIKE PATTERN ADOPTED DURING AN INTENSE DOWNHILL TRAIL RUNNING BOUT ON LOWER LIMB MUSCLES ACTIVITY AND NEUROMUSCULAR FUNCTION

Marlène Giandolini [1,*] Nicolas Horvais [2] Jérémy Rossi [1] Guillaume Millet [3] Jean-Benoit Morin [4] Pierre Samozino [1]

[1]Laboratory of Exercise Physiology, University of Savoie, Le Bourget-du-Lac, [2]Salomon SAS, Amer Sports Footwear, Annecy, France, [3]Human Performance Laboratory, University of Calgary, Calgary, Canada, [4]Laboratory of Human Motricity, University of Nice Sophia Antipolis, Nice, France

Introduction and Objectives: Downhill running and the associated eccentric actions generate muscle damage and excitation-contraction coupling failure [1]. A significant part of the peripheral fatigue observed after ultratrail races could be attributed to the downhill sections. Minimizing musculoskeletal damage and muscular fatigue is thus considered as a determinant factor of performance in ultratrail [2]. Our purpose was to study the influence of the foot strike pattern (FSP) adopted during a downhill run on the neuromuscular fatigue at knee extensors (KE) and plantar flexors (PF).
Methods: Twenty-three runners performed a 6.5-km downhill trail run (with 1 264 m of descent). FSP and muscular activity were sampled continuously and analyzed within six sections (Figure 1). FSP was identified using two accelerometers attached to the left shoe (heel and metatarsals) by measuring the time between the heel and metatarsals acceleration peaks (THM) [3]. A positive THM indicates a rearfoot strike while a negative THM indicates a forefoot strike. Electromyographic activity was recorded from the left *vastus lateralis* (VL), *biceps femoris* (BF), *gastrocnemius lateralis* (GL) and *tibialis anterior* (TA). KE and PF neuromuscular function was assessed Pre, Post and 2 days post (Post2d). Maximal voluntary contraction (MVC), percentage of voluntary activation (%VA), high-frequency doublet force (Db100), single twitch force (Tw) and low-frequency fatigue (LFF, decrease in the ratio of stimulation peak forces at 10 Hz over 100 Hz) were measured. ANOVAs were computed from neuromuscular variables. Multiple regressions were performed with THM and the time to cover sections as independent variables, and RMS values as dependent variables (n = 138). Multiple regressions were also performed with the average THM and performance (time to cover the run) as independent variables, and Pre-Post and Pre-Post2d percent changes of neuromuscular indices as dependent variables (n = 23).
Results: The running time was 34 ± 6 min. A total of 439 ± 34 steps were analyzed per subject. The downhill run decreased MVC for KE and PF at Post (large effect) and Post2d (medium effect) (Table 1). Decreases in Db100, Tw and LFF were observed at Post for KE (large effect). PF Tw and Db100 were decreased at Post (large and medium effects, respectively). %VA was lower at Post for KE and PF (large effect) and Post2d for PF (medium effect). From the multiple regressions, THM was positively related to VL and TA RMS ($p < 0.001$), and negatively related to GL RMS ($p = 0.035$). Positive correlations were reported between THM and percent changes in PF Tw and Db100 Post ($p < 0.05$). Positive correlations were also observed between THM and percent changes in KE Db100 at Post and Post2d ($p < 0.05$). The more anterior the FSP, the greater the decreases in the peripheral indices of fatigue for PF and KE.

Figure:



Caption: Description of the protocol design. Panel A: tests and measurements. Panel B: Profile of the downhill run, showing the six sections used for data analysis.

Conclusion: The downhill run induced peripheral fatigue for KE and PF of similar or even higher magnitude than those reported after an ultratrail [4]. This highlights the importance of eccentric mode of contraction in peripheral fatigue. Adopting a more anterior FSP led to a higher GL activity, likely explaining in part the greater peripheral fatigue at PF with this FSP. Greater severity of peripheral fatigue for KE with a forefoot strike may be attributed to a more flexed knee at initial contact, typical of this FSP [5]. This could lead (i) to lengthier lever arms between both the ground reaction force and weight vectors and the rotation axis (i.e. the knee joint), increasing thereby the torque produced eccentrically by KE preventing the lowering of the body center of mass; (ii) to greater KE lengths, which has been shown to worsen muscle damages [6]. In ultratrail, the total negative elevation (number of eccentric contractions) and the runners' speed in downhill sections (intensity of eccentric contractions) might be of greater importance for peripheral fatigue than the overall distance. Its severity could also depend on the FSP used.

ASSESSING THE EFFECTIVENESS OF FIELD-BASED ACL INJURY RISK SCREENING METHODS IN IDENTIFYING HIGH-RISK LANDING PATTERNS DURING A SPORT-SPECIFIC TASK

Aaron S. Fox [1,*] Jason Bonacci [1] Scott McLean [2] Michael Spittle [3] Natalie Saunders [1]

[1]School of Exercise and Nutrition Sciences, Deakin University, Melbourne, Australia, [2]Human Performance Innovation Laboratory, University of Michigan, Ann Arbor, United States, [3]College of Sport and Exercise Science, Victoria University, Melbourne, Australia

Introduction and Objectives: Screening methods that identify those at-risk of suffering an anterior cruciate ligament (ACL) injury are vital for the development of targeted ACL injury prevention strategies. Field-based screening methods offer a simplistic and accessible method to identify dysfunction that may lead to injury. The Landing Error Scoring System (LESS) [1] and Tuck Jump Assessment (TJA) [2] assess ACL injury risk via the scoring of an athlete's landing technique. Higher scores should reflect dysfunctional biomechanical patterns during high-risk sporting tasks; however, the relationship between scores from these screening methods and lower limb mechanics during sport-specific tasks is yet to be examined. At present, the ability of these screening methods to identify poor lower limb mechanics and potential injury risk during high-risk sporting tasks is unknown. The purpose of this study was to examine the association between LESS and TJA scores to lower limb biomechanical patterns during a sport-specific landing task.

Methods: Twenty-five female netball players (23.6 ± 3.2 years; 170.4 ± 7.6 cm; 67.6 ± 9.0 kg) performed ten trials of a sport-specific landing task and had their landing technique screened as per the LESS [1] and TJA [2] protocols. The landing task chosen for this study was a netball leap landing; which involved a six-metre run-up, followed by a single-limb take-off and land on the contralateral limb while catching a pass. Three-dimensional hip and knee joint rotations and external joint moments were calculated from lower extremity kinematics and ground reaction force (GRF) data collected during the sport-specific landing task. Data were extracted from initial contact (IC) to 300 ms post IC. A vertical GRF threshold of 10N was used to detect IC.

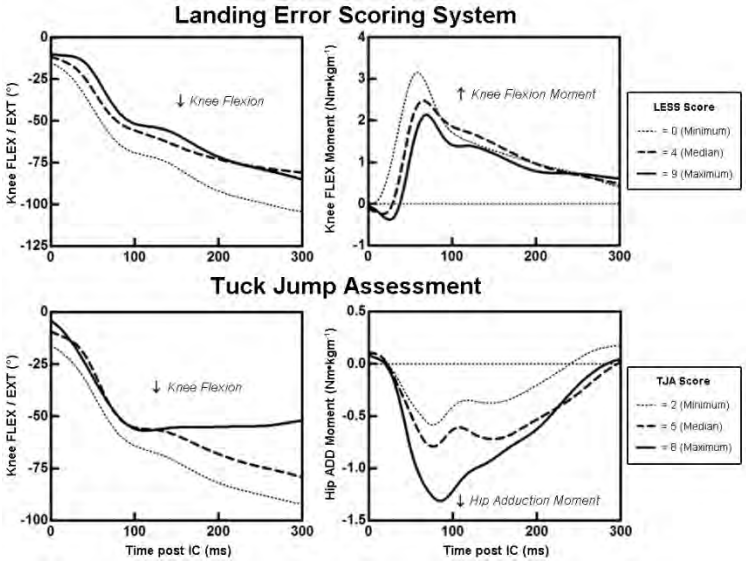
Principal patterns (PP) in biomechanical data were identified by submitting extracted joint rotation and moment waveform data to principal component analysis (PCA). Patterns were extracted for the variables of hip flexion/extension ($H_{FLEX/EXT}$), adduction/abduction ($H_{ADD/ABD}$), and internal/external rotation ($H_{IR/ER}$); knee flexion/extension ($K_{FLEX/EXT}$), adduction/abduction ($K_{ADD/ABD}$), and internal/external rotation ($K_{IR/ER}$); and H_{FLEX}, H_{ADD}, H_{ER}, K_{FLEX}, K_{ABD}, and K_{ER} moments. Principal pattern scores (PP-Scores), which measure the degree to which the shape of the waveform corresponds to each PP [3], were computed and used for subsequent analyses. Pearson's correlation coefficients (*r*) were calculated to identify significant associations ($p < 0.05$) between LESS/TJA score and PP-Scores.

Results: LESS scores ranged from 0 to 9. Increasing LESS scores were associated with landing patterns with greater H_{ER} (r =-0.48), and peak K_{EXT} and K_{FLEX} moments (r = -0.47); and reduced K_{FLEX} (r = 0.42) and peak transverse plane knee moments (r = -0.42).

TJA scores ranged from 2 to 8. Increasing TJA scores were associated with landing patterns with reduced H_{FLEX} (r = -0.46) and K_{FLEX} (r = 0.40); and greater frontal plane knee motion (r = 0.39), and H_{ADD} (r = -0.42) and H_{ER} moments (r = 0.41).

Figure 1 illustrates the relationship between LESS and TJA scores and relevant biomechanical patterns during landing.

Figure:



Caption: Figure 1: Mean data from participants achieving the minimum (dotted), median (dashed), and maximum (solid) scores on the LESS and TJA for relevant biomechanical patterns.

Conclusion: Higher LESS scores were associated with reduced knee flexion, while higher TJA scores were associated with reduced hip and knee flexion, and greater frontal plane knee motion and hip adduction moments. This suggests both methods may have some utility in screening for biomechanical patterns proposed as risk factors for ACL injury [4-6] during a sport-specific task. Interestingly, higher LESS scores were indicative of reduced transverse plane knee moments; and scores from neither method were associated with frontal plane knee moments. Both transverse and frontal plane knee moments have been linked to increased ACL injury risk [7,8], therefore screening methods that identify these risk factors may be more adept in identifying athletes at-risk of ACL injury. Future work should focus on examining and maximising the capability of screening methods to identify high-risk mechanics during a range of sport-specific tasks.

AS-0367

BIOMECHANICAL CLASSIFICATION OF GAIT FOLLOWING TOTAL KNEE REPLACEMENT - COULD FUNCTIONAL RECOVERY HAVE BEEN PREDICTED?

Paul R. Biggs [1,*] Daniel Watling [1] Gemma Whatling [1] Cathy Holt [2]

[1]Arthritis Research UK Biomechanics and Bioengineering Centre, [2]Institute of Medical Engineering & Medical Physics, Cardiff University, Cardiff, United Kingdom

Introduction and Objectives: Whereas patient satisfaction of hip replacements in the UK in generally reported as 93%[1], satisfaction of knee replacements is much lower at 82% [2]. Pain is the primary indication for TKR surgery, however functional improvement still has a critical role in patient satisfaction [3].

As with all interventions, one of the keys to maximising benefits is an understanding of which patients benefit the most. This requires the use of quantifiable post-operative outcome measures and preoperative 'predictors'. A Dempster-Shafter theory (DST) classification technique has been shown to accurately discern biomechanical data between healthy and osteoarthritic (OA) knee function arriving at a degree of belief of OA, non-pathological function and uncertainty. This facilitates the objective quantification of post-operative recovery [4].

Use of three-dimensional motion analysis techniques is variable within a clinical environment – partly due to practicality and costs [5]. This study aims to retrospectively explore if recovery of biomechanical gait function could have been predicted using only variables practically obtainable during clinic, namely subjective knee outcome survey scores, temporal spatial parameters, sagittal knee angles and ground reaction force (GRF) data.

Methods: Human motion analysis was initially performed on 25 healthy (NL) and 25 subjects with late stage knee OA whom had been recommended for TKR surgery. Four marker clusters were attached to the subjects and 3D positional data was acquired using nine Oqus cameras (Qualisys, Sweden) at 60Hz. Ground reaction force (GRF) data was collected using two force plates (Bertec, USA) at 1,080 Hz. Subjects walked barefoot overground at a self-selected pace until six clean force-plate hits were observed. Kinematics and inverse dynamic calculations were performed for the hip, knee and ankle within Visual 3D (C-Motion, USA). Principle component analysis was performed in order to represent the greatest variance of each waveform as discrete variables. Twenty-seven PCs were retained, representing an average variance of 85% of the twelve waveforms. This data was used to train the Cardiff Classifier in order to characterise OA and healthy biomechanical knee function. This methodology was then repeated to quantify the pre-operative and 1 year post-operative function of 12 TKR patients. Postoperative improvement in function was calculated as the percentage reduction in the belief of OA. Statistical analysis was carried out in SPSS using a Pearson correlation and an alpha level of 0.05.

Results: The training of the classifier achieved an out-sample accuracy of 98%. 7 subjects improved significantly (Δ39-75%) and the other 5 subjects displayed very little functional recovery (Δ 0-12%).

Pre-operative age (r=0.66, p=0.02), cadence (r=0.75, p=0.005), stance percent (0.70, p=0.012), peak flexion angle during swing phase (r=0.64, p=0.026) and the anterior GRF peak (r=0.637, p=0.026) were all significantly correlated to functional improvement 1 year post TKR. Pre-operative Knee Outcome Survey and Oxford Knee Scores had weak insignificant

correlations. No significant correlations were found between post-operative recovery and peak flexion angle during stance phase, BMI, peak medial GRF, or either peak of the vertical GRF.

Conclusion: The quantification of post-operative function is based on a strong training body. The results suggest that it may be possible to predict functional outcome after surgery using solely parameters practically measurable within a clinical setting. Subjects who walked slower pre-operatively while spending less time in stance phase had reduced functional recovery 1 year following TKR surgery. Both reduction of peak flexion during swing and peak anterior GRF in poor improvers could potentially be explained by reduced gait velocity [6]. Reduced anterior posterior force could also be a sign of quadriceps weakness, which has been shown to effect post-operative recovery [7].

Findings suggest that elderly subjects who have gait adaptations associated with reduced gait velocity gained less functional benefit from TKR surgery. These predictors should be tested further on unseen data.

BIOMECHANICAL EFFECTS OF TAPING AND BRACING ON KNEE JOINT STABILITY IN INDIVIDUALS WITH AND WITHOUT PATELLOFEMORAL PAIN.

Jim Richards [1,*] Ambreen Chohan [1] Jessie Janssen [1] James Selfe [1]

[1] Allied Health Research Unit, University of Central Lancashire, Preston, United Kingdom

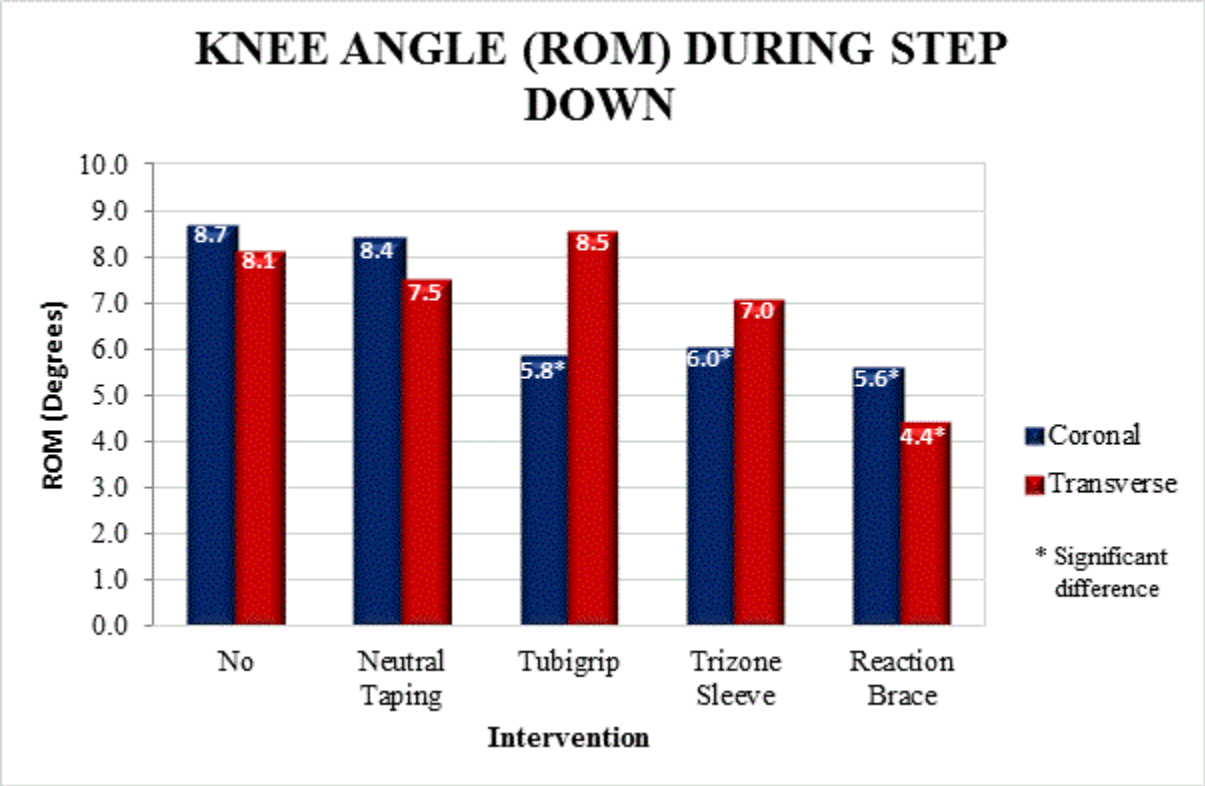
Introduction and Objectives: Over the last 30 years there has been considerable interest in different conservative treatments for patellofemoral pain. Although a consensus has emerged that low cost treatments such as taping and bracing are effective at relieving pain, there has been an ongoing debate about whether these effects are mediated by enhancing proprioceptive mechanisms. In addition few papers have been published comparing the biomechanical effects of such interventions on coronal and transverse plane knee control in normal subjects or subjects who suffer from knee pain and instability.

The purpose of this work was to explore the biomechanical effects of taping and bracing in healthy individuals and people with patellofemoral pain, and to determine the effect of different levels of conservative management on knee stability.

Methods: Twenty-four patients with patellofemoral pain and thirty-nine healthy individuals (age range:18-40 years). All healthy participants were free from lower back or lower limb problems and had not had any previous lower limb surgery. All patients had been referred for with a diagnosis of patellofemoral pain, but none had commenced treatment at the time of the study. Patient inclusion criteria were the presence of a traumatic peripatellar pain and patellofemoral pain provoked by one or a combination of the following: prolonged sitting, deep squatting, kneeling, ascending or descending stairs. Exclusion criteria were recent knee surgery (not including arthroscopy). After meeting the inclusion criteria, patients were then clinically examined to exclude referred pain from the spine and hip joint, leg length discrepancy, knee ligament, quadriceps tendon and meniscal pathology, Hoffa's and medial plica syndromes, femoral anteversion and tibial torsion. Participants were asked to perform a slow step down task. This was conducted under a range of randomised conditions including: (a) no intervention, (b) neutral patella taping, (c) tubigrip, (d) patellofemoral web brace with patellar stabilization and (e) a silicone reinforced compression sleeve. The kinematics of the pelvis and lower limbs, were recorded using a 10-camera Oqus Qualisys motion capture system. The calibrated anatomical system technique (CAST) allowed segmental analysis in the sagittal, coronal and transverse planes. All data were analysed using Visual3D (C-Motion Inc.) and SPSS.

Results: An independent samples t-test showed that the patients had a significantly greater knee coronal range of motion (ROM) than the healthy individuals, 9.5 and 6.5 degrees respectively ($p<0.01$) with no intervention (Figure 1). A mixed methods ANOVA identified changes in the knee coronal and transverse ROM between the interventions, $p=0.03$ and $p=0.01$ respectively. The brace with patellar stabilization reduced knee coronal and transverse ROM by 2.8 degrees ($p<0.01$), followed by the textured neoprene sleeve and tubigrip which reduced the knee coronal ROM by 2.7 degrees ($p<0.05$), with the neutral taping showing a 1.3 degree reduction in the patient group only ($p<0.05$). No differences were seen in peak knee flexion. At the end of the test the participants were asked to place the conditions in a rank order of which they thought helped most with joint stability and pain. The most popular order was the web brace with patellar stabilization or silicone reinforced compression sleeve, neutral tape or tubigrip and then no intervention.

Figure:



Conclusion: These changes in knee mechanics provide important evidence about the possible proprioceptive and mechanoreceptive effects of such treatments, and their role in the management of individuals with patellofemoral pain. This reinforces the view that coronal and transverse plane mechanics should not be overlooked when studying knee pain and instability.

This work provides evidence for a graduated management of knee instability, from neutral taping which produced a small improvement in coronal plane control, tubigrip and textured neoprene sleeves giving a further improvements coronal plane control and bracing producing the greatest improvement in coronal and transverse plane control. These results fit well with participants' perceptions of which they thought helped most with joint stability and pain level.

ULTRASOUND BASED SUBJECT SPECIFIC MODELLING OF THE HEEL

Sara Behforootan [1,*] Panagiotis E. Chatzistergos [1] Roozbeh Naemi [1] Nachiappan Chockalingam [1]

[1] Faculty of Health Sciences, Staffordshire University, Stoke on Trent, United Kingdom

Introduction and Objectives: Foot ulcers in people with diabetes are multi-factorial and linked to a variety of clinical risk factors, like peripheral neuropathy and vascular insufficiency[1], as well as biomechanical risk factors, such as increased plantar pressure [2]. Despite that, the mechanisms behind ulceration are not yet fully understood.

Subject-specific Finite Element (FE) modelling can significantly enhance our understanding on the biomechanical phenomena that lead to ulceration but its use in the clinical setting is still impractical. Indeed the development of detailed FE models requires considerable resources and time and significant computer processing power[3]. In this study a new method for the design of simplified 3D subject-specific models of the heel based on ultrasound images and ultrasound indentation tests is presented.

Methods: Ultrasound indentation tests were performed at the heel of a healthy subject using a new device comprising a linear array ultrasound probe and a load cell[4]. The instrumented probe was mounted on a rigid metallic frame equipped with a linear actuator and adjustable foot supports. Before testing, the subject's right foot was fixed on the device and the instrumented probe was positioned to image the frontal plane of the apex of the calcaneus (Figure 1A). The subject's heel was subjected to 5 preconditioning load/unload cycles followed by 3 measurement cycles to a maximum compressive force of 80N. Heel-pad thickness and the value of the applied force were sampled at 28Hz and used to calculate the average force/deformation curve of the indentation test(Figure 1C). After the end of the tests the probe was rotated by 90° to image the sagittal plane of the heel under a compressive force of 80N (Figure 1A). Moreover the width of the unloaded heel was also measured at the site of the testing using a calliper.

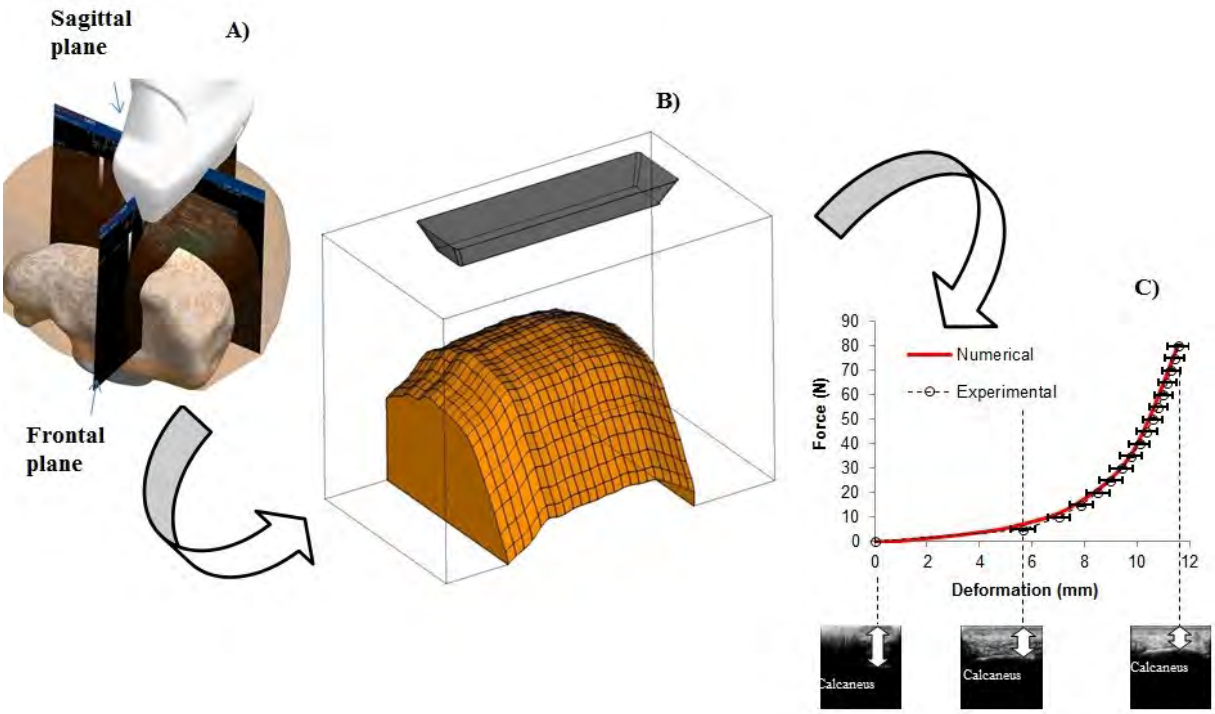
The indentation test was simulated using a 3D FE model comprising a rigid calcaneus and a hyperelastic (Ogden-1st order) soft tissue (Figure 1B). The geometry of the calcaneus was reconstructed using a frontal and a sagittal ultrasound image. The boundary of the calcaneus was outlined in both images and a surface was created by dragging the frontal boundary along the sagittal one. The thickness and width of the heel-pad model was modified to correspond to the heel-pad thickness and width measured in-vivo. The ultrasound probe was modelled as a rigid body that is in frictionless contact with the soft tissue (Figure 1B) and the loading procedure was simulated by imposing a displacement to the probe (equal to the maximum in-vivo deformation). This simulation enables the numerical estimation of the force/deformation curve of the indentation test and the inverse engineering of the tissue's material coefficients. Assuming that the heel-pad is nearly incompressible (v=0.475) leaves only two material coefficients to be calculated: μ and α which are indirectly related to the material's initial shear modulus and strain hardening/softening respectively[5].

The aforementioned inverse-engineered material coefficients were also used in a more geometrically detailed FE model of the heel which was designed based on MRI images. This model also comprised a rigid calcaneous and a soft tissue and was used to simulate the indentation test and estimate the indentation force/deformation curve. The numerical curves

estimated using the ultrasound and MRI based FE models were compared and their difference was assessed in terms of their Mean Square Error (MSE).

Results: The values of the coefficients μ and α which were calculated using the ultrasound based model were equal to 0.12kPa and 42 respectively. The MSE between the two numerical force/deformation curves was 0.70 while their difference in terms of maximum force was only 0.5%.

Figure:



Caption: A schematic representation of the method for the design of ultrasound based FE models of the indentation test and the inverse engineering of the heel-pad material coefficients. A) The two imaging planes for the reconstruction of the calcaneus. B) The geometry of the subject-specific FE model and C) the in-vivo and the final numerical force/deformation curves for the indentation test.

Conclusion: The comparison between the simplified ultrasound based model of the heel and the more detailed MRI based one showed that they exhibit very similar behaviour. The two estimated force/deformation curves for the indentation test were very close to one another indicating that the simplified ultrasound based FE model is a good candidate for the inverse engineering of heel-pad material coefficients instead of the much more challenging and expensive to generate and solve MRI based model.

A NEW 3D RECONSTRUCTION METHOD OF THE BODY ENVELOPE FROM BIPLANAR X-RAYS

Agathe Nérot [1 2,*] Julie Choisne [2] Célia Amabile [2] Xuguang Wang [1] Wafa Skalli [2]

[1]UMR_T9406, LBMC Laboratoire de Biomécanique et Mécanique des Chocs, IFSTTAR, Bron, [2]Arts et Métiers ParisTech, Insitut de Biomécanique Humaine Georges Charpak, Paris, France

Introduction and Objectives: The consideration of both the geometry of the bones and the external body shape of an individual is of great interest in musculoskeletal modeling. The low dose radiation EOS (EOS imaging, Paris, France) system allows obtaining 3D reconstructions of the skeleton in a standing posture from biplanar radiographs of the entire body [1]. As skin contours are also visible on the radiographs the 3D reconstruction of the body shape is now under study in order to develop an innovative tool providing both the internal skeleton and the external envelope of an individual. The purpose of this study was to propose and evaluate a 3D reconstruction method of the body shape based on the visible skin contours on biplanar X-rays.

Methods: The reconstruction method consisted in projecting a generic 3D body shape model on the sagittal and frontal plane radiographs. The silhouettes obtained on both views were then adjusted with the visible skin contours of the individual. Male and female body reconstructions were differentiated.

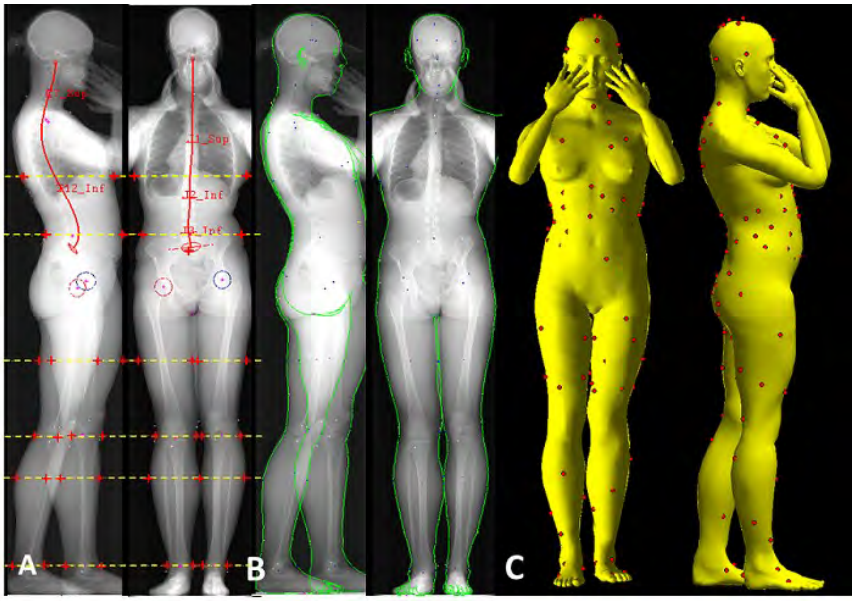
Generic model: Two body shape meshes representing a man and a woman with a stature of 1.7m were created and were pre-positioned in an EOS standard standing posture. The two models were characterized by 16 volumetric body segments. A set of descriptors (surface points and internal joints centers) were embedded and used as controls to guide the deformation of the generic models during the reconstruction process.

Reconstruction method: The target location of a limited set of control points (mainly joints centers) was first selected on the radiographs. These points were used to project and scale the generic model to match the radiographs. Then a set of 20 points was identified on both views to initially adjust the depth and width of specific body segments (hips, calf, waist etc.)(Figure 1A). A moving least square transformation was applied to preserve shape details. A final step consisted in interactively deforming the initial solution by dragging a set of control points on the surface of the model to match the skin contours using a kriging method (Figure1B). In this preliminary approach the arms of the generic model were not deformed as they were not fully visible on the radiographs.

Method Assessment: EOS acquisitions were performed for 12 volunteers. Preliminary results were assessed only from 4 subjects (2 males, 2 females) aged from 27 to 31 years old with BMI from 20.0 to 29.5Kg/m². 140 radio-opaque markers (Ø 2 mm and 5mm) were placed on the skin of the subject from feet to head. 3D reconstructions of the body shape were performed 3 times by 3 different operators. The accuracy of the proposed method was evaluated by computing the mean distance between the reconstructed human body shape and the markers skin contact points. As the different steps of the reconstruction process require some intervention of the operator, the reliability of the method was evaluated by measuring the intra- and inter-operator variability (NF ISO-5725,1994).

Results: Thighs and Lower legs showed the smallest distance with the markers, while the head and thorax showed the greatest errors. (Table 1) This may be due to the fact that most x-rays were cut above the eyes and were too narrowed to capture the lateral sides of the thorax in the frontal view. 95% CI is below 2.6mm.

Figure:



Caption: Reconstructions steps. A: Identification of points for the adjustement of body segments width and depth. B: Deformation of the generic model on the frontale and sagittal planes radiographs. C: Evaluation of the 3D reconstruction of the body shape with a set of 140 markers attached on the subject'skin.

Conclusion: This method allowed obtaining the 3D body shape from biplanar radiographs with a mean error on the geometry of 4mm on average. This method opens the way to further researches requiring both the internal skeleton and external body shape of an individual. Work is in progress to analyze the reconstructions of a higher number of subjects.

AN EFFICIENT ALGORITHM TO ESTIMATE PASSIVE FORCES IN SARCOMERES UNDER LENGTH CONTROL CONDITIONS

Gudrun Schappacher-Tilp [1,*] Getrud Desch [1]

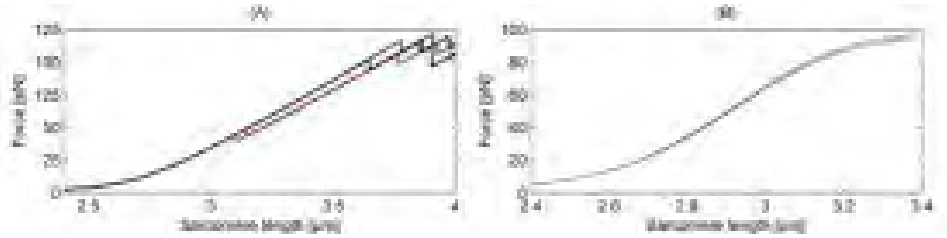
[1] Department for Mathematics and Scientific Computing, University of Graz, Graz, Austria

Introduction and Objectives: Passive forces in sarcomeres are mainly related to the giant protein titin. Titin's extensible region consists of spring-like elements acting in series. In skeletal muscles these elements are the PEVK segment, two distinct immunoglobulin (Ig) domains (proximal and distal), and a N2A portion. Distal Ig domains are thought to form inextensible end filaments in intact sarcomeres. Proximal Ig domains, on the contrary, unfold in a force- and time-dependent manner. Force-elongation relations of single titin strands can be simulated by Monte Carlo simulations [1]. In sarcomeres where more than a thousand of titin strands are arranged in parallel numerous Monte Carlo simulations are required to estimate the sum of forces based on the elongation of all titin strands. To simplify calculations the stochastic model of passive forces is often replaced by linear or non-linear deterministic and phenomenological functions. However, new theories of muscle contractions (e.g. [2,3]) are based on a prominent role of the structural properties of titin and necessitate a detailed analysis of titin forces in length control experiments. In our study we present a simple and efficient alternative to Monte Carlo simulations. Based on a structural titin model we calculate the expected passive forces in a sarcomere under length control conditions. Moreover, our approach provides a measure for the goodness of the expectation value.

Methods: The force of a single titin strand at a given length is a discrete random variable. It can assume only a finite number of values corresponding to the number of Ig domains which can unfold. Once we know the corresponding probabilities we can calculate the expectation value which scales to the expected force of all titin strands acting in parallel in a sarcomere. However, the expression of the corresponding probabilities is not trivial since the unfolding of one domain changes the unfolding rates of all other domains and leads to integral expressions which can only be computed by expensive numerical methods. Instead, we analyze a corresponding system of ordinary differential equations which can be solved by a simple implicit Euler method in a fast and stable way. Our analysis is based on rabbit psoas 3,400-kD titin isoform with 50 proximal Ig domains, 26 distal Ig domains forming end filaments, and 800 PEVK residues [4]. Force calculations are based on the worm-like chain model of polymer elasticity for proximal Ig domains and a modified worm-like chain model for the PEVK region [5]. Finally, our approach also allows us to take into account the hierarchical structure of mean unfolding forces of proximal Ig domains [1].

Results: We compare our results to well established Monte Carlo simulations. Single simulations show the characteristic saw tooth pattern of single titin strands in length control experiments. In sarcomeres the saw tooth pattern is smoothed out. Our approach leads to a smooth expectation value where the standard error of the expectation value is assessed as well. Not surprisingly the standard error rises with longer stretches but stays within 1.5% of the expectation value for stretches up to a sarcomere length of 4.5µm.

Figure:



Caption: Fig. 1: (A) Four exemplar Monte Carlo simulations of a stretching experiment with controlled lengths. (B) Expectation value and standard error of the expectation value of the same experiment based on the new approach.

Conclusion: We provide an intriguingly simple approach to predict forces based on titin elongation in a sarcomere based on a structural titin model. Moreover, the goodness of the expectation value can be assessed by analyzing the standard error of the expectation value.

USING FEA TO DETERMINE THE SAFE CORRECTION ZONE FOR HIGH TIBIAL OSTEOTOMIES

Jennifer L. Boyd [1,*] Cameron Brown [1] Andrew Price [1]

[1]Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, University of Oxford, Oxford, United Kingdom

Introduction and Objectives: High tibial osteotomy (HTO) is a joint-conserving surgery used to treat early-stage medial osteoarthritis. HTO shifts the mechanical axis (axis connecting the centres of the hip and ankle) from the pathological medial to the normal lateral tibiofemoral compartment [1]. It is hoped that HTO will allow patients to remain active and free from pain, as well as delay or reduce the need for joint replacement. HTO remains, however, an operation with unpredictable results [2], perhaps due to a lack of understanding of how the surgery affects the mechanics of the knee. We do not, for example, know which re-alignment will be best for individual patients. Correcting to 62% re-alignment has been suggested [3], but other correction re-alignments (for example, 50%) have also been successful. Overcorrections should be avoided; otherwise lateral tissues may become damaged (limiting future treatment options).

We used finite element (FE) models to investigate how different knee alignments (ranging from native medial to extreme lateral mechanical axis) affected the tibiofemoral stress/pressure patterns during the second ground reaction force (GRF) peak of walking (when maximum loads occur during walking).

Methods: Sets of FE models were created based on data from 3 healthy subjects: 2 female, 1 male; aged 25-32 years; BMI 20.6–21.9. Informed consent was given and absence of MRI contra-indications was verified prior to data collection.

Motion analysis data was collected first. A modified Helen Hayes marker set was used, with additional registration markers placed around the knee. Marker trajectory data (Vicon 612, Vicon Motion Systems Ltd.) and GRF data (OR6 platform, AMTI) were collected while subjects walked within a 12-camera capture volume. Data was extracted from the second GRF peak. The FE model loads were based on the forces and moments at this time point.

Next, fluid-filled registration markers were placed around the knee and 7T MRI scans (resolution 0.3mm x 0.3mm x 0.3mm, Siemens) were taken. Bone, cartilage, and meniscal structures were segmented (ITK-SNAP 2.4.0) in each MRI scan, and then smoothed (Blender 2.68a) before being assembled into the native knee geometry (SolidWorks 2014). Marker locations and ligament origins/insertions were also identified in the MRI scan.

After registering the two data sets, FE models (Abaqus 6.12) of the native knee were created. These models combined geometry from the MRI scans and loads from GRF data. The stresses/pressures on the articulating proximal tibial cartilage and meniscal surfaces were recorded. Clinically, HTO shifts the medial-lateral (M-L) location of the mechanical axis; we simulated this shift by altering the knee adduction-abduction moment. Sets of models were created which shifted the mechanical axis from the native medial alignment (~27% M-L tibial plateau width) to an extreme lateral alignment (80% M-L width) in increments of 3% M-L width. Stresses/pressures on the tibial cartilage and meniscal surfaces were again recorded.

The results from the three subjects were then analysed. Maximum stress and pressure magnitudes varied between subjects so each subject's results were first normalized according to these maximum values. Then, the normalized results of each subject were averaged.

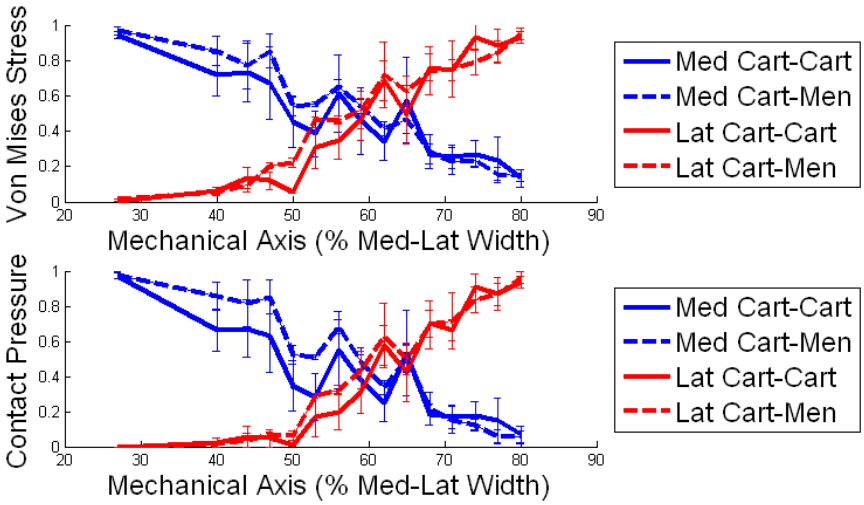
Results: Both stress and pressure decreased in the medial compartment and increased in the lateral compartment as the mechanical axis was incrementally shifted towards the lateral compartment. Results could be split into three categories.

Category 1: native alignment (27% M-L width) to 50% M-L width. At 50% alignment, medial results decreased to nearly half their maximum results, with negligible increases in lateral compartment results. HTO corrections within this zone would be considered "safe" (though alignment changes must be large enough to merit undergoing the surgery).

Category 2: 53% to 65% M-L width. Medial and lateral results were approximately equal. HTO corrections within this zone would be considered "potentially safe". At 65% alignment, lateral results had noticeably increased, potentially enough to damage lateral tissues.

Category 3: 68% to 80% M-L width. Medial results decreased, with accompanying increases in lateral compartment results. HTO corrections within this zone would be considered "not safe" since it is likely that lateral compartment tissues would be damaged.

Figure:



Caption: Average normalized stresses and pressures calculated for different knee alignments.

Conclusion: These results suggest a safe correction zone within which HTO can be performed. The mechanical axis should be moved far enough from the native alignment to warrant surgery, but not beyond 65% M-L width. Shifting the mechanical axis beyond 65% noticeably increased lateral compartment results, potentially damaging these tissues.

AS-0373

ACCURACY OF THE KNEE AXIS ORIENTATION AGAINST EOS, A STANDING BI-PLANE X-RAY SYSTEM

Morgan Sangeux [1 2,*] Christophe Sauret [3] Helene Pillet [3] Wafa Skalli [3]

[1]The Royal Children's Hospital, [2]Murdoch Childrens Research Institute, Melbourne, Australia, [3]Arts et Metiers ParisTech, Paris, France

Introduction and Objectives: Gait analysis is often performed clinically to assist with decision to perform femur and/or tibia de-rotation osteotomies. However, clinicians mostly rely on the hip or knee rotation profile(s) to make such decision and these are among the least accurate outputs of gait analysis [1]. The lack of accuracy of the hip rotation profile comes from the difficulty to locate the knee axis accurately. Anatomically, the knee joint axis is considered in line with the posterior aspects of the knee condyles [2]. Conventional methods rely on manual palpation or visual alignment of a knee alignment device. Their accuracy depend on the experience of the assessor. Functional methods are considered an alternative because they do not rely on the assessor's expertise but rely on the joint movement to determine the knee axis.
EOS is a new low-dose bi-plane imaging system which allows simultaneous visualisation of the bones and external markers in 3D [3]. The aim of this study was to quantify the accuracy of conventional and functional methods to locate the knee axis against an EOS based benchmark.

Methods: Thirteen healthy adults with no history of gait pathology participated to the study. Approval was granted by the appropriate ethics committee. Light-reflective markers were attached to the subject and tracked by a 6-camera motion-capture system (Vicon Motion Systems) [3]. The knee axis was determined using a conventional, marker based, method through manual palpation of the epicondyles and three functional methods; the axis transformation technique (ATT/SARA, [4]), the geometrical method [5] and a method closely related to the dynamic KAD (DynaKAD, [6]). The functional methods were applied to two activities; open chain active or passive knee flexion-extensions, and walking.
The reference method was the condylar axis obtained from EOS. The accuracy of the methods were expressed as the angular difference of the various knee axes in the transverse plane.

Results: The conventional axis was external compared to the EOS axis, 15° (SD: 6°) on average. The DynaKAD method was the closest to the EOS axis for all calibration movements. The best results were obtained for the passive flexion-extension (0° SD: 7°). The geometrical axis performed well on the passive knee flexion-extension movement (mean: 4°) but not (mean: 15°) on the walking movement. The ATT/SARA method was, in average, more than 10° too external for all calibration movements.

Conclusion: We assessed the accuracy of various method to locate the knee axis for gait analysis against the EOS medical imaging benchmark. The DynaKAD method applied to the passive knee flexion-extension activity provided the axis closest to the EOS reference. This study was performed on healthy adults and these results need to be confirmed on those with pathology.

Table:

		---------- Calibration movement ----------				
Family	Method	Active	Flexion-extension	Passive	Flexion-extension	Walking
Functional	Geometrical	14 (6.8)		4 (7.5)		15 (11.8)
	ATT/SARA	14 (6.5)		10 (5.5)		12 (6.0)
	DynaKAD	10 (5.7)		0 (7.3)		5 (6.1)
Conventional		15 (5.9)				

Caption: Results on accuracy of the various methods to locate the knee axis. The accuracy is expressed as the angle difference in the transverse plane in °.

OBTAINING QUICK RUNNING MACROSCALE BEAM MODELS OF WHOLE BONES FROM HIGHER RESOLUTION STRUCTURAL REPRESENTATIONS

Anantharaman Gopalakrishnan [1 2,*] Andrew T M Phillips [1 2]

[1]The Royal British Legion Centre for Blast Injury Studies at Imperial College London, [2]Civil and Environmental Engineering, Imperial College London, London, United Kingdom

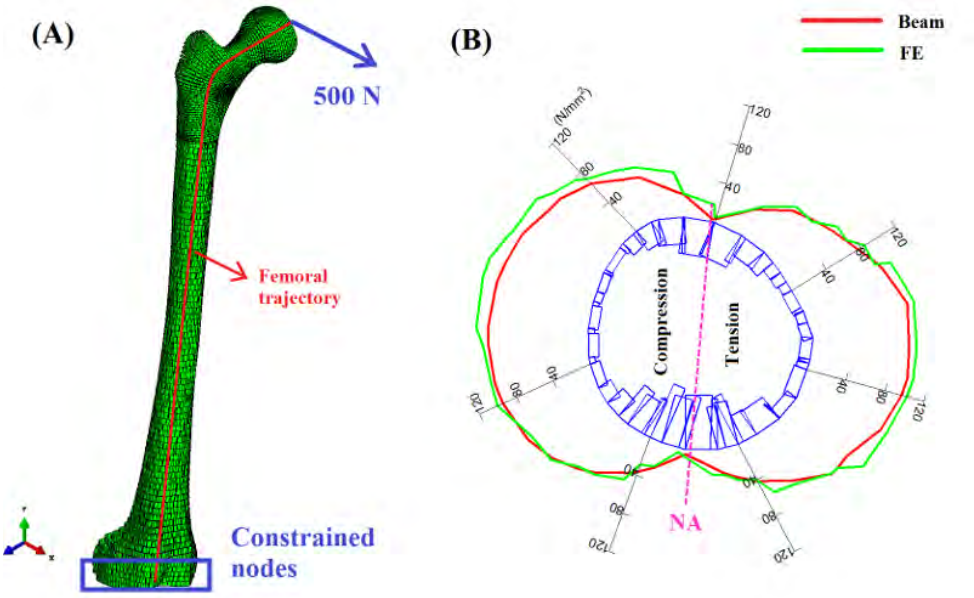
Introduction and Objectives: Finite element (FE) models of whole bones have been shown to provide realistic estimates of the stress distributions induced by a variety of loading conditions, with computation times typically in the order of a few minutes. While this is acceptable for standalone evaluations of a bone's behaviour, it becomes infeasible to integrate FE models within other computationally demanding simulations such as multi-body dynamic (MBD) simulations. MBD techniques can be used to simulate limb motions and inter-limb reaction forces during blast or impact events, and the integration of a quick running, sub-simulation estimating bone stresses could give real-time predictions of fracture risk during such events. The goal of this study was to develop a quick running macroscale 'beam model' of femur to be solved using the stiffness method. The mesoscale structural model of the femur developed by Phillips et al. [1] was used as the reference model from which the beam model was derived. It was hypothesized that by (a) defining a roughly longitudinal, three dimensional trajectory for the femur, (b) obtaining cross-sections of the structural model along this trajectory at regular intervals and (c) creating a series of short beam elements with appropriate cross-sectional properties connected along the defined trajectory, an equivalent beam model could be obtained. The normal stresses induced in the beam model of the femur due to axial loading and biaxial bending were compared to results from the finite-element structural model subject to the same loading condition.

Methods: The longitudinal trajectory to the femur consisted of straight lines in the regions of the femoral head and shaft. These lines were the axes of cylinders that were fitted to the cloud of cortical surface nodes in the respective. A third degree polynomial was fitted to the femoral neck, thus connecting the two angled, straight line sections of the trajectory. The trajectory was divided into 144 intervals (5mm intervals in the shaft, 2mm in the neck and head) with consecutive points of division taken as the start and end nodes of 12 DOF beam elements, forming a series of 144 beam elements. The cross section of each beam element was determined by slicing the structural model with a plane passing through the mid-point of its corresponding beam nodes, at right angles to the trajectory tangent. The intersection of the triangular shells representing cortical bone in the structural model (taken to be triangular prisms, due to their thickness) and truss elements representing trabecular bone (taken to be of circular cross section) with the plane, constituted the cross-sectional profile of the corresponding beam element. Cross-sectional properties including the area, the second moments of area and torsion constant were computed and used to derive a global stiffness matrix for the entire beam model.
The load case presented here is a 500N point load (see Figure 1A) applied in the anterior direction on the head of the femur. All nodes below the fifth beam node from the base of the femur were constrained in all six degrees of freedom. With these loads and boundary conditions, the stiffness matrix was solved to compute the displacement and forces at each node, from which the normal stress distribution at each beam's cross section was derived. The same loading

conditions were emulated in the FE structural model where the stresses and displacements were computed using ABAQUS (3DS). The FE model's stress tensor was transformed into the corresponding beam's cross-sectional coordinate frame and the normal component of stress was compared to the values from beam theory.

Results: Figure 1B compares the normal stresses from the beam and FE structural models for points located on the outer perimeter of cortical bone, at the mid-plane of a beam from the femoral mid-shaft region. For each of the vertices of the cortical perimeter (Figure 1B) on each of the 144 beam mid-planes, the absolute errors between normal stresses from both models were expressed as a percentage of the mean normal stress (from the FE model) over all cortical points in the model. The averaged value of these errors over all the vertices was 9.5%. Analysis times were around; FE model: 90s, beam model: 0.1s.

Figure:



Conclusion: The simplistic beam model succeeded in computing normal stresses to a good level of accuracy compared to the more complex FE structural model. The limited loss of accuracy could be considered a reasonable trade-off for the extremely low computational time of the beam model. It is thus considered feasible to integrate the beam model into more intensive computational pipelines such as multi-body dynamic simulations of a blast event, in order to estimate the stresses in bones and predict the occurrence of fractures under dynamic motions and loads.

THE ASSESSMENT OF BALANCE IN DIFFERENT POSTURES

Glen M. Blenkinsop [1,*] Michael J. Hiley [1] Matthew T. G. Pain [1]

[1]School of Sport, Exercise and Health Sciences, Loughborough University, Leicestershire, United Kingdom

Introduction and Objectives: Traditionally balance has been assessed by relatively simple analyses of the trajectory of the centre of pressure (COP) to calculate quantities such as: range, standard deviation, sway area, and sway length. Some COP signals may be considered to contain subtle structure in the form of time correlation information which may be extracted through nonlinear techniques [1]. Further information may be extracted by assessing multiple signals, such as centre of mass motion or joint angles and torques. The purpose of this research was to determine which balance metrics are best for assessing balance in different postures and providing insight into the underlying process of balance control.

Methods: Twelve experienced handstanders performed balance trials with eyes open and eyes closed conditions in double leg stance, single leg stance, and handstand. Each trial type was repeated five times and each trial was performed for a maximum of 30 seconds duration. Kinematic data were collected via a nine camera vicon system (200 Hz), using 53 markers to divide the body into 18 segments. Marker displacements were filtered with a fourth order zero lag, low-pass Butterworth filter with a cutoff frequency of 10 Hz, before quaternion algebra was used to calculate: segment centre of mass linear displacements, velocities, and accelerations; and segment angular velocities and accelerations. Kinetic data were collected via two Bertec strain gauge force plates (200 Hz), and raw COP data were used to assess balance via: traditional measures (trial duration, sway area, sway length, standard deviation, range, sway velocity), nonlinear dynamics (sample entropy, Lyapunov exponent), and recurrence quantification analysis (recurrence rate, determinism, Shannon entropy, divergence, trend). Kinetic and kinematic data were used to calculate 3D joint moments and forces via wrench notation, to assess balance via: estimates of neurological delay (delay, R^2, joint torque from proportional and derivative gains), and movement corrections (number of small, medium, and large corrections per second, mean torque, torque impulse, burst duration).

Results: Data suggests that the best balance metrics for distinguishing between each of the six conditions were the traditional balance measures of sway length and sway velocity. Nonlinear measures of sample entropy, determinism, divergence, and Shannon entropy successfully differentiated between each posture, but not between eyes open and eyes closed conditions within each posture.

Neurological delay estimates were approximately: 234 ms for double leg stance, 191 ms for single leg stance, and 176 ms for handstand. Neurological delay estimates were typically higher for trials with eyes closed compared to trials with eyes open conditions for all postures.

Movement correlation analyses show that balance in standing exhibits bursts of torque activity that are longer and with a higher torque impulse compared to balance in handstand. Lower numbers of movement corrections per second are evident in standing trials, with the largest number of corrections occurring in handstand with eyes open and single leg stance with eyes open.

Reduced mean torque and torque impulse during all movement corrections in handstand are indicative of the reduced muscular strength of the muscles found in the forearm compared to the lower leg. It would appear this leads to the requirement for a larger number of corrections per second, but with reduced burst duration, when balancing in handstand.
Conclusion: If the aim of a study is to assess balance performance, with no interest in the underlying control of balance, such as an intervention study, then the traditional measures of sway length and sway velocity appear to be sufficient. If a researcher aims to delve further into the underlying processes of balance control, more advanced analyses will be required. Nonlinear measures of balance offer insight into the underlying deterministic processes that control balance, offering measures of system determinism, complexity, and predictability. Assessments of neurological delay and movement corrections appear to provide further insight into the control of balance whilst also helping to distinguish one condition from another.

INCREASED ACTIVATION AMPLITUDE LEVELS OF GLUTEUS MEDIUS IN WOMEN DURING ISOMETRIC AND DYNAMIC CONDITIONS FOLLOWING A 4-WEEK PROTOCOL OF LOW LOAD ECCENTRIC EXERCISES

Alexandre C. Barbosa [1,*] Rafaela Carvalho [2] Douglas Bonifácio [2] Fábio Martins [2] Michelle Barbosa [3]

[1]Physiotherapy, Federal University of Juiz de Fora, Governador Valadares, [2]Physiotherapy, [3]Health Education, Federal University of Jequitinhonha and Mucuri Valleys, Diamantina, Brazil

Introduction and Objectives: Gluteal weakness is thought to contribute to greater hip adduction and internal rotation, generating a postural knee valgus during functional activity, consequently increasing the stress to the patellofemoral joint. In this regard, a body of work has emerged, utilising surface electromyography (sEMG) measurement of the gluteal muscles during functional (dynamic and isometric) tasks, reporting differences in onset times, amplitude levels and activity durations. The objective of the present study was to use a protocol involving low load eccentric exercises to observe the effects on the three subdivisions of gluteus medius (GMed) activation through surface electromyography (sEMG) and digital dynamometry.

Methods: Eleven female subjects having femoral instability participated in a four-week protocol (three sessions per week/nonconsecutive days). At each session, two low load eccentric exercises (12% of maximal isometric voluntary contraction – MVIC) in abduction, extension and external rotation were applied to the hip joint (through shin guards). The number of repetitions and series varied in each session, providing asymmetric stimuli, not allowing accommodation and providing constant neurophysiological response by the mechanoreceptors (Table 1). The sEMG of the GMed subdivisions (anterior, mid and posterior) during a squat and MVIC were assessed. The digital dynamometry was also assessed during MVIC. Parametric paired t-test was used to compare the results before and after treatment with α=0.05.

Results: The results showed an increased sEMG activity of GMed (mid and posterior portions) during isometric voluntary contraction and squat after the protocol. No difference was noted to the anterior subdivision of GMed. Another finding was the significant difference to the dynamometry results, showing improvements to generate strength to the GMed as a whole muscle in abduction with 8.15±2.34 kgf to 9.11±2.63 kgf at the final assessment (p=0.0001).

Figure:

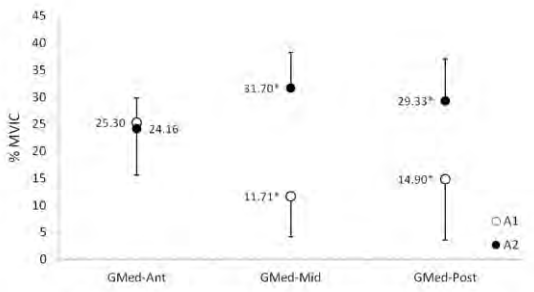

Figure 1 Normalised RMS values (mean and standard deviation) for the subdivisions of GMed muscle for pre and post assessment (isometric condition). *indicates significant difference between pre and post intervention data (p<0.05).

Conclusion: For dynamic stabilization of the hip, the ideal pattern to improve positional control seems to be a protocol that combines muscle control without exhausting the musculoskeletal system and concomitantly activates the receptors in the muscles. In this way, the sensory map may continuously be corrected by sensory feedback according to proprioceptive priority, given by the influx of afferent receptors. The four-week low load exercise protocol was effective to increase the activation of the GMed mid and posterior subdivisions, improving also the capacity to generate strength as a whole muscle during the proposed tasks.

Table: Table 1 Rehabilitation guidelines: GMed eccentric contractions. All sets and repetitions were applied to Exercise 1 and 2.

Protocol	Day 1	Day 2	Day 3
Week 1	3 sets of 8 repetitions	3 sets de 10 repetitions	3 sets de 12 repetitions
Week 2	4 sets de 8 repetitions	4 sets de 10 repetitions	4 sets de 12 repetitions
Week 3	3 sets de 12 repetitions	3 sets de 10 repetitions	3 sets de 8 repetitions
Week 4	4 sets de 12 repetitions	4 sets de 10 repetitions	4 sets de 8 repetitions

A NEW INVARIANT PARAMETER CHARACTERIZING THE POSTURAL ALIGNMENT OF YOUNG HEALTHY ADULTS

Celia Amabile [1 2,*] Helene Pillet [1] Virginie Lafage [2] Wafa Skalli [1]

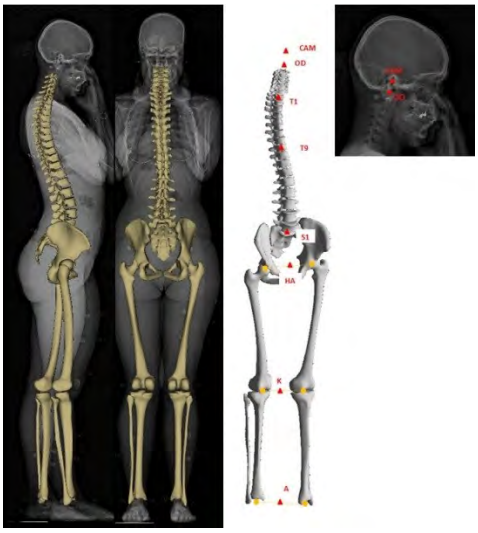
[1]LBM/Institut de Biomécanique Humaine Georges Charpak, Arts et Métiers ParisTech, Paris, France, [2]Department of Orthopaedics Surgery, NYU Hospital for Joint Diseases, New York City, United States

Introduction and Objectives: Postural troubles can have negative impact on skeleton disorders for aging adults. The first step in understanding these aging postural troubles is to observe and quantify the erected posture of young healthy adults' skeletons from radiographies. However, previous studies in the literature focused on the alignment of the spine and pelvis segments [1], rarely including the head neither the lower limbs. Our study aims to describe the postural alignment of young asymptomatic subjects from head to feet from bi-planar standing radiographies.

Methods: 69 asymptomatic subjects were included in the study: mean age 26.3years old (SD: 4.7). 3D reconstructions of the head, spine, pelvis and lower limbs segments' skeleton were performed from bi-planar radiographies (EOS Imaging, Paris, France) using well documented models [2-4] (Figure). In addition, two stereo-corresponding points localizing the acoustic meati were digitized to compute their center (CAM) [5]. Full description of the postural alignment of the volunteers was made by evaluation of parameters in 3D in the anatomo-gravital frame (frontal plane is the vertical plane going through both acetabulum centers, and transversal and sagittal planes are orthogonal to the patient frontal plane). The origin of the frame is the middle of the centers of each acetabulum (HA). Firstly, reference values for each parameter studied were computed. Secondly, relationships between these parameters were investigated.

Results: Values found for spinal curvatures, pelvic parameters and lower limbs geometrical parameters (Table) were similar to those reported in the literature [1,4,5]. Inclinations of different lines were investigated to characterize the erected posture. The closest line to the vertical passed through the following points: CAM, the most superior point of dentiform apophyse of C2 (OD), the centers of C3 to L5 vertebral bodies, and the center of the sacral plate (S1). Its inclination was in average of 3.1° (SD: 1.9°). The line joining either CAM or OD to HA are the less variable between subjects with an angle (SD) respectively of 2.9° (1.7°) and 2.9° (1.6°) with the vertical. It would be interesting to record those two inclinations for comparison with aging and pathological populations, as the head, characterized by the segment OD to CAM, might be the last one to be adjusted in compensatory mechanism to keep the head upon the pelvis. The line CAM-HA has been reported to be a good indicator to identify postural trouble [5]. Offsets from HA of both knee's center and ankles' center were in average less than 6cm (SD<2cm) ahead of HA and at less than 1cm (SD<12mm) of HA in the medio-lateral direction. This can be an estimate of the alignment of the lower limbs with the upper body. While well-known correlations were found between spinal curvatures and pelvic parameters: L1S1 lordosis with sacral slope (R^2=0.87) and with pelvic incidence (R^2=0.62); pelvic incidence with sacral slope (R^2=0.73), no other correlations were found with the lower limbs' parameters, confirming the pelvis as an independent link between the spine and the lower limbs for this population of young adults.

Figure:



Caption: Bi-planar radiographies with 3D model: identification of CAM, OD, T1, T9, S1, HA, K (middle of both knees points) and A (middle of both ankles).

Conclusion: A description of the postural alignment in 3D, of the geometry of the spine, pelvis and lower limbs, in sagittal and frontal planes of the young healthy adult has been reported. Head upon the pelvis was an invariant. As expected, the spine is overall almost vertical (Incl close to 0°). This study would serve as a basis for future comparisons when investigating aging populations.

AS-0378

A NUMERICAL MODEL TO PREDICT THE 1-STEP BALANCE RECOVERY THRESHOLD AND REACTIONS FOR YOUNG AND ELDERLY

Pascal Vallee [1,*]Thomas Robert [1]

[1]LBMC, Université de Lyon - IFSTTAR, Bron, France

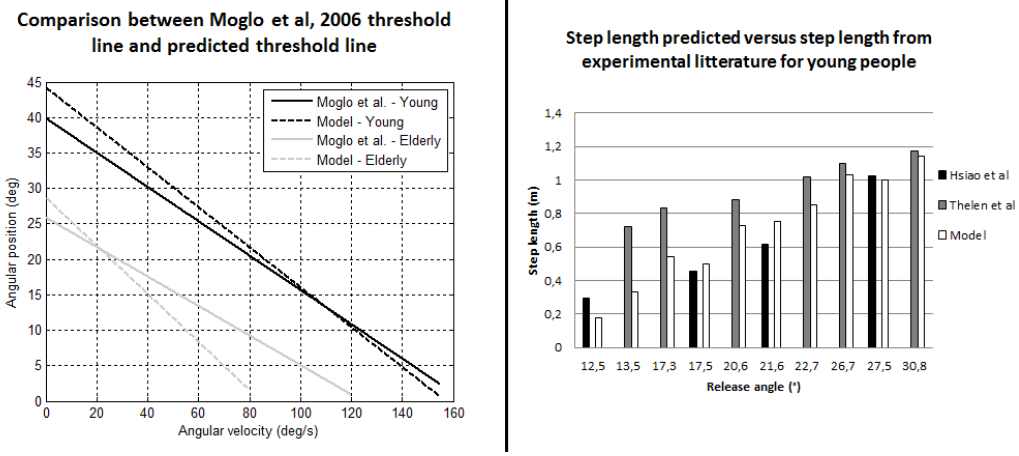
Introduction and Objectives: Falls are a major problem which represents 37.3 billion of medical care every year. To understand and prevent these events, it is necessary to be able to predict if a perturbation will necessarily induce a fall or, if not, what would be the most efficient balance recovery (BR) reactions. Models have been proposed to estimate which states are recoverable or not. However, these models rely on hypotheses that are too restrictive to correctly predict the risk of fall: no recovery step [1] or only instantaneous step [2] allowed, or oversimplify the ability of a human to make the desire recovery steps [3]. In this study we propose a numerical model which considers the stepping ability to predict: 1) the threshold of 1-step BR; 2) the most efficient (i.e. shortest and fastest) recovery step when perturbed beyond the threshold. This model could be unbalanced by any kind of external perturbation and will be assessed against experimental datasets from the literature for young and elderly subjects.

Methods: The human body is modeled by a 2D inverted pendulum in sagittal plan with: 1) an inertia wheel to represent hip strategy with a bang-bang acceleration profile; 2) a base of support (BoS) within which the center of pressure can be moved to represent the ankle strategy; 3) the possibility to make a step, bounded by a preparation time and constraints on the swing phase [4]. It evaluates the time evolution of the XCoM [3], considering the maximal ankle and hip reactions. It then looks if any feasible recovery steps can capture this point, which is a necessary condition to reach a steady balanced state, i.e. if it is possible to recover from the initial perturbation. This model is assessed against three experimental datasets from the literature: 1) a study which established the 1-step BR threshold line in the center of mass's state plane, by considering different kind of perturbations [5]; 2) Two tether release studies with increasing release angle (up to the 1-step BR threshold), imposing maximal step performance [6] or not [7]. All of these studies included a group of young healthy subjects and a group of elderly. For [5] we compare the 1-Step BR thresholds, while for [6] and [7] we compare the step length and timing. Model's parameters related to subject's anthropometry, set to the mean of each group of each study. Parameters related to the maximal reactions were derived from the BR characteristics reported in these studies and were identical for the three situations (see table).

Results: The proposed model predicts relatively well the 1-Step BR threshold line (see Fig., left). The main difference concerns states with small lean angle but high angular velocity for elderly. It may come, in part, from inaccurate experimental results in this area of the state plane, as they were obtained via a procedure that is really difficult to control. Moreover, the model fits well the recovery step characteristics, when performed at maximal performance. For [6], which experimental design imposes the shortest steps possible, predicted steps are between 1 cm and 8 cm shorter and between 5 ms and 40 ms quicker in average for young and elderly, respectively. For [7], results are similar for the larger release angles. However, predicted steps at smaller angles are too short and too quick (see Fig., right). As there were no explicit instructions about stepping performance, subjects were likely to perform non optimal (larger and longer) BR steps,

less difficult and safer. However, when perturbations get closer to the threshold, subjects' reaction had to get closer to the maximal performance.

Figure:



Caption: Simulated vs. experimental 1-Step BR threshold 'left) and BR step length (right)

Conclusion: Our model is able to predict the 1-step recovery threshold and the characteristics of this BR steps when performed at maximal performance, for different groups of population and for different types of perturbation. It is notable that these results were obtained against three different experimental datasets but with a single set of parameters per group of subjects. Moreover these parameters were not optimized but derived from the BR characteristics reported in these experimental studies. This model could be used to identify the potentially hazardous situations and to better understand the balance recovery mechanisms, e.g. the influence of the different BR parameters and their potential degradation with age or a disease.

Table:

Paramters	Young	Elderly
Reaction time (ms)	75	85
Step preparation time (ms)	150	170
Max Step Length (m)	1.2	0.87
Max Foot accel. (m/s²)	165	100

EFFECTS OF TACTILE SURFACE ON OLD ADULTS' GAIT AND PERCEPTION OF SLIPPERINESS IN A SIMULATED WINTER ENVIRONMENT

Yue Li [1,*] Sharon Ravindran [1 2] Adam Katchky [3 4] Vicki Komisar [1 5] Tilak Dutta [1] Geoff Fernie [3 4]

[1]Technology R&D Team, Toronto Rehabilitation Institute - University Health Network, [2]Division of Engineering Science, [3]Department of Surgery, University of Toronto, [4]Toronto Rehabilitation Institute - University Health Network, [5]Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, Canada

Introduction and Objectives: *Detectable tactile surface indicators* (tactile surfaces) are applied to the surface of curb ramps to help people with visual impairments identify street crossings. Although these surfaces do not impede rolling safety [1], the physical demands for walking have not been fully explored [2]. Snow and ice are known to impede detectability of these surfaces [3], but their effects on gait, stability and fall risk in older adults have not been examined. This study investigates whether older adults alter speed and step width on tactile surfaces compared to smooth paving in a simulated winter environment.

Methods: This study took place in WinterLab, one of Toronto Rehab's Challenging Environment Assessment Laboratories. Two types of walkway surface (simulated smooth concrete paving [concrete] and tactile paving [tactile]) and two contamination conditions (no contamination [dry] and snow covered surface [snow]) (Figure 1) were tested. The walkways were level and each walkway was 4m long and 0.5m wide. Nine able-bodied older adults (65-78 years; 3 male, 6 female) participated. All wore the same footwear (winter boots) and walked at a preferred self-selected pace. The ambient temperature in WinterLab was controlled at 9.3±1.0°C, and surface temperature was controlled at 0.8±0.9°C. The following temporal-spatial gait parameters were calculated using an optical motion capture system (Motion Analysis) tracking reflective makers placed on participants' footwear:

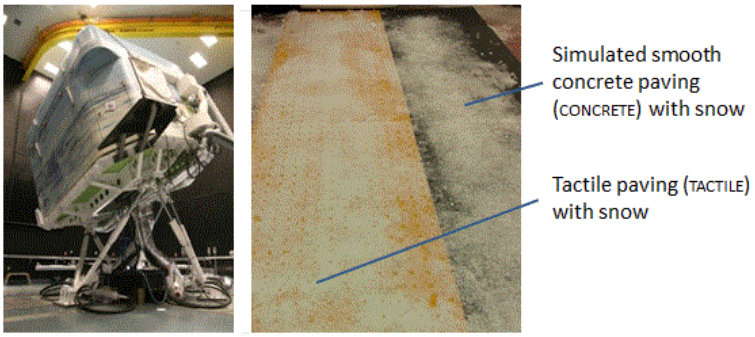
(1) Step time (Time between two consecutive heel strikes)
(2) Step length (Anterior-posterior distance between the heel markers of two consecutive heel strikes)
(3) Step speed (Step length/step time)
(4) Step width (Medial-lateral distance between the heel markers of two consecutive heel strikes)

Participants were asked after each trial to rate the perceived slipperiness of the surface (0 - not slippery to 10 - extremely slippery). All data were analyzed across the two surfaces and two contamination conditions with a mixed model repeated measures ANOVA ($p < 0.05$).

Results: Surface type had significant effects on step time, step length, step speed and step width (Table 1). Slower gait speed and increased step width on the tactile surface could indicate fear of falling [4]. Thies et al.[5] tested older adults on level and sloped tactile paving at room temperature and found that gait speed and step width remained comparable on smooth concrete and tactile paving as did step time. However, our study demonstrated the significant effects of tactile paving on gait when the ambient temperature was around 10°C with snow on the walkway. As anticipated, walking on snow contaminated surfaces significantly challenged stability in the direction of progression, as indicated by greater step time and reduced step speed and length as the participants felt that the snow-covered walkway was more slippery (Table

1). Interestingly, there was no significant difference in step width between dry and snow. It has been reported that increases in step time and step width, as well as decreases in step length and walking speed are used to avoid a slip on slippery surfaces [6]. No changes in step width could be due to a lack of stepping adaptability to the snow covered surface in older people. Future study with a larger sample size is needed to confirm this finding.

Figure:



Caption: WinterLab (left) and the two walkways with snow contamination (right).

Conclusion: This is the first study to examine gait on tactile vs concrete paving with snow contamination in winter-like temperatures. Older adults found dry tactile paving to be more challenging to negotiate than smooth dry concrete paving. Snow covering increased the perception of slipperiness less on the tactile paving than on the concrete paving and resulted in less of a reduction in speed. The effect of sloped tactile paving on gait measures associated with stability and falls risk in older adults will be examined in the second stage of this study. The experimental setup developed for this baseline study could be used to assess alternative tactile paving designs.

Table:

	Surface (p value)	Snow (p value)	concrete		tactile	
			dry	snow	dry	snow
Step speed (m/s)	0.001*	0.0001*	0.95 (0.03)	0.85 (0.03)	0.87 (0.03)	0.83 (0.03)
Step time (s)	0.002*	0.0003*	0.58 (0.03)	0.61 (0.03)	0.61 (0.03)	0.62 (0.03)
Step length (cm)	0.015*	0.004*	54.9 (2.50)	51.7 (2.50)	52.2 (2.50)	51.3 (2.50)
Step width (cm)	0.02*	0.09	8.3 (0.80)	7.90 (0.80)	9.5 (0.80)	8.7 (0.80)
Perceived slipperiness	0.81	0.02*	0.22 (0.37)	1.22 (0.37)	0.56 (0.37)	0.78 (0.37)

EFFECT OF HANDRAIL HEIGHT ON THE TIMING AND KINEMATICS OF REACH-TO-GRASP BALANCE RECOVERY REACTIONS DURING LEVEL-GROUND WALKING

Vicki Komisar [1 2,*] Alison C Novak [2] Emily C King [2 3] Brian E Maki [1 2 4 5] Karl F Zabjek [2 6] Geoff R Fernie [1 2 4 5]

[1]Institute of Biomaterials and Biomedical Engineering, University of Toronto, [2]Toronto Rehabilitation Institute - University Health Network, [3]Mechanical and Industrial Engineering, [4]Department of Surgery, [5]Institute of Medical Sciences, [6]Department of Physical Therapy, University of Toronto, Toronto, Canada

Introduction and Objectives: Handrails are often installed on stairs, ramps and in corridors of care facilities to promote balance recovery and accessibility, and reduce the risk of falls [1]. To be an effective safety feature, a handrail must be installed at a height that enables fast and accurate reactive grasping, and allows a user to generate the high forces and moments needed to stabilize their centre of mass. Handrail height significantly affects the highest voluntary forces and moments that a person can generate on a handrail while standing [2], but the effect of handrail height on the speed and accuracy of perturbation-evoked grasping is not known. This study examined the influence of handrail height on the speed and accuracy of reach-to-grasp reactions in young adults after balance loss during level-ground walking.

Methods: Data were collected in the Challenging Environment Assessment Laboratory (CEAL) at Toronto Rehab. In CEAL, a 5mx5m lab is mounted on a robotic platform to deliver support-surface perturbations (Figure 1). Data from 8 of 11 young adults (21-30y; 3M) have been analyzed.

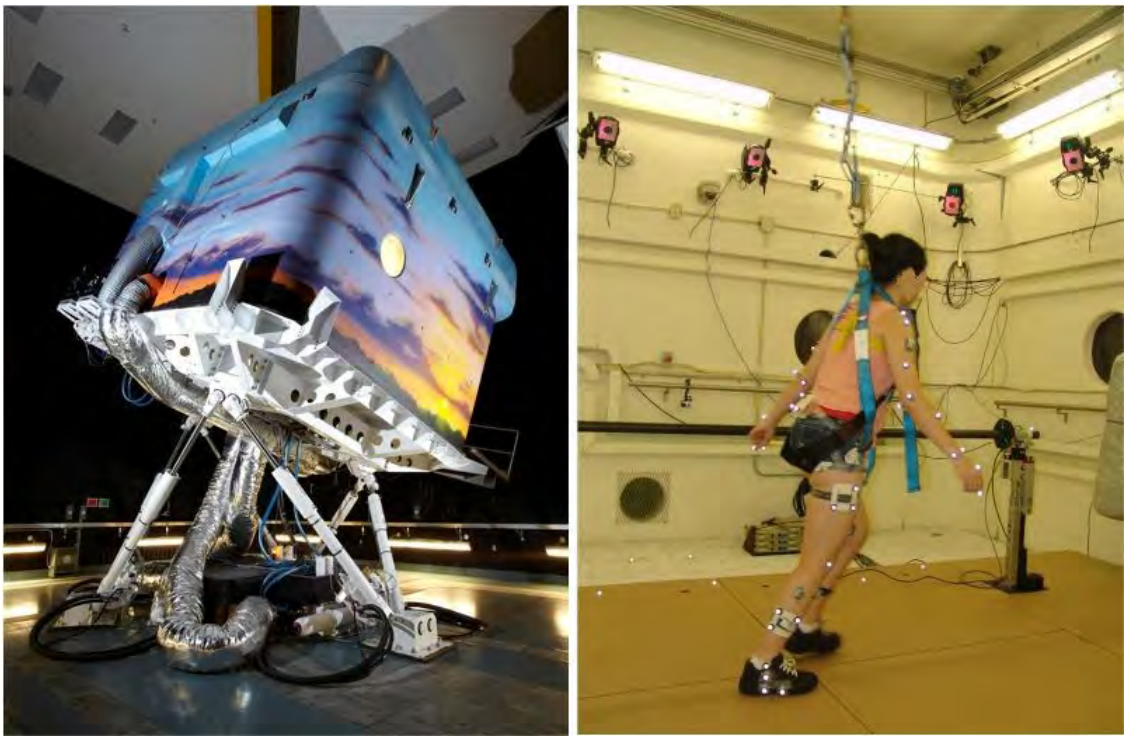
Harnessed subjects walked back and forth with their arms at their sides beside a height-adjustable handrail, while completing a verbal counting task. Subjects wore standardized running shoes with soles covered by felt and cotton fabric. The walking surface consisted of force plates covered by fiberboard, which allowed subjects to walk normally but, with the fabric-covered shoe soles, prevented effective foot planting following balance loss due to low foot-floor friction. Balance loss was induced via sudden backward platform translation (acceleration 3.75m/s^2; peak velocity 1.13 m/s; displacement 0.34 m). Three handrail heights per subject were tested: 50% (LOW), 57% (MED) and 64% (HIGH) of the subjects' height. Four balance recovery trials were collected for each height.

Reach-to-grasp accuracy and hand velocity were estimated from a motion capture marker on the base of the second metacarpal; handrail contact time was measured using a handrail-mounted optical sensor. Reach onset latencies were determined using EMG from the right middle deltoid. Onset latency and contact time were defined relative to perturbation onset (platform acceleration>0.1m/s^2 [3]). One-way repeated measures ANOVAs were conducted for all variables of interest (significance $p \leq 0.05$). Sphericity was checked with Mauchly's test and Greenhouse-Geisser corrections were applied where necessary. Post hoc comparisons with Bonferroni corrections were performed for metrics that varied significantly with handrail height.

Results: Descriptive statistics for key reactive graspin metrics are presented in Table 1. Middle deltoid onset latencies (p=0.372) and time to handrail contact (p=0.883) did not vary with rail height. Handrail overshoot decreased as height increased (p =0.001). Further, overshoot for LOW was significantly higher than MED (p=.05) and HIGH (p=0.008), but MED and HIGH did not differ significantly (p =0.679). Peak hand velocity in the lateral and vertical directions also

increased with handrail height, although only the vertical velocity increase was significant (lateral p=0.066; vertical p<0.001). Further, peak vertical hand velocity was significantly lower for LOW than for MED (p=0.013), and significantly lower for MED than for HIGH (p=0.015).

Figure:



Caption: Figure 1. The Challenging Environment Assessment Laboratory. Left: The motion base. Right: Inside the lab. Motion capture cameras on the walls collect kinematic data; a handrail-mounted optical system estimates contact time.

Conclusion: Within the range tested, handrail height does not affect time to rail contact or reaching reaction onset latency following balance loss on level ground for young adults. This suggests that other balance recovery metrics such as forces and moments that a person can generate on the handrail may be more important determinants of a handrail's effectiveness in preventing falls in this population at a given installation height. The increases in both peak hand velocity and accuracy (lower rail overshoot) with handrail height may provide insights into why time to rail contact was consistent even though the initial distance between the hand and rail differed between rail heights. Repeating this experiment in older adults will improve our understanding of how handrail height affects balance recovery in broader populations.

Table:

Balance recovery metric	Handrail height		
	LOW	MED	HIGH
Middle deltoid onset latency (ms)	201 (30)	190 (24)	211 (40)
Time to handrail contact (ms)	490 (34)	483 (47)	483 (42)
Handrail overshoot (m)	0.117 (0.059)	0.061 (0.016)	0.046 (0.034)
Peak vertical hand velocity (m/s)	1.747 (0.462)	2.385 (0.405)	2.823 (0.478)
Peak lateral hand velocity (m/s)	2.375 (0.465)	2.533 (0.385)	2.628 (0.484)

Caption: Descriptive statistics (Means (SD)) for key reach-to-grasp balance recovery metrics with respect to handrail height.

TIBIALIS ANTERIOR AND VASTUS LATERALIS CONDUCTION VELOCITY DURING ISOMETRIC CONTRACTION AT LOW LEVEL FORCE IN DIABETIC INDIVIDUALS WITH DIFFERENT STAGES OF NEUROPATHY

Eneida Y. Suda [1,*] Thiago Tavares Kawamura [1] Marco Kenji Butugan [1] Neli RS Ortega [2] Isabel CN Sacco [1]

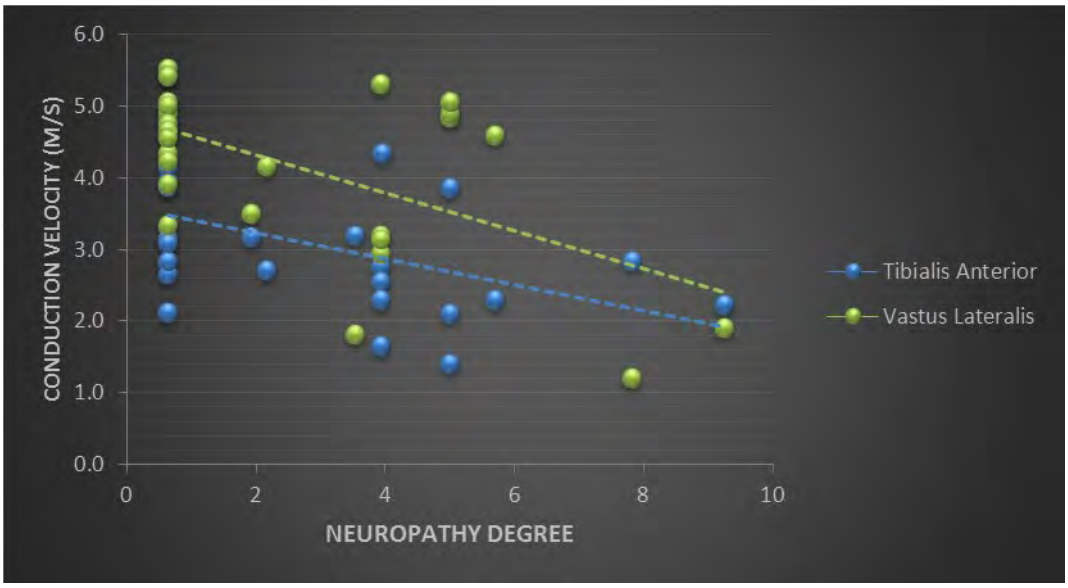
[1]Physical Therapy, Speech, Occupational Therapy dept., [2]Medical Informatics, University of São Paulo - School of Medicine, São Paulo, Brazil

Introduction and Objectives: Diabetic neuropathy is one of the most prevalent complications of diabetes mellitus, affecting both sensory and motor nerve fibers. Although the most common early reported symptoms are sensorial, with neuropathic patients citing loss of tactile sensitivity, prickling sensation and pain, motor dysfunction is observed in this population. Neuromuscular impairment is related not only to nerve integrity but is also related to other factors as the state of motor end plates and skeletal muscle fibers. The diabetic neuropathy is a progressive phenomenon and related alterations could be different for earlier and more advanced stages of the disease. Therefore, the aim of this study is to investigate if different diabetic neuropathy degrees have distinct muscle fiber conduction velocity (MFCV) during isometric contraction at low level force (20%) for one proximal and one distal lower limb muscles.

Methods: Ten control subjects (49.4±9.6yrs) and 19 diabetic patients (58.6±4.8yrs, 14.8±13.1yrs of diabetes diagnosis, 196.9±79.1 mg/dL blood glucose) were evaluated. The participants were assessed for (i) vibratory perception (128Hz turning fork), (ii) tactile sensitivity (10g Semmes-Weinstein monofilament) and (iii) presence of typical neuropathy symptoms. These three groups of variables were used as linguistic inputs in a fuzzy system to determine the neuropathy degree (score 0-10). The neuropathy score was used to classify the patients into different disease severity stages. The score value was also used to classify the individuals into neuropathy classes: (a)x≤2.5: absent; (b)2.5≥5.0: moderate/severe. Multichannel Surface EMG (64 electrodes matrix: 15 x 4, OT Bioelettronica, Torino, Italy) was acquired during 20% of maximum isometric voluntary contractions (MIVC) of tibialis anterior (TA) and vastus lateralis (VL) musclesTA was evaluated during dorsiflexion performed with knee in full extension and the ankle in neutral position. VL was evaluated during knee extension performed at 90° of hip flexion and 45° of knee flexion; force levels were controlled by a knee and an ankle ergometer (strain gage load cell) and fluctuations of ±2% of the absolute torque level, controlled by a visual biofeedback system, were accepted. MFCV was determined for an epoch of 500ms using a maximum likelihood estimation method [1]. Correlation analysis were performed in order to analyze the association between MFCV and neuropathy degree, determined by the fuzzy system. The neuropathy and control groups were compared using ANOVAs, followed by Newman-Keuls post-hoc test ($p<0.05$).

Results: MFCV decreased significantly for both TA (r=-0.461) and VL (r=-0.571) muscles with neuropathy progression (Figure 1). TA muscles showed lower MFCV values for moderate/severe subjects when compared to control ones (Table). Although this difference was not observed for VL, it is clear that the disease progression leads to a higher impairment. TA muscles have higher proportion of type I fibers, that are more affected in diabetic patients, and the level of contraction evaluated (20% MIVC) probably recruited lower motor units what would explain the difference observed only for TA and not for VL muscle.

Figure:



Caption: Correlation between MVIC values and neuropathy score.

Conclusion: MFCV decreases linearly and progressively with neuropathy progression in TA and VL muscles. TA muscles presented lower MFCV in later stages of neuropathy when compared to control subjects that may be related to changes in muscle fiber contractile properties since TA has a higher proportion of type I fibers that are lost in the course of the disease.

SEX-RELATED DIFFERENCES IN DORSIFLEXOR RATE OF TORQUE DEVELOPMENT

J Greig Inglis [1,*] Justin Parro [1] David A Gabriel [1]

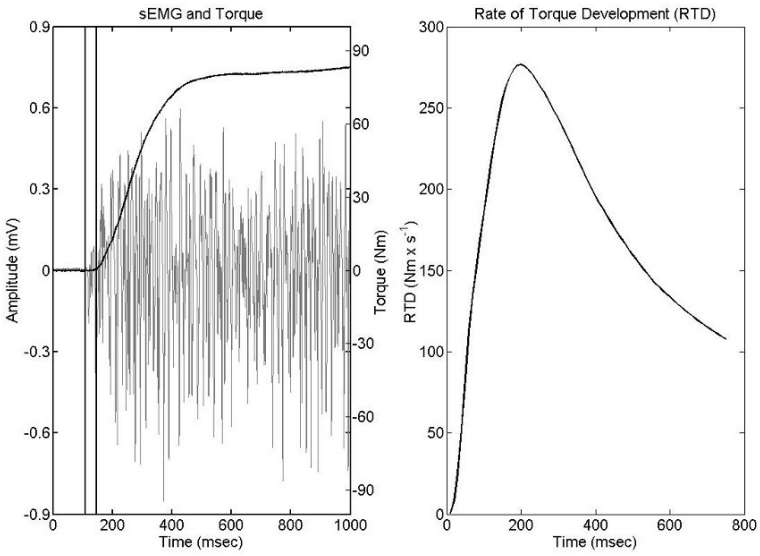
[1]Kinesiology, Brock University, St Catharines, Canada

Introduction and Objectives: Sex-related differences in the maximal rate of torque development during isometric elbow flexion persist, even after normalization with a maximal voluntary contraction (MVC). In contrast, Hannah and colleagues (2012) demonstrated that normalization with respect to MVC eliminated sex differences during maximal isometric knee extension. The purpose of this study was to determine if the findings of Hannah and colleagues (2012) extend to maximal isometric contractions of the dorsiflexors. The dorsiflexors were chosen because of their importance in ankle joint stability, balance, and the risk of falling with age (Schultz et al., 1997).

Methods: Forty-eight participants (24 males and 24 females) completed three maximal isometric contractions of the dorsiflexors. The contractions were five seconds in duration with three minutes of rest between each trial. Dorsiflexion torque and surface electromyographic (sEMG) activity of the tibialis anterior were recorded concurrently. The criterion measures were: maximal torque, maximum rate of torque development, electromechanical delay (EMD), root-mean square amplitude (RMS) during maximum torque, and the rate of increase in sEMG during the first 30 ms of activity (Q_{30}).

Results: All measures were highly stable across trials and participants were very consistent at reproducing their own scores, resulting in intraclass reliability coefficients ranging from R=0.68 to R=0.99. There were no significant differences between males and females with respect to EMD (p=0.30), Q_{30} (p=0.20) or sEMG RMS amplitude (p=0.67). However, there were significant sex-related differences with respect to maximum torque (p<0.0001) and the maximum rate of torque development (p=0.00015). An analysis of covariance using maximum torque eliminated significant differences with respect to the maximum rate of torque development (p=0.39).

Figure:



Caption: Left panel: represents the first 1000 milliseconds of a MVC. Torque (black line) onset is identified with the first vertical line, and TA sEMG activity onset (grey line) is identified by the second vertical line. Right panel: the associated dτ/dtmax of the same MVC.

Conclusion: The similarity in sEMG between males and females despite significant sex-related differences in maximal torque is consistent with our previous study (Lenhardt et al., 2009). The results support the findings of Hannah and colleagues (2012) who showed that differences between males and females with respect to the maximal rate of torque development are related to maximal torque. The sEMG results reinforce the fact that neural factors were not involved in sex differences in the maximal rate of torque development of the lower limb, which runs counter to previous observations for the upper limb (Inglis et al., 2013). Sex-related differences in the maximal rate of torque development in the dorsiflexors were related to simple differences in maximum torque, in the absence of any neural factors as assessed by sEMG activity. Understanding that sex differences in the maximal rate of torque development in the dorsiflexors is primarily determined by maximal torque suggests that standard resistive exercises may be sufficient for maintaining the ability to respond to perturbations that could lead to falls. Subsequently, more sophisticated sensorimotor training may be unnecessary.

HYPOTHESIS AND VERIFICATION ON COM DRIVEN CONTROL DYNAMICS DURING GAIT IN CHILDREN.

Maria Cristina Bisi [1,*] Rita Stagni [1]

[1]DEI - Department of Electrical, Electronic and Information Engineering "Guglielmo Marconi", University of Bologna, Cesena, Italy

Introduction and Objectives: The understanding of how the central nervous system (CNS) controls the numerous degrees of freedom in order to perform a specific motor task is still an open question. Recent approaches suggest that the CNS usually chooses among the infinite solutions available by optimizing a certain cost function, but sometimes uses sub-optimal choices still in full respect of the physiological constraints [1]. A recent work hypothesized that the stabilization of the centre of mass (CoM) trajectory could be a leading factor during gait in healthy and stroke patients [2]. Moreover, a recent study [3] showed that newly walking toddlers manifested characteristics of the pendulum mechanism already after one month of walking experience, even if showing strategies and patterns far from the adult-like gait. These results suggest that the control of CoM trajectory could be one of the driving factors allowing the CNS to choose among the infinite available solutions, even when not choosing the optimal one. Verifying this hypothesis on adult subjects is difficult because their gait is highly structured and repeatable, indicating that an optimal choice has been found; on the other hand, toddlers are still too variable, unstable [4] and far from showing an adult like gait. Gait maturation continues until age 6 [5]: the gait of 6-year old children can be considered stable from the motor control point of view, as they do not fall during level walking and show a good grade of coordination, but they still show higher segmental kinematic variability than adults [6]. The described aspects can facilitate the evaluation of the CoM driven CNS control dynamics. The hypothesis of the present work is that the trajectory of the CoM is a leading factor of the CNS gait control dynamics, allowing 6-year old children to reach a steady state point in gait development, despite the shown variability: if this is true, the variability of CoM kinematic should be lower than that of other kinematic variables.

Methods: 4 children [5.7±0.5y, 116±5cm, 21±3kg] and 7 young adults [22±1y, 161±6cm, 56±6kg] participated in the study. Participants were asked to walk along the gait analysis laboratory: each participant performed 15 walks, divided in groups of 5. Every 5-walk-test, participants were asked to perform some coordination exercise (e.g. standing on a foot) in order to obtain a 7 minute pause. 3D-Kinematic (SmartD, Bts, Italy) and inertial sensor data (Opal, Apdm, US) were collected during the tests (sampling frequency respectively of 200Hz and 128Hz). 18 reflective markers were positioned on anatomical landmarks according to Plug in Gait protocol. A single triaxial inertial sensor was positioned on the lower trunk approximately at approximately CoM level. For each walking test, joint angles, CoM trajectory and CoM acceleration were obtained. In order to evaluate intra-test and inter-test variability, the relative standard deviation (std%) of each estimated variable was calculated between the 5 walks of each test and among the 3 repetition of the 5-walk-test.

Results: Joint angles results showed higher variability in children than in adults both for the intra-test and the inter-test conditions: in particular children hip flexion/extension and intra/extra rotation, and ankle flexion/extension angles showed std% 6 times (or more) greater than adults' ones. CoM trajectory in the inter-test condition showed similar std% results for the two groups, while, in the intra-test, mediolateral std% was higher in the children group (5 times). In both intra-test and

inter-test conditions, children CoM acceleration showed std% similar to adults' for the antero-posterior and the vertical axis, while higher on the mediolateral axis.

Conclusion: The results of the present study supports the hypothesis that the trajectory of the CoM is a leading factor of the CNS gait control dynamics: children showed lower variability in the CoM kinematics (trajectory and acceleration) than in joint angles. Based on present results, it could be argued that, during gait, the CNS control is focused on the progression of the CoM and not on its lateral stabilization: children variability on the mediolateral axis was always higher than adults' one. In order to further verify and validate this hypothesis, an uncontrolled manifold approach can be applied [2]. Understanding control dynamics during walking is of fundamental importance both for improving basic knowledge and for enhancing rehabilitation techniques in neurologic and/or elderly patients.

COMPARISON OF THE ACTIVITIES MEASURED AT THREE ELECTRODE LOCATIONS ON EQUINE GLUTEUS MEDIUS MUSCLE IN WALK AND TROT

Rebeka Zsoldos [1,*] Anna Vögele [2] Björn Krüger [2] Ulrike Schröder [3] Theresia Licka [3]

[1]Department of Sustainable Agricultural Systems, University of Natural Resources and Life Sciences Vienna, Vienna, Austria, [2]Institute of Computer Science II, University of Bonn, Bonn, Germany, [3]Department for Small Animals and Horses, University of Veterinary Medicine Vienna, Vienna, Austria

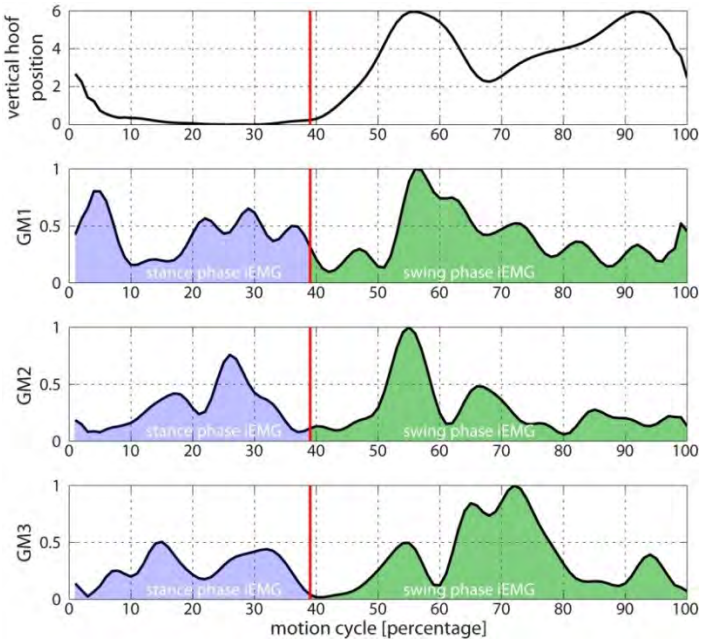
Introduction and Objectives: The equine gluteus medius muscle (GMM) is the largest unsegmented muscle of the horse; its main function is to extend the hip and retract and abduct the limb. The muscle provides the visible shape of the croup, and due to its location directly under the skin, it is an ideal candidate for detecting intramuscular activation differences with surface EMG (sEMG). If present, these differences may elucidate how the anatomical and temporal distribution of activation contributes to the efficiency of muscle use. Therefore, the aim of this study is to describe the sEMG muscle activation pattern of three selected locations of the GMM during walk and trot.

Methods: Measurements were obtained in six horses without lameness, walking and trotting on a treadmill. Three electrodes were placed over the left and right GMM at the midpoint between origin and insertion about 5cm apart on the medial (GM1), middle (GM2), and lateral (GM3) part of the GMM. The resulting EMG signal was rectified and the sampling rate was reduced to 120 Hz. Butterworth low-pass filter was applied (fourth order; cut-off frequency, 20 Hz) and integrated EMG (iEMG) was calculated for each motion cycle. Only the right side results were used for this study. For each horse a minimum of 7 motion cycles at walk and a minimum of 13 motion cycles at trot was considered. Based on the vertical movement of the right hind hoof, the motion cycle was divided into the stance phase as well as the swing phase (Fig.1), and the ratio between the iEMG during those two phases was calculated by dividing the stance phase iEMG by the swing phase iEMG (“PhaseRatio”). The correlations of the values of the three electrode positions were calculated during each stance and swing phase for each horse; and for all horses correlations of the values at all three locations were also calculated.

Results: The stance phase iEMG ranged from 0.2 to 35 (mV%) in walk and from 0.1 to 41 (mV%) in trot. The swing phase iEMG ranged from 0.06 to 21(mV%) in walk and from 0.1 to 47(mV%). The cycle ratio values ranged from 0.13 to 6.77 in walk and from 0.09 to 7.53 in trot. As expected, of all correlations (100%) there were many significantly positive correlations (28%) between the three locations at walk and trot during both stance, and swing phase, as well as for the PhaseRatio. However, there were a number of significantly negative correlations (9%) between GM1 and GM2 for stance phase iEMG and between GM1 and GM3 for swing phase iEMG both in walk and trot.

For all horses in trot, there were significantly positive correlations between GM2 and GM3 for stance phase iEMG ($r= 0.988$, $p<0.01$), swing phase iEMG ($r= 0.933$, $p=0.006$), and cycle ratio values ($r= 0.848$, $p=0.03$); however, no correlation between GM1 values and the values of the other two locations was significant. For all horses, there were no significant correlations of the values obtained at the three locations in walk.

Figure:



Caption: Figure 1. In Horse 1 the vertical movement of the hind hoof and iEMG of the medial (GM1), middle (GM2), and lateral (GM3) part of the gluteus medius muscle during one motion cycle (stance and swing phase) in trot.

Conclusion: In individual horses, there were both positive and negative correlations for sEMG parameters obtained at the three locations over the same muscle. This is surprising, as it indicates that the medial part of the muscle (GM1) is acting more independently than the middle and lateral parts (GM2 and GM3) and that potentially these muscle fibres act in a different way than was previously thought, but in a motion cycle related pattern. The reasons for the lack of concerted action of the medial part of the GMM may include a difference in the neuromuscular activation of the muscle fibres, as a single nerve fibre may activate a number of muscle fibres that are neither evenly distributed within the muscle, nor directly adjacent to each other. Also, the function of the GMM may be more highly differentiated than it is currently perceived to be, with the large areas of origin and insertion allowing for partially opposing functions present in a single very large muscle. Further investigations using array and needle EMG at selected locations of this large muscle are required to support these hypothetical considerations. The negative correlations observed between sEMG activities at different locations during the swing phase but not the stance phases of the GMM indicate a complex intramuscular distribution of workload. This may be due to specifics of innervation or even mechanical fascia effects; how this differential use of a single, albeit large, muscle is linked to avoidance of overexertion of muscle fibres and/or increased muscle efficiency is as yet unclear, but the prevalence of these negative correlations at trot, where more work is done by this hip extensor than at walk is pointing in this direction.

COMPLEXITY OF ISOMETRIC FORCE PRODUCTION IS ASSOCIATED WITH TIME TO ACHIEVE STEADY STATE WHEN MOVING TO A NEW FORCE LEVEL

Samantha L. Winter [1,*] Mark Burnley [1] Sarah Forrest [2] John Challis [3]

[1]School of Sport and Exercise Sciences, University of Kent, Chatham Maritime, [2]Sport and Exercise Science, Aberystwyth University, Aberystwyth, United Kingdom, [3]Department of Kinesiology, The Pennsylvania State University, State College, United States

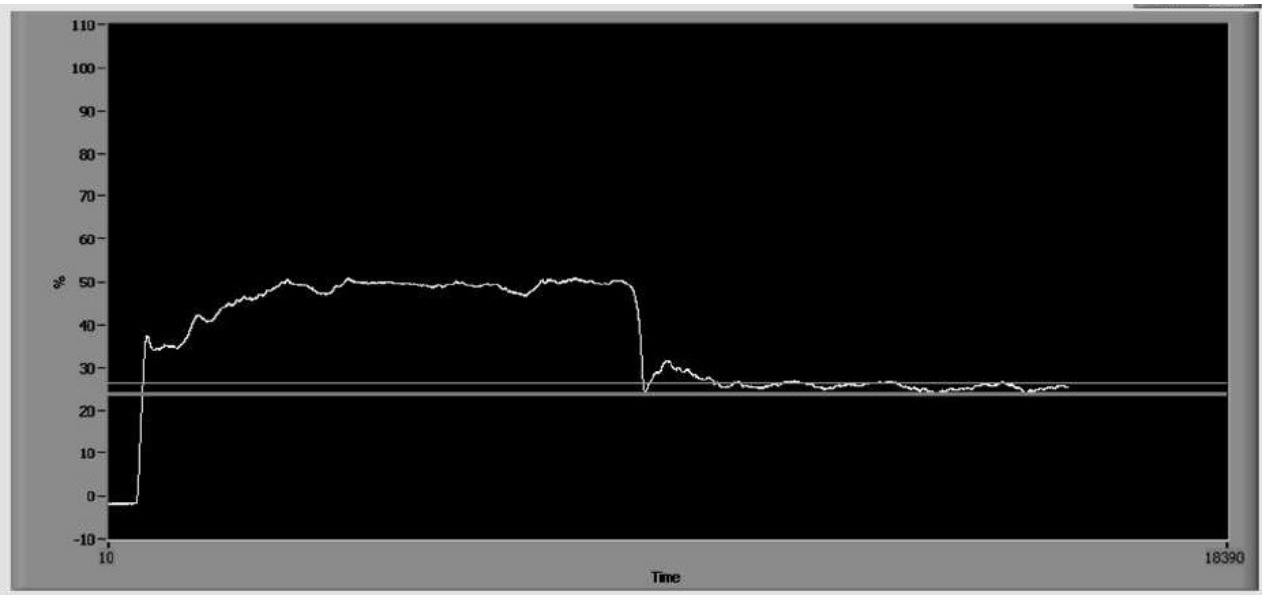
Introduction and Objectives: Motor output and function has been shown to decline in later life, for example older adults have increased stimulus response times [1]; reduced strength [2] and changes in the variability of force production [2]. The loss of complexity hypothesis [3] suggests that a decrease in complexity is associated with ageing as the integration of complex physiological systems declines, and that this reduced complexity is associated with constrained behaviour and a loss of adaptability or flexibility in reponse. The function consequences of this loss of complexity in the fluctuations seen in isometric force records have not been investigated. However, it is possible that the reduced complexity, and more slowly repeating and constrained fluctuations in force seen in older adults [4] would limit ability to adapt to altered force requirements. It was hypothesised that reduced complexity for isometric force records in older adults would be associated with an increase in the time taken to achieve a steady state when moving to a new isometric force level.

Methods: Young (18 to 25 years) and older (65 to 72 years) neurologically healthy adults produced isometric abduction contractions of the index finger using the First Dorsal Interosseus. Participants established a steady state force at a given effort level (a percentage of maximum voluntary contraction force - %MVC) by matching a target displayed visually. A second feedback condition used both the visual display and an audible tone that varied in pitch when subjects moved below or above the target. The target was then suddenly and unpredictably increased or decreased at a randomly decided time point and participants were instructed to match this new target as quickly as they could, and to hold the new contraction intensity as steadily as possible (Figure 1). The conditions investigated were: increasing force from 5% to 25% MVC, 25% to 50% MVC, 25% to 75% MVC, and decreasing the force from 25% to 5% MVC, 50% to 75% MVC and 75% to 25% MVC. The functional reaction time was taken to be the point at which the force exceeded 3 standard deviations (SD) from the mean force in the direction of the new force level. The time to steady state was the time from the end of the functional reaction time to the start of the 3 second window with the lowest standard deviation for force. The complexity of the force record before the target change, after the target change, and during simple continuous force production with no target change was determined for the different effort levels (5%, 25%, 50%, 75% MVC) using Approximate Entropy (ApEn) [5].

Results: Confirming previous results older adults exhibited reduced complexity indicated by reduced ApEn values at effort levels >25% MVC ($p<0.001$) and this was the case for both the simple continuous force task ($p<0.001$) and the section of the force record after the change in target force ($p=0.0438$). There was no difference in the MVC abduction force for older and younger adults ($p=0.885$). There was also no difference between older and younger adults in the magnitude of the

fluctuations in force, as quantified by the standard deviation of force ($p>0.05$). Functional reaction time was increased by around a third in older adults ($p<0.001$) in both feedback conditions. Fuctional reaction time was reduced for both age groups by the addition of the audible signal. Confirming the hypothesis, the time to steady state after the function reaction time increased from a mean of 2.83s in younger adults to 3.23s for older adults ($p=0.025$), and this difference was unaffected by feedback condition. Post-hoc tests showed that the time to steady state differed for old and young adults at starting effort levels >5% MVC.

Figure:



Caption: Figure 1: Display of force record showing a trial moving from an initial target of 50% MVC to a target of 25% MVC.

Conclusion: Force levels associated with reduced complexity in older adults compared to younger adults were associated with an increased time to steady state when moving from an isometric contraction at one effort level to an isometric contraction at a new effort level. This suggests that there is a change in the neuromuscular system with age evidenced by the reduced complexity that constrains response to altered force requirements. These findings have implications for the control of muscle force production in later life.

AS-0387

ASSESSMENT OF AN INNOVATIVE COLLAR DESIGNED FOR PEOPLE AFFECTED BY NECK WEAKNESS

Silvia Pancani [1 2,*] Christopher J McDermott [3] Jennifer Rowson [1 2] Wendy B Tindale [2 4] Claudia Mazzá [1 2]

[1]Department of Mechanical Engineering , [2]INSIGNEO Institute for in silico medicine, [3]Sheffield Institute for Translational Neuroscience, University of Sheffield, [4]NIHR D4D Healthcare Technology Co-Operative, Sheffield, United Kingdom

Introduction and Objectives: Inertial sensors are a valid tool to assess the neck range of movements [1,2]. In this study we translated methods previously used in other contexts to the assessment of a collar (Sheffield Support Snood, © Device for Dignity Healthcare Technology Co-operative) specifically designed for people affected by neck weakness caused by diseases such as motor neuron disease. Commercially available collars are designed to immobilize the neck and as such are uncomfortable and strenuous to wear for long time. The Sheffield Support Snood (SSS), developed to overcome these limits, is characterized by a less bulky structure and is adjustable with ad hoc supports according to the disease development. The aim of this study is to define a protocol for the clinical assessment of neck collars and use it to compare the performance of the SSS to those of other commonly used commercial neck collars.

Methods: Twelve healthy subjects (age 26±2) participated in the study. Inertial magneto units (IMUs) were chosen as part of the design of a protocol suitable for future clinical applications. Two IMUs (OPAL, APDM) were located on the forehead and sternum of each subject. The protocol included a series of active head movements (AHM, flexion/extension, axial rotation and lateral bending), performed first reaching the maximum amplitude and then at maximum speed.

The SSS performance was compared to two other commonly used collars, i.e. the Vista (Aspen Medical Products) and the Headmaster (Symmetric Designs, Figure 1). The SSS was tested in a stiffer (six supports: two frontal, two lateral and two posterior) and a less stiff (one A-shape frontal support) configuration. The protocol was repeated by each subject in random order wearing each collar and without any collar to have a reference measure. The sensors orientation was estimated using a functional calibration approach [2] and a quaternion-based algorithm that integrates the angular velocity [3]. The drift associated to the estimate of the orientation by integrating the gyroscope data, was corrected using a spherical interpolation [4]. The differences between AHM performed with or without collars were quantified using the maximum range of motion (ROM). Statistical analysis was performed using a one-way repeated measure ANOVA with a post-hoc Tuckey analysis.

Results: Table 1 shows the ROM obtained for the different collars. In the AHM the ROM measured with the SSS with a frontal support was significantly reduced with respect to the trials without collar only in flexion and axial rotation, showing that the support under the chin supported the neck during the flexion without affecting a subject's capability to perform extension or lateral bendings. This was confirmed in the axial rotation, where there were no significant differences between the task performed with the SSS with one and six supports: the addition of four supports to sustain the neck during extension or lateral bending doesn't affect a subject's capability to perform an axial rotation. The ROMs measured with the SSS in its stiffer configuration and the Vista were significantly lower than those observed without the collar in all tasks, but no significant differences were observed between them, suggesting that the six-supports SSS is comparable to the Vista.

Figure:

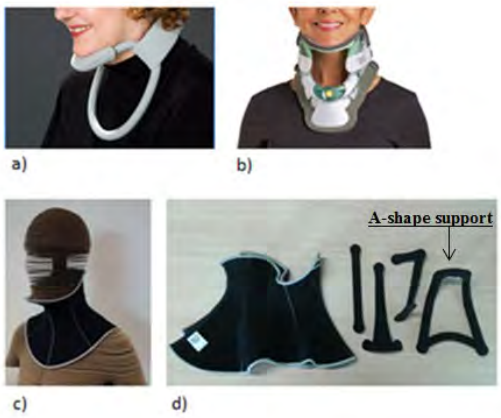

Figure 1 a) Headmaster Collar b) Vista Collar c) Sheffield Support Snood d) Sheffield Support Snood with supports.

Conclusion: The adopted protocol, which is easily translatable in a clinical context, is suitable for the assessment of neck collars. It allowed to detect significant differences in the neck motions when performed with and without collars and was highly informative in characterizing different collar performances. The SSS in its stiffer configuration was comparable to the Vista in terms of ability to support the neck and its structure appeared to be effectively adaptable to a subject specific need.

Table:

		No collar	Headmaster	SSS with one support	SSS with six supports	Vista
Extension ROM (deg)	Max Amplitude	54 (13)	50 (12)	43 (7)	35 (10)*	35 (7)*
	Max Speed	80 (12)	70 (13)	67 (11)	60 (18)*	61 (15)*
Flexion ROM (deg)	Max Amplitude	52 (9)	28 (13)*	36 (13)*	36 (12)*	27 (10)*
	Max Speed	52 (11)	30 (14)	40 (13)	37 (12)	32 (11)
Axial Rotation ROM (deg)	Max Amplitude	145 (12)	116 (21)	101 (30)*	96 (33)*	77 (30)*
	Max Speed	143 (15)	117 (23)	105 (35)*	105 (32)*	81 (29)*
Lateral Bending ROM (deg)	Max Amplitude	80 (12)	70 (13)	67 (11)	60 (18)*	61 (15)*
	Max Speed	82 (14)	72 (13)	71 (15)	63 (18)*	62 (16)*

ASSESSMENT OF ANTEROPOSTERIOR (AP) KNEE JOINT LAXITY USING NON-INVASIVE NAVIGATION IN HEALTHY VOLUNTEERS

Roberto J. Alho [1 2,*] Fraser Henderson [1] Philip Rowe [2] Jon Clarke [1 2] Frederic Picard [1 2]

[1]Orthopaedics, Golden Jubilee National Hospital, [2]Biomedical Engineering, Strathclyde University, Glasgow, United Kingdom

Introduction and Objectives: The knee joint displays a wide spectrum of laxity, from inherently tight to excessively lax even within the normal, uninjured population [1, 2]. The amount of anteroposterior (AP) laxity is dependent on the amount of force applied as well as knee positioning [2]. The assessment of AP laxity in the clinical setting is performed by manual passive tests such as the Lachman and pivot shift tests which are highly specific in the diagnosis of cruciate ligament injuries [1]. The Lachman test is usually performed at 30º of knee flexion in a clinical setting.

Non-invasive assessment based on image free navigation has been clinically validated and used to quantify mechanical alignment and coronal knee laxity in early flexion [3]. The software was further developed to allow the measure of AP laxity. When used on cadavers the software demonstrated good AP laxity results with flexion up to 40° [4].

If this technology was validated throughout flexion in live subjects, it could aid clinicians in identifying and quantifying ligamentous injuries and the planning and follow-up of total knee arthroplasty (TKA) patients in a clinical setting.

This study aimed to validate the repeatability of the assessment of anteroposterior (AP) knee joint laxity using this non-invasive system in normal, healthy subjects.

Methods: Twenty-five healthy volunteers were recruited and examined with ethical approval from the University of Strathclyde. The non-invasive system, consisting of an infrared camera, externally mounted optical trackers and computer software was used to evaluate each volunteer (Figure 1). Each of the volunteers had both legs examined by a single examiner performing two registrations. The registration included initial identification of key bony landmarks and manipulations of the volunteer's leg to achieve a virtual model of the lower limb. From this registration the supine mechanical femoral-tibial alignment (MFTA) was determined and assessment of AP laxity through flexion using the Lachman test was carried out.

Validation of the assessment of AP knee joint laxity was assessed through intra-examiner repeatability using Coefficients of Repeatability(CR) calculated with Microsoft Excel and Interclass Correlation Coefficients (ICC) using SPSS software [5]. The acceptable limits of agreement for this project were set at 3mm for anteroposterior tibial translation.

Results: Outliers were identified in the first 10 volunteers, therefore only the last 15 volunteers (30 knees) were analysed for repeatability.

The non-invasive system demonstrated consistent and comparable supine MFTA acquisition in extension consistently within the pre-validated +/-1º coronal alignment [8, 10], with a CR of 1.6° and good reliability (ICC 0.81).

The most reliable and repeatable AP laxity assessments were at 30º and 45º with both these assessments demonstrating good reliability (ICC 0.82, 0.82) and good repeatability (CR 2.5, 2.9). AP laxity at 60º demonstrated good reliability (ICC

0.79) with acceptable repeatability (CR 3.3mm). The AP laxity assessment at 0º, 15º, 75º and 90º demonstrated moderate reliability (ICC ≤ 0.75), and poor repeatability (CR ≥3.0mm) as shown in Table 1.

Figure:

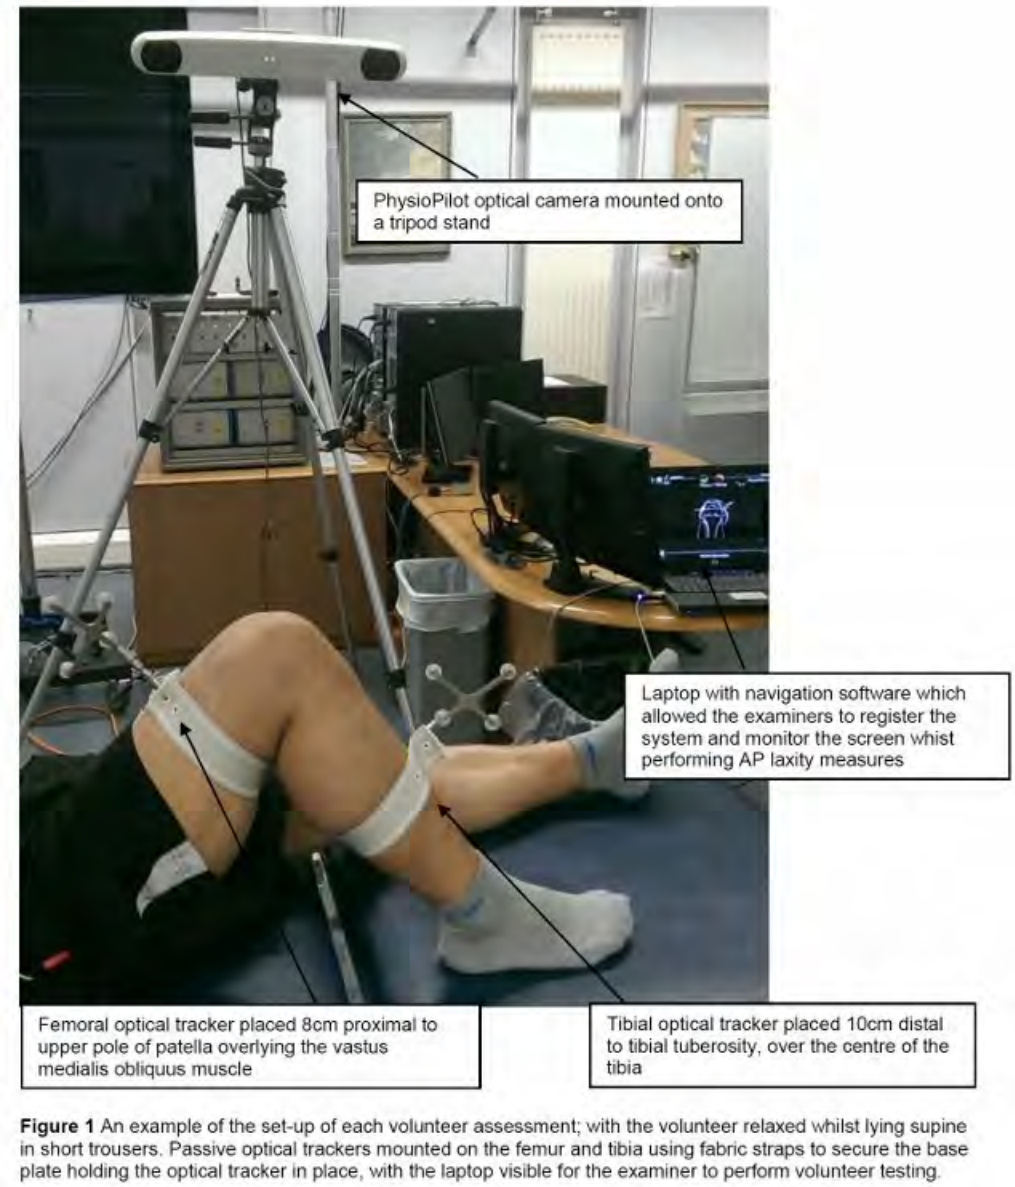

Figure 1 An example of the set-up of each volunteer assessment; with the volunteer relaxed whilst lying supine in short trousers. Passive optical trackers mounted on the femur and tibia using fabric straps to secure the base plate holding the optical tracker in place, with the laptop visible for the examiner to perform volunteer testing.

Caption: Figure 1

Conclusion: The non-invasive system was able to reliably and consistently measures knee AP laxity between 30° and 45° flexion, which is the clinically relevant range for this assessment. This system could therefore be used to quantify abnormal knee laxity and improve the assessment of instability in the knee in a clinical setting.

Poor AP laxity results outside the limits of agreement were achieved at 0º, 15º, 75º and 90º, possibly due to difficulties in hand placement and lack of standardisation in the force used during the Lachman examination in early and late flexion. The software has been previously validated to 40º of flexion in cadavers, but due to no standardised force in AP laxity assessment in this study, the software cannot be validated throughout the whole range of flexion in living subjects.

The initial 10 outlier results seemed to indicate a learning curve, with the initial assessments showing much wider variation.

Table:

Assessment	**Degrees**	Coefficients of Repeatability (CR)*	Interclass Correlation Coefficients (ICC)**
Supine MFTA in extension (º)	0º	1.6	0.81
AP laxity (mm)	0º	3.7	0.70
	15º	4.8	0.72
	30º	2.5	0.82
	45º	2.9	0.82
	60º	3.3	0.79
	75º	4.6	0.76
	90º	5.6	0.73

*A CR of under 3mm for AP translation demonstrates good repeatability.

**An ICC of ≥0.9 demonstrates excellent reliability, an ICC between 0.75 and 0.9 demonstrates good reliability, and an ICC ≤ 0.75 indicates moderate to poor reliability [5].

Introduction and Objectives: When designing a medical device (MD), the primary objective is to improve the patient's conditions. Therefore, there must be a strong focus on continuous interaction with the human elements. The procedure that has been devised to the search for concepts and the validation of an innovative temporomandibular joint (TMJ) prosthesis point out the roles and relationships between the definition of needs, the biomechanical characterization studies, modeling, mechanical and clinical validations (Fig.1).

Methods: When applying principles of mechanics and mechanical engineering to solve health-related problems by designing MDs there are some very specific requirements (interaction with human factors, implantability…) and technical solutions are specific to the field [1].

Before the design phase, the biomechanical systems have to be described. This provides the specifications, defines the functions and criteria and quantifies acceptance levels. Quantifying these characteristics, requires some very specific metrology techniques to determine the articular displacements and actions. TMJ articular displacements were described and quantified by stereo photogrammetry while muscle efforts were evaluated by electromyography and magnetic resonance imaging. The protocol was subjected to a repeatability study [2] [3].

For a healthy volunteer, three to five readings were always taken in order to evaluate the influence of changes in behavior and establish significant values. Then, for a representative sample (32 volunteers) of the population, the values followed normal distributions and the intra- and inter-individual variability of the characteristics could be described.

To complement these techniques, which can be too invasive, modeling was used. The finite element models (FEM) of the joint and jaw that were created and validated determined stresses and strains on the surface of the bone. The previous characterization study produced the input data to choose the muscular actions and the boundary conditions [4].

The search for concepts was based on functional analysis and these models of the TMJ. By building FEMs, simulations can be repeated, innovative concepts can be validated and technological solutions optimised. The models allow to predict the performance of implants and to compare behaviors of the healthy and implanted structures. Then the influence of geometry, the links between implant and bone tissues could be considered to guide the decisions when creating new technical solutions.

Results: The intra- and inter-individual variability of the characteristics may result from a range of causes: temporal, pathological, behavioral… Inter-individual variability is linked only to anatomical-physiological factors such as geometry, local distribution of tissues… Elaborating concepts, the aim cannot be to control these variations and then, the limited use in addition to difficulties in producing a custom-made prosthesis guide the designer to manage and integrate anatomical variations.
